8.—Paralysis of the recurrent laryngeal nerve is not so commonly a symptom of aneurysm as to suggest that disease at once. It of course occurs with mediastinal growths also, and Ortner has reported its pressure in mitral stenosis and regurgitation, the paralysis resulting from pressure of the distended left auricle. Schrötter doubts the correctness of this explanation, however. Kraus records a case in which the paralysis was due to compression between the left branch of the pulmonary artery and the ligamentum arteriosum. Schrötter's case was one in which a clinical diagnosis could not be established satisfactorily. Mitral stenosis and regurgitation were thought to be present, and patulous ductus arteriosus and communication between the ventricles were thought of. The interesting signs were absence of the usual dullness due to patulous ductus arteriosus, though a shadow was seen with the fluoroscope at the base on the left of the sternum; there was a presystolic systolic murmur at the apex, increasing toward the base, and loudest at the juncture of the third and fourth rib with the sternum, a diastolic murmur of rolling character at this point and a soft diastolic murmur at the apex. The murmurs were weaker at aortic and pulmonary regions, the pulmonary second sound much accentuated. The patient died of cardiac failure, and the postmortem showed a patulous ductus arteriosus and endocarditis involving the mitral tricuspid and pulmonary valves. The left recurrent laryngeal was compressed for about 1 cm. between the dilated ductus arteriosus and the aorta, and upon microscopic examination showed marked degeneration. Schrötter thinks that under similar conditions the observation of paralysis of the recurrent nerve might be an aid in the diagnosis of patulous ductus arteriosus of mitral stenosis and regurgitation could be excluded. 21.—Heineke puts to himself the question why perforative peritonitis runs a more severe and fatal course than other forms of inflammation of the same membrane. In order to answer this question satisfactorily he has performed a number of experiments upon rabbits in whom he produced perforative peritonitis by puncturing one of the coils of the small intestine through a minimal wound in the abdominal wall. Hemorrhage was always avoided as much as possible during this operation. The first symptoms usually appear after from 6 to 8 hours. The animals become apathetic, the abdomen distended; sometimes there is diarrhea, and occasionally a purulent discharge from the eyes. Death usually occurred in from 6 to 12 hours after the operation. The temperature behaved variably. In some cases there was a rapid fall—as low as 30°. In others it rose to 40°. At the autopsy a considerable quantity of turbid bloody fluid was usually found in the abdominal cavity. An attempt was then made to find out which system of the body was primarily concerned in the causation of death: whether the heart or the vascular system. In the first hours after the perforation, blood pressure reacted normally to various forms of stimulation. Even in the early stages of collapse the heart was able to do an excessive amount of work for a short time. In the late stages the heart was still in fair condition, but the vasomotors were paralysed. It was impossible, therefore, to raise the blood pressure. The paralysis of the vasomotors was apparently central, not peripheral. Nevertheless, there is some reason to believe that the nutrition of the heart muscle is impaired as the result of a deficient supply of blood, for when more blood is supplied its activity is restored. The effect upon respiration was very similar to that upon blood pressure. It gradually became more and more impaired, until finally it was arrested before the heart ceased to contract, as a result of centric action. Heineke therefore concludes as follows: First, the cause of death in perforative peritonitis in rabbits is a paralysis of the centres of the medulla oblongata. Second, this involves first the vasomotor centres, next the respiratory centres. Third, although the circulation is disturbed before the respiration, the latter ceases before the former. Fourth, the paralysis of the vasomotor centres is the cause of the disturbance of circulation. Fifth, the heart is not directly involved. Sixth, the circulatory disturbances are entirely analogous to those of infectious diseases. Seventh, the paralysis of the nervous centres is the result of the absorption of the products of bacteria from the peritoneum into the blood. Eighth, the mere perforation of the abdominal organs produces in rabbits some disturbance of the circulation. [J. S.]

22.—Worobjew, as a result of a careful study of the statistics obtained from various authors who have discussed the relation of rheumatism to valvular heart disease, reaches the conclusion that their figures are not based upon material studied strictly scientifically. Their results are very different, but there does not appear to be sufficient proof that rheumatism is the chief cause of valvular disease. He has therefore made a thorough study of all cases of valvular heart disease which were admitted to the hospital at Moscow, in which it was possible to determine the etiological condition. The total number of cases was 180. In 54 of these acute rheumatism was given in the history. In only 20 of these however, could a distinct relation be determined between the valvular disease of the heart and the rheumatism. In the remaining 34 cases the symptoms of valvular heart disease commenced some time after the acute attack. In 126 cases no relation to acute rheumatism could be determined. In regard to the development of valvular heart disease, in 90% of the patients it commenced in chronic form, and the remaining acutely. Comparing cases according to age it appears that the acute infectious diseases are very common etiological factors in the early stage, and various local processes such as arterial sclerosis, in the latter periods of life. Worobjew concludes therefore, that although acute articular rheumatism plays a more important part than any other single form of infectious disease, it is, never-

theless, less important than all the other forms together. However, the majority of non-rheumatic forms of endocarditis are probably chronic from the beginning. [J. S.]

23.—Ehstein, in a brief discussion of the history of the stethoscope mentions the fact that Laennec preferred a solid instrument for listening to the heart's sounds, and his opinion has been shared as recently as 1884, by Haupt. In the concluding part of his paper he describes a form of stethoscope that he regards as perhaps the most available for ordinary usage. This consists of a hearing piece that fits the external ear accurately, particularly the tragus, which can be placed in either end of the instrument. The external diameter of the tube, however, differs at the two ends, making it possible to apply it to large or small surfaces as preferred. It is divided in the centre. He believes that the hollow is preferable to the solid stethoscope. [J. S.]

24.—Hirsch and Beck have performed a series of experiments in order to determine the effect upon the circulation of the viscosity of the blood. It is well known that the resistance of the forward movement of the liquid in a tube depends upon the length and calibre of the tube, and the internal friction of the liquid itself. Poiseuille has devised a variety of formulas to express this resistance, for a description of which we must refer the reader to the original article. The method employed was essentially that of Oswald. The instrument consists chiefly of a tube in the form of a U with a long and a short end. In the upper part of the former there are two dilatations. The U part is also wide, and ends in a small bulb with a round opening at the top, in which a long straight tube can be placed. To the upper end of the long tube a rubber tube with a mouth-piece is attached. The blood drawn from a vein is placed in the U, and is then drawn up until the constriction in the dilatation at the upper end of the long tube is passed. The apparatus is placed in a thermostat and the pressure upon the rubber tube released. The time required for the blood to pass the constriction is then noted and the result is expressed in the ratio required for fresh analin to pass the same point. The details of the experiment cannot be given here, but the author reaches the following conclusion. There is no relation between the specific gravity and the viscosity of living human blood, although in a general way a diminished specific weight corresponds to a diminished internal friction. The viscosity of the blood is influenced not only by the corpuscular elements but also by the viscosity of the serum. The relation of the normal viscosity of the human blood, of specific weight from 1.045 to 1.055, is about 5:1 to that of water at 38°. [J. S.]

25.—Strübel has sought for some method of rendering the investigations of the physical properties of liquids more readily determined for clinical purposes, than are any of the methods now employed by physicists and chemists. In order to determine the refractive index of liquids he uses an instrument he has devised, which consists of a small hand telescope whose magnifying power is about 10 diameters. In the lower end of this telescope a prism of certain definite formula is placed. This may be immersed in liquids, and inclined until the refractive index of the liquid can be readily determined. However, as Strübel was anxious to take the refractive index of blood, a second prism was constructed with a concave undersurface, by which it is readily possible to determine the refractive index of a single drop of liquid. A great number of experiments were made upon urine, apparently normal but of different specific gravity, and from cases of various forms of renal disease, upon solutions of urea, glucose, and the various salts found in the urine. He finds that the refractive index is a specific quality that does not necessarily vary as do the specific gravity and the freezing point. Experiments made upon the serum of horses showed that it is possible to detect very slight alterations in the strength of the dilution by this method. Strübel concludes that the determination of the refractive index is easy, exact, and constitutes a new physico-chemical constant. It is to be hoped that for physiological and chemical, as well as for clinical and pathological questions, a new criterion can be obtained as soon as the method has been thoroughly worked out. It is particularly available for investigations upon the blood. [J. S.]

26.—Not satisfied with the condition of our knowledge of the bacteriology of the lungs, Boni has undertaken a series of experiments in order to determine whether actual sterilization exists in the lungs of human beings and

various animals. The technique was as follows: After opening the thoracic cavity the lungs were drawn forward with sterile pincers, the visceral pleura thoroughly scarred with a red-hot knife, and then portions of the subjacent pulmonary tissue cut out and placed in various solutions, an effort being made to avoid the larger bronchial tubes as far as possible. The portions of the lungs in bouillon cultures were then thoroughly crushed with sterile instruments, and the bouillon divided into 3 portions, one of white mice, one for the inoculation of agar plates, and one for the intra-peritoneal inoculation of guinea-pigs. Other portions of the lung were examined histologically in order to determine whether an inflammatory process existed or not. Practically 5 forms of bacteria were found. The *Diplococcus pneumoniae*, the *Streptococcus pyogenes*, the *Staphylococcus aureus* and *albus*, the *Bacillus pneumoniae* of Friedländer, and the *Bacterium coli commune*. He examined the lungs of a child who had died about 24 hours after a severe scalding. Thirty-four hours later the autopsy was performed and the *Staphylococcus albus* and the *Diplococcus pneumoniae* were found in the cultures and in the inoculated animals. As however, experiments upon human beings always contain a certain element of doubt, he performed a larger series of experiments upon the lungs of hogs obtained from the slaughter house, and found in 20 cases, only 6 completely sterile. In the others one or more varieties of micro-organisms could be found, some of which were virulent, and some harmless. Similar experiments were also made upon 10 apparently healthy guinea pigs, and their lungs were found almost invariably sterile. Boni is convinced that his positive results cannot be ascribed to contamination during the operation. He thinks it would be remarkable if the surface of the pulmonary alveoli which are perpetually in communication with the outer air, should be sterile. He summarized his results as follows. First, the lungs of guinea-pigs are usually free from germs, but in many cases may contain microorganisms, including such as are pathogenic; second, the lungs of recently killed animals (hogs) contain, in the majority of cases, germs, many of which are pathogenic. The most common of these is the pneumococcus. It is therefore certain that the lungs of healthy men in most cases contain a variable number of bacteria, among which the pneumococcus is most common. Fourth, the virulence of most of these forms is diminished. Fifth, in the healthy lungs of animals the *Bacillus tuberculosis* is not present. [J. S.]

27.—Schmidt and Strasburger continue their contribution to the fermentative phenomena of the contents of the intestinal tract. The studies in this instance concern the so-called fermentative dyspepsia of the intestines of adults. For this purpose various diets are given, essentially the same as those used by the authors in their previous experiments upon the subject of fermentation. Their results are based upon the study of 11 cases; 3 entirely healthy; 4 with fermentative dyspepsia, and 4 representing the transitional form. In general their results are as follows. In fermentative dyspepsia the total quantity of the dry feces is about twice the normal quantity. The quantity of nitrogen is increased; the amount of fat is about normal; the quantity of digested carbo-hydrates is greatly increased. The clinical picture of this condition they describe as follows. The patients are usually in middle life; their subjective disturbances are very indefinite, and they appear to exaggerate their suffering. Sometimes the tongue is coated; the breath is heavy; the abdomen slightly distended, and occasionally slightly tender. With the exception of the depression of the ensiform process there is no abnormal resistance. The stomach contents are usually normal in constitution. Defecation usually occurs from 2 to 4 times a day; the feces are semi-solid and exhibit the characteristics that have already been described. The condition showed some tendency to improve, and the treatment consisted of the administration of astringents and antiseptics. According to the previous investigations of Schmidt and Strasburger it appears that the seat of this condition is in the small intestine. The changes are probably functional rather than organic. The cause is still indefinite. The important feature in diagnosis is the occurrence of early fermentation which usually ceases after 24 or 36 hours. The absence of symptoms of gastric or cholic disease is also important. The prognosis is rather doubtful; many of the patients are improved by strict diet,

but the treatment always requires a long time, and the patients are apt to relapse. The histories of the cases are appended to the article. [J. S.]

23.—Ginsburg has studied the records of 250 cases that have come to autopsy in the clinic at Zurich. Eighty-five of these cases had been complicated by embolism. Emboli were found in 62 cases in the kidneys; in 53 cases, in the brain; in 11, in the lungs; in 3, in the mucous membrane of the intestine, and in the superior mesenteric and pleural arteries; in 2 cases in the skin, and in one case each in the iliac artery, the tibial, brachial, coronary arteries, the cerebral pia mater and in the uterus. Embolism had occurred 131 times. Of course in many of the cases there were multiple emboli. There appeared to be no particular relation to age. In the cases from 18 to 20 years embolism had occurred 4 times, that is, in 50% of all cases of this age. In the more advanced ages the proportion of the cases of embolism was sometimes more, but usually less. Regarding the clinical symptoms the most interesting were those in relation to embolism in the brain. All of them came on suddenly, with the ordinary characteristics of an apoplectic attack. In 9 cases unconsciousness remained until death. In one case recovery occurred, and in the remaining 5 the clinical details failed. Embolism of the superior mesenteric artery came on with intense pain in the abdomen, collapse, and in one case, considerable bright red blood in the stools. In both cases there was vomiting of blood. The author also describes some other interesting cases of embolism of the brachial or pleural arteries, in the extremities. [J. S.]

29.—Bamberger describes the case of a man, 27 years of age, who apparently had never wept from the left eye. A small opening was observed lying about 3 cm. to the outer side of the external of the eye, into which the sound could be passed for a distance of a half a cm. About every 10 minutes a tear-drop appeared at this opening and rolled down the cheek. Methods employed to stimulate the secretion of saliva had no effect on this, and it appears to be an abnormal opening connecting with the left lacrimal gland. [J. S.]

3. On the Epidemic of Smallpox in Berlin. KLEINE.
4. An Apparatus for Pasteurizing Milk at Home. A. HIPPIUS.
5. The Topography of the Brain. (Conclusion). WALDEYER.
6. A New Syphilis Bacillus.

JUSTIN de LILLE and LOUIS JULIEN.

1.—The case which Leyden reports is interesting because it was apparently carried by the use of tetanus antitoxin. The patient was a man of 22 who was received in the hospital on the third day after he had shown the first signs of tetanus. He was given 5 c.cm. of antitoxin the same day by sub-dural infusion, after 10 c.cm. of cerebro-spinal fluid had been removed. The latter, when injected into mice, produced tetanus and demonstrated that the man actually had this disease. The symptoms of tetanus were not severe when the man was injected, excepting that he had a temperature of 105.8° F. Soon after the injection the temperature fell, and on the next day and subsequently there was but very slight fever; the pharynx-cramp also was much improved soon after the injection. Leyden has never seen a case of tetanus previously in which the temperature reached so high a point and in which recovery occurred. For this reason and because of the apparently rapid and favorable response of the fever and other symptoms to the injection, he decided that the serum saved the man's life. He states that the man gave a history of tetanus two years before, and refers to this as indicative that the patient had not acquired any immunity (permanent immunity at any rate) to the disease from a previous attack. It is stated, however, that tetanus was not caused in animals after injecting the man's blood, and that the cerebro-spinal fluid caused the first symptoms only after six days. It seems within the range of possibility, therefore, that these facts may indicate that the man had acquired some immunity and that his recovery was due to this

quite as much as to the serum, especially as his symptoms were all mild except the fever. The case was interesting from an etiological standpoint. No point of entrance could be found and it was thought to be possibly an instance of respiratory infection. No tetanus bacilli could be found in the sputum. [D. L. E.]

2.—The cases reported by Herbold are of no special interest excepting that they indicate the existence of many opportunities in China for infection with tetanus through the excessive uncleanness of the Chinese. Herbold expresses some hope that tetanus antitoxin may in time become sufficiently cheap to allow of its use as a prophylactic in cases in which tetanus might occur. He has used it in one or two instances in which he feared the possible development of tetanus, and the disease did not appear. Naturally, since tetanus does not occur after every wound, this does not show that the antitoxin had a prophylactic action. Two of the patients with actual tetanus received antitoxin "with good effects," but both died. Of the other two, one, a mild case, ended in recovery, and the other, which was severe, proved fatal. [D. L. E.]

3.—Since the end of April there have been twelve cases of smallpox in Berlin, a city usually entirely free of the disease. When isolated cases do turn up, they almost always occur in Russian or Italian immigrants, or in persons who have been in personal contact with Russians or Italians. Berlin, and Germany in general, are so well protected by vaccination that the disease almost never appears in natives unless imported from countries where vaccination is not properly insisted upon, and the chief sources of danger are the people of the two nations mentioned. This small epidemic was no exception. The first known case occurred in a railroad employé, who in his occupation frequently came in contact with foreigners and probably acquired the disease in this way. All the cases afterwards reported could be traced with much probability to this first case. In several instances infection evidently took place through the medium of persons who were still in the incubation state of the disease. In some instances the contagion was almost certainly carried through a chain of two or more insusceptible persons, finally reaching one who was susceptible. The wide distinction of the cases throughout portions of the city separated by great distances was remarkable. In persons who had been vaccinated or revaccinated the case was not so severe; of the unvaccinated, several, including a six months old child, died. One child was vaccinated after infection and the eruptions of smallpox and vaccinia were afterwards present coincidentally, but the variola was mild. It was noticed that several cases came from two houses which were separated by a third house. The immediate source of infection for these cases was thought to be a case in this third house, which had been severe chickenpox, but which was almost certainly smallpox. The chief ordeal of the epidemic was that every one in an infected house or who has in any way come in contact with a case should be vaccinated at once, no matter when he was last vaccinated; and, furthermore, all cases diagnosed chickenpox should be reported at once and investigated by a medical health officer. [D. L. E.]

4.—The apparatus consists of a tin vessel large enough to hold five milk bottles and surrounded by an air jacket. The bottles are placed in the vessel, water is passed in around them and warmed by a petroleum lamp to a temperature of 70° C., as indicated by a thermometer which goes with the apparatus. The vessel is then covered. The temperature of the milk does not go above 60° C. at first, but after the covering the apparatus, both milk and water reach a temperature of 65° C. in fifteen minutes after the heating is stopped. If a lamp is now placed under the apparatus the air-jacket becomes heated and the contents of the apparatus can be maintained at about 65° C. for as long a time as desired. It is best, after the pasteurization has been completed, not to keep all the milk in the apparatus but to remove all but one bottle, the latter being given the child at its next feeding after cooling properly. This bottle is then replaced by another. This so-called "fractional pasteurization" is recommended as a very successful means of producing asepsis without causing chemical changes in the milk. The results of analysis of the fat, sugar, casein and phosphates are given,

and seem to show practically the same chemical conditions before pasteurization as after, even when the process was carried on as long as twelve hours. (To be continued.) [D. L. E.]

6.—The authors claim to have found the specific cause of syphilis. Their studies were carried out with blood from syphilitics, the blood being removed from a vein with a syringe. They found the same round bodies that had been found by others (Levi, Loeb, etc.) but attempts at making cultures of these bodies or their injections into animals were without results. It is known from previous work that coagulated blood of syphilitics does not seem to have infection proven when injected into susceptible persons. The authors therefore used blood plasma of syphilitics and serum obtained from artificially produced blisters, and state that they isolated a bacillus. The organism was cultivated on various media. It is a polymorphous bacillus, 5 to 8 micron long and 0.15 to 0.3 micron in width, sometimes thread-like. It takes ordinary stains but should not be fixed at a temperature over 60° C. Osmic acid and saturated bichloride solution containing some acetic acid are the best fixatives. It does not decolorize by gram. It clouds a gelatine medium, liquefies gelatine. On agar and glycerin and peptone agar it forms moist, creamy colonies of greenish color. On solid media the colonies are invisible. It does not coagulate milk, but precipitates the casein. It produces no pyocyanin or indol. Old cultures appear under the microscope to be entirely granular; inoculations into animals were usually positive even then, however, and the authors believe that these granular bodies (those described by Levi, Loeb, etc.) constitute the resistant element of the organism. Their reasons for considering the organism to be the cause of syphilis are as follows: It is found in syphilitics who are in the florid stage; it gives an agglutination reaction with the blood serum of syphilitics and does not with non-syphilitics; it produces symptoms and lesions in animals which are closely similar to those seen in man; it fixes the alexine of animals inoculated with syphilitic blood plasma; its injection into persons who have syphilis produces no result; both in man and in animals the bacillus disappears at the time of death. [D. L. E.]

WIENER KLINISCHE WOCHENSCHRIFT.

July 18, 1901. (XIV Jahrgang, No. 29).

1. The Influence of Food Upon Uremia. ALEXANDER STRUBELL.
2. The Diagnostic Value of Specific Precipitates. RUDOLF KRAUS.
3. Lightning Stroke and Electric High Tension. S. JELLINEK.

1.—After a full review of the literature upon food in acute and chronic nephritis, Strubell details his experiments upon 5 rabbits and 18 dogs, all of which had their kidneys removed, to produce experimental uremia. The statistics follow in full. He concludes that convulsions often accompany uremia in animals, contrary to von Limbeck's opinions; that animals, in which uremia is induced experimentally, live longer upon carbohydrates than upon albumen, fat, etc. From his experiments, Strubell shows that uremia in animals resembles uremia in man. Therefore he believes that when uremia is threatened in acute or chronic nephritis, a diet of carbohydrates, or at least of vegetables, should be given from time to time, once or twice a year. [M. O.]

2.—Kraus details his series of experiments in the formation of specific precipitates when filtered cultures of colon bacilli are added to coliserum (the serum of horses immune to colon bacilli), making agglutination tests at the same time. He concludes that homologous agglutinating coliserum forms a specific precipitate with the filtrate of related colon bacilli; that filtered colon bacilli, which will not agglutinate heterologous coliserum, will not cause specific precipitates; that filtered colon bacilli, which agglutinate heterologous coliserum in small quantities, give very little precipitate when much serum is used; with serum which gives typical precipitates with homologous colon bacilli, the formation of precipitates is wanting in this heterologous nitrate; that agglutinating cholera serum which shows typical precipitates with filtered cholera bacilli, gives no precipitate

with nitrates of vibrios which are not agglutinated by cholera serum, that filtered vibrios, which are agglutinated by a small quantity of cholera serum, show but a few flocculi with cholera serum, which forms a typical precipitate with filtered cholera bacilli; and that the specific precipitates, from these conclusions, possess as great a diagnostic value as does the agglutination itself. [M. O.]

3.—Jellinek reports the histories of 10 people and two animals struck by lightning. The first case, a man of 20, was found dead, with his clothes untouched, only his collar showing burns. On the top of his head the hair was burned off down to the neck, where there was a deep burn. There were burns of the back, buttocks, hips, legs, etc., and one of the third degree in the lower abdomen, scrotum, and penis, strictly confined to the left half of the body. The thoracic organs were found hyperemic, the abdominal organs anemic. Jellinek believes that the burns were caused, not by direct flames, but by the great internal resistance offered by the human body. Where the current entered remains unknown. Perhaps the severe burns occurred where the skin was especially moist from rain or perspiration. After reviewing the different theories advanced to explain death from lightning stroke, Jellinek states that the thermic effect of the electric current, with the consecutive increase in volume of the cerebro-spinal fluid, may play an important role, or the commotion may cause compression of the medulla. Experimental work upon the subject is also detailed, and other cases are reported with diagrammatic illustrations. In one case lightning caused a peripheral sciatica only. One stroke of lightning affected each of three individuals in a different manner. From experiments Jellinek found that not only the tension, but also the strength of the current will cause the burn. The current always seeks the road which offers the least resistance. But the way by which the current comes is as important as the strength of the current. Many works and experiments are quoted. [M. O.]

CENTRALBLATT FUER INNERE MEDIZIN.

July 27, 1901.

A Substitute for the Kieldahl Method of Estimating the Nitrogen of the Urine, to be Used for Clinical Purposes. A. JOLLES.

The methods carried out by adding 5 c.cm. of distilled water to the same amount of urine, taking 5 c.cm. concentrated H₂SO₄ of 1.84 specific gravity, heating, adding permanganate solution (about 4 gm. to the litre in strength), cubic centimetre after cubic centimetre until the color does not disappear after 15 minutes heating. Then decolorize with oxalic acid, coal tar, and gradually add 32% soda solution until the reaction is alkaline, shaking and cooling after each portion of soda is added. The fluid is then washed into the shaking vessel of Jolles' ozometer and the nitrogen determined volumetrically after Jolles' method. (*Zeit. f. Phys. Chem.*, Bd. XXIX, p. 236). The method was devised because of the time necessary for a Kieldahl nitrogen estimation. The actual working time necessary for such an estimation is, however, scarcely more than 20 minutes, and at the time for oxidation (with urine) and distillation and titration need not be more than two hours at most. Jolles' figures correspond sufficiently closely for clinical purposes to those obtained by the Kieldahl method, but are of course less accurate, and his method would seem scarcely to recommend itself through the rapidity with which it is carried out. [D. L. E.]

JOURNAL DES PRATICIENS.

July 27, 1901. (15me. Année, No. 30.)

1. The Treatment of Keratitis. F. TERRIEN.
2. Over-feeding in the Pathoguy and Treatment of Lithemia. PASCAULT.

1.—Keratitis is always infectious, whether primary or secondary. The cornea may be infiltrated, which is generally seen with some endogenous cause, hereditary syphilis, tuberculosis, etc., or ulcerated, from some ectogenous cause, as traumatism. Pericorneal injection is noted at once. Clinically Terrien separates keratitis into 3 divi-

lons, parenchymatous, superficial, and ulcerative keratitis. Parenchymatous keratitis is simply corneal infiltration. Its treatment will be hot compresses, smoked glasses, and a few drops of a weak atropine solution. Care must be taken to stop the atropine, should the intra-ocular tension rise too high. Internally mercury, potassium iodide, cod liver oil, iron, iodoform, salt baths, etc., are given. Superficial keratitis generally follows conjunctivitis in alcoholic subjects. An occlusive dressing and dark glasses may be necessary, or even median tarsorrhaphy. Corneal ulcers are the most common form of keratitis. Occlusion, with atropine and antiseptics are useful. Iodoform and methylene blue are also used. Hygiene and internal treatment are advised. The ulcer, especially when due to streptococci or pneumococci, may become neuro-paralytic, serpiginous, or phlyctenular. Then it must be cauterized. To diminish the intra-ocular tension and so prevent perforation, eserine is useful. If perforation occurs, atropine is again to be employed. Leucomata result from corneal ulcers. Yellow oxide of mercury will aid in clearing them up, with corneal massage. Finally, when the leucomata are large and centrally located, they may be covered with India ink to counterfeit the pupil. [M. O.]

2.—Pascual states that he who eats meat only gains less than he expends. This is also true of alcohol, spices, etc., as they cause gastric hypersecretion, and so lead to over-eating. Then as more is eaten, more is stored in the cells of the organism, the period of **prelithemic excess of function**. The liver is then over-worked, standing it well at first, but badly later. The excess becomes peptones, glucose, lactic or oxalic acid. Uric acid, creatinine, xanthine, etc., are then formed, the period of **lithemic excess of function**. Finally the nutritive and functional cell activity weakness, and loss of function, slowly results. Constipation appears, with fermentation. Clinically the lithemic is dyspeptic (hepatic); chemically he is hyperacidic (uric); physiologically he is intoxicated from hepatic insufficiency. Fat results, or lithemic glycosuria. Lactic acid, oxalic acid, and gravel appear in the urine, carbonic acid in the expired air, fatty acids in the perspiration, or these products remain in the individual, causing catarrh, ptosis, passive congestion, lithiasis, gout, arterio-sclerosis, etc. All the troubles are due to the liver and kidney, and the lack of elimination finally causes death. Purgation is necessary, with tonics, hydrotherapy, massage, alkaline drinks, vegetable diet, etc. These patients should learn to masticate, to drink properly, and to eat regularly, not too much or too often. Meat, alcohol, etc., should be cut off completely. Vegetables, bread, and fruit should form the main articles of the diet. [M. O.]

ARCHIVES DE MEDECINE DES ENFANTS.

June, 1901. (Volume IV. No. 6).

1. Umbilical Infection. PORAK and DURANTE.
2. Intermittent Albuminuria. H. GILLET.
3. Hypertrophic Cirrhosis of the Liver. H. AUDEOUD.
4. Infectious Endocarditis.

A. ZUBER and P. ARMAND-DELLILE.

1.—Death in new-born infants follows infection. Though infection be plainly present, either localized or widespread, its source, the point of entrance of the micro-organism, is difficult to find. Porak and Durante report in full four cases of generalized septicemia, the point of entrance of the germ in all cases being the umbilicus. The local, umbilical symptoms are suppuration, gangrene, erysipelas, hemorrhage, etc., often hardly enough to attract attention. The infection may enter along the umbilical vessels, or along the embryonic tissue of the cord. In the former case, there are no local symptoms. General septicemia follows. The liver is most often affected, the lung coming next in frequency. In the liver, degeneration occurs with jaundice. Secondly, dyspepsia may also occur. Two other cases, with jaundice, are described. The worse the local symptoms, the less dangerous, as a rule, is the infection. But these cases show how careful the physician must be in his work upon the umbilical cord. [M. O.]

2.—Gillet defines intermittent albuminuria as the condi-

tion in which albumen is not continually found in the urine. Accidental albuminuria occurs when the albumen appears in the urine only once. For diagnosis, specimens of urine passed at different parts of the day must be examined. Most of the cases of intermittent albuminuria are cyclic albuminuria. The majority of cases are also orthostatic, due to standing up and walking about. As a rule the albumen is found only in the day time. In a few cases it can always be found at the same time of day, or it may last a few days and then disappear for a few days. There is generally oliguria, more constant even than the albuminuria; and urobilin is present even when the albumen is not. Clinically Gillet divides children into three groups; those who seem perfectly well; those with vague symptoms of anemia, neurasthenia, dyspepsia, lithemia, growth, etc.; and those with distinct nephritic symptoms. The great number of cases belong to the middle group. It may follow nephritis, the infectious diseases, the diatheses and dyscrasias, auto-intoxications, and intoxications. It may last for years. The prognosis is generally favorable. The treatment is hygienic, diet, baths, rest in bed, with regulation of the intestinal function, etc. The general condition should be improved. A table of 15 cases follows. [M. O.]

3.—Audeoud reports two cases of **hypertrophic cirrhosis of the liver** in infants of 14 and 15 months, both of whom died two months later. In one the disease began at 12, in the other, at 14 months, with digestive symptoms; then the abdomen enlarged, with ascites and hypertrophy of the liver and spleen. Jaundice followed with disturbance of the skin and urine. Contrary to statistics, both cases were girls. Audeoud could find no cause in either case. The cirrhosis occurred quickly, probably due to a microbe which entered from the intestine. Both spleen and liver are enlarged, and jaundice and ascites existed. The disease ran a very acute course. Hypertrophic biliary cirrhosis is called "Hanot's Disease" in France. [M. O.]

4.—Zuber and Armand-Delille report a case of **infectious endocarditis** in a boy of 13, who had had four attacks of rheumatism. The origin of the infection could not be found. The aortic valves were most affected. The microbe found was a *cocco-bacillus*, like that described by Litten in a non-septic case of malignant endocarditis. [M. O.]

JOURNAL DE MEDECINE DE BORDEAUX.

July 28, 1901. (31me. Année, No. 30.)

1. Lumbar Puncture in Diagnosis. JEAN ABADIE.
8. Torsion of the Pedicle in Cystic Salpingitis.

ANDRE BOURSIER.

1.—While discussion of the therapeutic use of lumbar puncture is still rife, there remains no doubt of the service rendered by this measure in diagnosis. The cerebro-spinal fluid, normally clear, is cloudy in meningitis, purulent in suppurative meningitis. Or it may be bloody, showing ventricular hemorrhage, fracture of the skull, etc. The pressure, increased in disease, was formerly measured for diagnostic purposes. The freezing-point of the fluid is less than normal in tuberculous meningitis. The amount of albumen is increased in hydrocephalus, and acute meningitis. Bile pigment has been found in the fluid when excessive jaundice occurred. After the ingestion or the subcutaneous injection of potassium iodide or methylene blue, the appearance of either of these substances in the cerebro-spinal fluid shows that the pia-arachnoid has become permeable. Bacteria are easily found in it, so that the diagnosis etiologically may be settled. Lately, lymphocytosis in the fluid has been shown to denote tuberculous meningitis; while polymuclear leukocytes denote cerebro-spinal meningitis. Lymphocytes are also seen in tabes and general paralysis. It will at once be recognized how important a diagnostic factor lumbar puncture has become. [M. O.]

2.—Boursier reports another case of torsion of the pedicle of a cystic salpingitis on the right side, in a woman of 34. In this case, as in the others reported, the condition was not diagnosed before operation. Boursier states that the condition is only found with hydrosalpinx, generally on the right side, with only one or two twists of the pedicle. The fluid as a rule shows that it was hemorrhagic previously. The exact causes of the condition are as yet unknown. [M. O.]

Society Reports.

MEETING OF THE NEW YORK MEDICAL ASSOCIATION.

(Continued from Page 776).

Modifications in the Methods of Operative Surgery Resulting from Laboratory Research, Dr. Joseph D. Bryant, New York. Tindall, Lister and Pasteur were mentioned as laying the foundations for modern antiseptics. The essayist referred to antiseptics as the older and aseptics as the younger. Erysipelas, pyemia and other infectious diseases were abundant in Bellevue Hospital several years ago. Now, through a perfect asepticity, they have diminished and pyemia is so seldom found as almost to escape the notice of the physicians. The doctor referred to Lister's plan of antiseptic procedure, and the progress of aseptics in the last few years through which 60 to 70% of the patients are saved. Modern gunshot wounds result in 40% recoveries, instead of 95% of deaths as before. Modern methods of practice rescue from 20 to 50% of cases of bowel obstruction.

The Use of the Pneumatic Cabinet in the Treatment of Diseases of the Heart, was the subject of a most scientific and interesting discourse by Dr. Charles E. Quimby, New York. The author first took up the points of blood tension, nutritive interchange, and cardiac lesions, and said that the function of the heart and vessels is a simple mechanical process. To decrease vascular tension and increase cardiac nutrition are ideal therapeutic measures in cardiac disease. We must not only lower vascular tension, but develop those alternations of tension required to maintain the circulation. The author then gave a description of the pneumatic cabinet and the technic of treatment, and a close perusal of his paper will repay any specialist or general practitioner for the trouble of reading it. The cabinet which he employs is the very one that the profession condemned not many years ago, and which he has proved to be one of the most successful means of treating heart disease, as verified by his cases and reproductions of his sphygmographic tracings. Pneumatic differentiation applies to the different atmospheric pressures upon the lung in the thoracic cavity and on the cutaneous surface. From the standpoint of applied physics, pneumatic differentiation represents the nearest treatment to cardiac disease of all measures available. The doctor then had lantern slides showing the conditions of the different cases he had treated by the representative sphygmographic tracings. Reference was made to aortic and mitral regurgitation. Patients suffering from cardiac and arterial tension are being successfully treated by the cabinet apparatus, and clinical results have proved the effect of this method.

Gun-shot Wounds of the Hip Joints by Reduced Calibre Projectiles," by Major Louis A. LaGarde, Washington, D. C., proved to be one of the most valuable contributions presented. The doctor has just been detailed by the Government as "Lecturer on Gun-Shot Injuries in the Army Medical College." The Major gave a most vivid description of tests made upon the cadaver with small-calibre bullets, the results of gunshot injuries received in battle, and the comparative force of impact or hole produced by the old-fashioned 45 and 56 calibre bullets of the civil war with the smaller sizes, 30 and 32, now in use. Of 389 cases of hip-joint injuries received in the Civil war, Otis informs us that by the treatment then employed the mortality was 84 per cent, and those results are a fair average of the gun-shot injuries in the Crimean and other great wars, during the pre-antiseptic era of treatment. Gunshot wounds then inflicted were prone to invite sepsis from the great amount of focal injury, especially on the bones and joints. The missiles of the military rifle varied from 50 to 55 calibre in diameter and were composed of soft lead, easily deformed by impact; wounds of the larger joints were marked by an area of destruction corresponding to the original calibre of the bullet. Bones hit by these bullets were characterized by loose spicula with fissures running into the marrow and the bullet often lodging around the joint structure. The change in the armament of all the countries was coincident with new wound treatment. All the Governments have now discarded the large calibre bullet for one of 26 or 30 calibre. Furthermore, the lead of this new bullet is encased in

hardest steel, so that the deformation is seldom observed. The doctor showed a Springfield rifle bullet, weighing an ounce, 45 calibre, made of lead, which deformed easily on impact. He also showed the bullet from a 30 calibre Krag. The rotation of the bullet at the muzzle in both guns differs widely, and the rotation itself is said to have something to do with the destructive effects. The bullet from the Springfield rifle is said to be turned 899 times per second at the muzzle as it issues from the gun. The gunmaker has given a shorter twist in the new rifle, making the new bullet (referring to the 26 and 30 calibres) revolve 2100 times per second as it issues from the gun. From 600 to 1500 yards the humane advantages of the smaller bullets are demonstrated upon the cancellous tissues of bone. A specimen was shown demonstrating the effect of the new bullet upon the spongy end of the bone, showing perforation. Now, as to the results. In the Spanish-American and Philippine wars there were 5.8% mortality as compared with 81% in the Civil war, in gun-shot wounds of the knee—a reduction of over 78% in mortality. The doctor had used the X-rays in diagnosing the course of bullets in two soldiers, who were hit, respectively, at 700 and 800 yards at San Juan Hill.

In the Anglo-Boer war, Mauser bullets had, at medium and long ranges, passed through the joint without causing solution of continuity in the neck of the bone, and also produced a clean-punched-out hole without comminution.

Dr. Alleman, here interposed the question as to whether the destruction of tissue at short distances was more than at long distances. He had seen an instance of a Krag bullet, at short range, where the bullet went through the foot, and the wound of entrance and exit were the same, the patient recovering without a great deal of destruction of tissue.

The essayist replied that at close range the effect upon the soft tissues was not different. In the muscle and skin the channel differs very little at 20 feet from that at 2000 yards in the compact substance of the bone, where the ball meets a great resistance. At all the ranges and especially with the maximum velocity near the muzzle, the destruction is very great. "We all know that the point ends of bones are much softer than in the middle of the shaft, and for that reason those wounds in war which were dreaded so, are to-day less in destructive effects than they are in the middle of the shaft. I would ten to one rather treat a man to-day with gun-shot injury of the hip or knee, by a small, reduced-caliber bullet, than I would wish to treat him for a gunshot injury of the tibia or foot. The destructive effects in proximal range are always great, because of the superior velocity of the projectile.

Asthma of Blood Origin, Not Nerve or Reflex, by Dr. G. N. Jack, Depew, N. Y. The doctor said that asthma is not a disease, but a symptom dependent upon toxemia, intestinal derangement and particularly the condition of the blood. Dr. George F. Cot, of Buffalo, referred to varieties of asthma, and said that it is shrouded in mystery. One investigator has shown that it is caused by vaso-motor paresis, and another by neurosis. No one knows what actually takes place in the bronchial tubes. Dr. Cot suggested that if the afflicted one would inhale easily or slowly, not quickly, he would get relief.

The Present Status of the Pathogenesis of Concomitant Strabismus, Dr. Alvin A. Hubbell, Buffalo. (Read by title.)

The next paper on the program was on Acne by Dr. Edmund L. Cocks, New York. This disease occurs in females more frequently than it does in males. It is a disease of lowered vitality and impaired digestion. Constipation, which is always present, should be removed. 75% of all cases occur before the age of 18, between 15 and 25 is the limit. In many women just before and after the menstrual period this affection comes on. Diet of a certain kind is an exciting cause, but there is a class of micro-organisms which are responsible for acne. Another cause given is intestinal intoxication. The doctor thought the treatment to be difficult and serious, but it is curable by constant and persistent treatment and attention. Dr. Reese, Cortland, N. Y., believed that acne was due to laziness, that patients are not regular in moving their bowels. It is easily cured by tincture of green soap, scrubbing the

face with a nail brush; and cascara, as a laxative, will cure every case.

Concluding the morning's program, Mr. Curtis gave an exhibition of his high-tension electrical machine and ozone generator.

MORNING SESSION, OCTOBER 24, 1901.

Dr. Wm. G. Le Bouillier read a paper entitled **Differential Leukocyte Count in Fractures**. His report consisted of 65 differential counts in single fractures and 39 counts in compound fractures, comprising fractures of the skull, nose, ulna, and aseptic compound fractures of the femur and radius.

Prostatic Obstruction to Urination—Its Remedy by Enucleation of the Diseased Parts, Dr. J. W. S. Gouley, New York. He reviewed the anatomy of the prostate and mode of radical treatment, and referred to the enucleation of the diseased glands through the perineal incision. The operation is performed ordinarily when auto-catheterization is difficult or impossible, but there is no doubt of its indication in the earlier stages of cellular enlargement. The process of enucleation, if carried out with deliberation and gentleness, is effected without difficulty. The doctor then showed one of his latest instruments, which he considered an improvement on the rubber one by Dr. Parker Syms.

In the discussion, Dr. Parker Syms gave credit to Dr. Gouley for radical treatment and relief in hypertrophy of the prostate. The mortality, he thought, was very high in prostatectomy when operating on enfeebled old men and when the work is left as the last resort. It should be done, if at all, as soon as serious obstruction to the act of urination is observed. If those cases in which cystitis and infection occur, without relief, the mortality is practically 100%. Death ensues in time in all these cases. He proposed that there should be made a small laparotomy wound above the bladder, then perineal section, and then the operator, with two fingers of the left hand within the abdomen, presses down the prostate so that he can reach it in the perineum and enucleate it with the index finger of the right hand. That suggestion has been modified with advantage by Dr. Johnson, of New York, who, instead of doing a laparotomy and going through the perineum, makes an incision down to the bladder, but below the peritoneal fold, and the cases that have been reported by him have been successful. "I have devised a retractor which I think will make it possible to enucleate the diseased portions of any hypertrophied prostate through a perineal wound." (The doctor here exhibited his instrument, a retractor with a rubber bulb on the end of a catheterlike tube).

Dr. Eugene Fuller said he always enucleates or removes the obstruction, that he is not one of those who are frightened at the idea of the supra-public operation. It is necessary to know how to perform the operation, how to treat the wound, and how to manage your bladder wall. If you do that, the mortality itself is not great. He takes the prostate out a great many times by the perineal route, but there are a great many cases where the supra-public route is more preferable. "I have a gentleman now, aged 81, whose arteries are so atheromatous that they are like pipe-stems. He is convalescent, up and around after a prostatectomy. I did a perineal prostatectomy on him." He had a stone weighing $\frac{3}{4}$ of an ounce; it was not dragged through the perineal wound, but a secondary suprapubic operation was done and the stone was removed without difficulty. "I do not think one should be wedded to any one surgical procedure."

Dr. Lee, recently of St. Louis, said that he did not look upon hypertrophy of the prostate as most men do, as a senile condition. He believed that old, uncured gonorrheas had a great deal to do with hypertrophy of the prostate; also the condition of the kidneys or anything that will produce a cystitis has a tendency to produce hypertrophy of the prostate. Method of treatment must depend upon the conditions that exist, a great many hypertrophies being due to conditions outside of the prostate. A thorough examination of the interior of the bladder should be made with the aid of the cystoscope. He had seen hypertrophy subside 50% by removing a villous papilloma which obstructed the outflow of urine. He was thoroughly convinced that vasectomy and castration reduced the size of the prostate. There seems to be a great objection to men

being castrated, but for years, for every conceivable ailment, women have been castrated.

Dr. Gouley, in closing, said he had made one thousand dissections of parts of the prostate and claimed that you cannot injure the bladder wall. The smaller the prostate the more difficult it is to remove. As to the accepted terminology, the doctor said: "The sooner we get rid of the word 'hypertrophy of the prostate,' the better. There is no such thing as hypertrophy of the prostate. It is rather under-nourished than over-nourished. The great enlargement of the prostate is due to atresia of the acini of the prostate. He also claimed there was no such thing as "a prostate gland," but that there are many prostate glands in that body which consists of $\frac{3}{4}$ of muscle tissue. "It is these prostate glands that we endeavor to enucleate." He proposed further to discuss the matter at the coming 1902 meeting of the American Medical Association. He, like some of the others, was not wedded to any one operation; he performs many, but whichever it is "It is the one that is indicated and when I do it, I do it fearlessly." (Applause).

(To be Continued).

THE NEW YORK OBSTETRICAL SOCIETY.

Meeting held October 8, 1901.

The President, Dr. H. J. BOLDT, in the Chair.

Dr. Grandin presented a specimen of **Tubal Gestation**, diagnosed hemato-salpinx by a colleague. Superficial examination of the uterine scrapings suggested chorionic villi. The patient had had amenorrhea for six weeks, and two attacks of abdominal pain. A small mass was felt near the right broad ligament. On opening the abdomen, six ounces of blood were found in the peritoneal cavity.

Dr. G. Ward, Jr., presented a specimen of **Multilocular Cyst of the Kidney**, from a patient, forty-nine years old, with a family history of carcinoma. In May, 1900, he removed ovaries, broke up adhesions, and performed ventro-fixation. A smooth globular growth was felt in the left hypochondrium, but with the hand in the abdomen, the cystic character of the tumor, its mobility, and its probable nephritic origin were noted. In December, 1900, symptoms referable to the cyst appeared, gradually increasing. The tumor increased in size, filling both hypochondriac regions. Dr. Einhorn agreed that nephrectomy was the only means of relieving the patient. The other kidney was apparently normal; the urine passed averaged thirty ounces daily, specific gravity was 1010, and there were no albumen, sugar, or casts. Celiotomy was performed June 11, 1901, and the growth found adherent to the colon and omentum. The whole mass was enucleated, the pedicle being ligatured with chromicized gut. The wound healed by primary union and the patient returned home on the 20th day. For ten days she was about, gradually regaining her strength, then she had pain at the site of operation and fever. An abscess was found and drained. For a few days there was apparent improvement, then fecal matter appeared through the opening, her condition became worse, and death took place fifty-six days after the operation. The autopsy showed an area of gangrene involving the colon adjacent to the tumor. The other kidney was normal. Multilocular cyst of the kidney is a rare disease, and is almost always bilateral. Dr. Jarman reported a similar case. The left kidney was affected, and he made a curved incision over the hip, through which the kidney was removed. About the sixth day the temperature was 106° and she complained of chills. The fever passed away and the patient got well. This was five years ago, and she is still well. Dr. Boldt believed that this incision was preferable to opening the abdomen.

Dr. L. Broadhead presented a specimen of **Placenta Duplex or Biloba**. The supplementary placenta measured 15x6.5 cm., while the main placenta measured 14.5x11 cm. There was a space of about 5 cm. between the two placental masses, which were connected by the chorion and three fetal vessels, one of which was of large size. The

supplementary portion (placenta succenturiata) may remain in the uterus. If at the edge of a placenta, which seems to be complete, the torn ends of vessels are noted, that is evidence that a portion of placenta has been left behind, and search for it should be made at once.

Dr. Edgar presented a reproduction of the mammary changes produced during menstruation. He drew attention to the prominent veins, darkening and edema of the areola, erect and congested nipple, and dry scales in the orifices of the ducts. He believed that the mammary changes of early gestation were valueless even for an uncertain diagnosis of pregnancy. Dr. Graudin thought that the mammary signs were of value only in connection with the other signs of pregnancy. Dr. Jewett had been accustomed to attach some diagnostic importance to the mammary changes in a first pregnancy in the absence of pelvic disease. Dr. Edgar said that in the absence of uterine disease the mammary changes at the menstrual period are practically the same as those which occur in the first three months of pregnancy. It is the rule among the upper classes to find changes similar to those shown 22 or 48 hours before the expected menstrual epoch.

Dr. LeRoy Brown read a paper entitled "A Comparative Study of Immediate Recovery Following Vaginal, Total Abdominal and Supra-Vaginal Hysterectomy Involving 130 Cases."—Dr. Brown three years ago had advocated the vaginal operation. Results apparently left nothing to be desired. During the past two years, this method has been gradually replaced by the abdominal, more conservative route. He compared the immediate recovery of patients following these operations. 34 vaginal hysterectomies, 35 abdominal hysterectomies and 54 supra-vaginal hysterectomies were performed. Of the 36 vaginal hysterectomies, there were two deaths, of 36 abdominal hysterectomies one death, and of 59 supra-vaginal hysterectomies five deaths. There was shown to be a slight difference in favor of the vaginal route, which he attributed to the presence of the sutures in the abdominal wall. The patient made a recovery after one method of operating as evenly as another. Both have gauze drainage, which must be removed; one has the abdominal wound, the most prominent feature of the operation. This wound with its pain and frequent dressings, impairs the morale of the patient. After the gauze drainage is removed, the patient, following vaginal hysterectomy, is thoroughly at ease, mentally and physically. The one, following abdominal hysterectomy, is worried and anxious. He regards the vaginal operation as the more difficult, while the abdominal route is much the safer method. It is not his custom to close the pelvic peritoneum in either operation. The recovery of patients from supra-vaginal hysterectomy is surgical in every respect; there is no suppurating cavity to close by contraction and granulation. The true advantage of the supra-vaginal method was in the absence of any drain with its attendant painful removal, the absence of the resulting suppurating, closing cavity, and the time gained in the discharge of the patient from surgical care. Leaving the cervix, while of distinct advantage, is accompanied by some risk, since, if secondary infection occurs, the effusion under the flaps can only be reached by a secondary operation. That drainage through the cervix was a bad practice he was personally convinced. The five deaths from supra-vaginal hysterectomy were caused by sepsis. In all the fatal cases the sub-peritoneal space was drained by the gauze wick through the cervix. He concluded that (1) while the result of a supra-vaginal hysterectomy was most satisfactory; the operation was marred by the possibility of secondary infection. When infection occurs, it can be reached by a secondary operation. (2) The chances of infection are greater when the sub-peritoneal space is drained through the canal of the cervical stump, or when the canal is left open. (3) In total abdominal hysterectomy there is less likelihood of secondary complications, and though objectionable on account of the

suppurating cavity, it offers a surer means of uninterrupted recovery.

Dr. Bache Enniet advocated the supra-pubic route for all classes of work. He advised thorough disinfecting of the uterine canal by curetting before opening the abdomen, then by carbolic acid and the thermo-cautery after excision. He always stitched the peritoneum over the cervical stump. Dr. Vineberg considered that the cases of abdominal hysterectomy packed with gauze were not cases without drainage, for the drainage in these cases was of the best kind. Dr. Waldo has given up the partial operation because he did not get good drainage. Dr. Brown emphasized the fact that, if going to drain, we must remove the cervix to have thorough drainage. In supra-vaginal hysterectomy it is better not to drain, but to close the cervix. Supra-vaginal hysterectomy had been employed for fibromatous uteri, or in pus cases in which the pus was sterile. Total hysterectomy was generally done in more desperate cases or those in which a large area of raw surface was exposed.

BOSTON GYNECOLOGICAL SOCIETY.

Meeting held October 9, 1901.

Dr. H. O. Marcy opened the discussion upon **Fibroid Tumors of the Uterus**, referring to early abdominal surgery. He spoke of the difficulties encountered and the prejudice manifested to this department of surgery. He mentioned the excellent work of Dr. Burnham and Dr. Gilman Kimball, of Lowell, who performed 225 ovariectomies with sixty-nine recoveries, and extirpated the uterus twelve times with five recoveries. Dr. Marcy said that Storer was the first to accomplish successful removal of the uterus. Massachusetts, by its early and continued success, has become the home of abdominal surgery. He spoke of the early management of the pedicle by Dr. Storer, who treated it extraperitoneally, leaving the ligatures outside the wound. Dr. Marcy, seeing the advantage of such disposition, carried the pedicle downward after sewing it off with tendon sutures. Hemorrhage preventing recovery was formerly a serious obstacle. Adhesions after abdominal operations are prevented by the careful introduction of fine sutures, applied superitoneally, that all incised portions of the peritoneum, as well as the pedicle, be completely turned backward, presenting a smooth, closed surface. Dr. Marcy spoke of the friendly criticism which he had always had from members of the society, and expressed his gratitude for the valuable suggestions offered from time to time. He referred to Lister's early use of animal ligatures. First catgut was used, and now kangaroo tendon, both thoroughly aseptic, and the sutures are buried. The uterus could sometimes be saved when uterine tumors existed, but he thought that generally unwise, because the uterus was not infrequently seriously affected. When the uterus is the centre of a tumor, pregnancy cannot occur. The removal of the whole mass affords immediate relief. He showed a specimen of a uterine fibroid removed from a patient aged 72, who thought that she had been cured. To show the bad effects resulting from the use of buried silk sutures, Dr. Marcy exhibited a specimen containing a silk knot. A man some three months before had had a testicle (left side) removed; soon after the other testicle became the seat of pain and though the patient had been in two different hospitals for treatment, he obtained no relief until Dr. Marcy removed the silk knot. Dr. Marcy also showed specimens from two cases of gall-stones, upon which he had recently operated. In one of the cases there were over a hundred gall-stones of varying sizes; in the other there were two stones, one large, and one small.

Dr. Frisbie, in discussing uterine fibroids, advised the removal of fibroids before serious symptoms occur. Dr. W. T. Brown said that Dr. Burnham was the first operator who successfully removed the entire uterus. He stated that the pioneers of abdominal surgery were not all model operators, since one of the earliest operators went to lunch in the midst of an abdominal hysterectomy. Fibroids are

usually of multiple origin, and occur mostly in women who are forty years of age or more, in whom the preservation of the uterus is of minor consequence. Dr. V. D. Miller said that she had seen tumors of this class as large as a fetal head of the fourth or fifth month of pregnancy. When there were no adverse symptoms, she questioned the propriety of operation for their removal. Dr. A. E. Miller felt in doubt whether growths of this character should be interfered with. Dr. G. Ryder remarked, that myomectomy often resulted in failure, owing to the occurrence of growths in other parts of the uterus. Dr. A. L. Norris reported a case in which a fibroid was located in the right cornu of the uterus, the patient doing well. He thought that if physicians looked for such tumors, they would find them oftener than they suppose. Dr. A. P. Clarke referred to the methods employed in France, where hysterectomy has been too common. Myomectomy is indicated for the removal of fibroids in young women. Tuffier reported 500 cases of myomectomy, and proposed that abdominal hysterectomy for fibroids should be the exception. Enucleation of fibroids with preservation of the uterus and the adnexa is the operation of choice. Two factors come into consideration, the greater perfection with which the operation is now performed, and the smaller number of uterine fibroids now seen, extending as high as the epigastrium. Tuffier has removed from one to seventeen fibroids of varying size from a single uterus. He speaks of having resorted to enucleation in 19 consecutive cases, with 18 recoveries. The contraindications to myomectomy are manifest when the uterus contains many tumors in varied states of telangiectasis, when the growths have become sphacelate, or the adnexa are irretrievably diseased. Advanced age of the patient may delay recovery. In such cases total hysterectomy is to be preferred. Dr. Clarke stated that his experience has led him to look upon enucleation as less practicable. Dr. G. W. Jones was not in favor of myomectomy on the ground that more time was required, and the danger from hemorrhage was greater. Dr. G. Ryder was opposed to myomectomy for the same reason. Besides, the uterus and its appendages, in cases of fibroids, are in a more or less diseased state.

Dr. Marcy, in closing the discussion, took the ground that aseptic wounds should not be drained. He reported a case in which delivery was delayed by the presence of the fibroid. He spoke of the advantages of resorting to myomectomy in cases of fibroids in young women. When the tumors are multiple, abdominal section is preferred, since there is a better chance of saving the uterus. Multiple fibroids have resulted fatally because the patient has refused to have them removed. The greater the age of the patient, the worse is the danger from such growths. The surgeon should first make a decision, and should never urge an operation for the sake of performing it. If the disease, when left to itself, is likely to tend toward a fatal issue and there is a fair chance of recovery with an operation, to decide against the measure would be a sin of omission. Consultation is often advisable. The operator should be well prepared to meet any emergency that may arise in a case, in order that a high standard of surgical skill may be maintained, and human life be not trifled with.

Extra-buccal Nutrition.—Von Leube is quoted in the *Journal des Praticiens*, (June 1, 1901, No. 22), as dividing the means of giving sustenance, when food cannot be given by the mouth, into nutritive enemata and subcutaneous injections. The best results will be obtained by combining these methods. The enemata, composed of albumen, (milk, 300 g., peptone, 60 g., raw eggs, 3 g., and salt, 3 g.) and of carbohydrates, (starch, 50 to 100 g., or sugar 15 to 20 g.) represent 550 calories each, and can be given twice daily, after a detersive injection. For the subcutaneous injections a fat is used, 50 to 100 g., injected slowly once a day, representing 920 calories. Thus 2000 calories can be given daily. From this it is plain that artificial alimentation is no longer impossible. [M. O.]

THE OUTBREAK OF TETANUS IN ST. LOUIS.

By A. C. ABBOTT, M. D.

of Philadelphia.

Professor of Hygiene and Bacteriology in the University of Pennsylvania.

To the Editor of The Philadelphia Medical Journal:

In reply to your request for an expression of opinion concerning the cause of the serious accident reported from St. Louis in connection with the administration of antidiphtheritic serum, permit me to say that the evidence at hand does not warrant a final opinion on the subject. If, however, we can take as trustworthy such data as have reached us through the daily papers, it might not be unprofitable at this time to use them as a basis for speculation that may or may not aid in the elucidation of the matter.

Of primary importance to an analysis of the circumstance is manifestly the discovery of the real cause of the fatalities. That they are attributable to the serum employed seems beyond reasonable doubt, but whether they resulted from infection by the specific microorganism of tetanus, or from intoxication by the poison of tetanus that was circulating in the blood of the horse at the time the serum was prepared, cannot now be decided, though we are inclined to regard the latter supposition as the more likely explanation, for the following reasons:

In the first place the conditions under which diphtheria antitoxic serum is usually prepared are not in any way favorable to the growth of the tetanus bacillus, should it by accident gain access to the serum during the course of its preparation. The tetanus bacillus is, in technical parlance, an obligate anaerobe, that is to say, it is one of that group of microorganisms that exhibits no evidence of life in the presence of free oxygen. As the blood when drawn from the animal contains oxygen, and as no effort is made in the preservation and preparation of the serum to exclude oxygen, it is evident that the conditions from this standpoint are directly opposed to the opinion that tetanus bacilli were growing in the serum: and inasmuch as it is the custom to employ antiseptics (phenol, trikresol or formaldehyde) for the preservation of serum, we have here an additional reason for skepticism as to the multiplication of tetanus bacilli in the serum. It must be admitted, however, that neither the oxygen in the serum nor the strength of antiseptic used can be certainly said to destroy the spores of bacillus tetani.

Admitting that tetanus spores did gain access to the serum, and admitting as we are, I think, forced to do, that they could not have developed under the conditions, the question arises, is it likely that they were originally introduced in sufficient numbers to fully account for the accident without any multiplication on their part, and that they simply lay dormant in the serum until its injection into susceptible human beings? We can scarcely conceive this to be the case, unless the source from which they came was much richer in them than one ever observes outside a culture flask, a grossly

infected wound or, perhaps, imperfectly cleansed and disinfected instruments and apparatus employed in the study of the disease and its exciting organism. Had the serum contained the bacilli or spores of tetanus in any such numbers as this, tetanus would almost certainly have developed in some one or another of the very susceptible animals employed for the standardization of the antidiphtheritic strength of the serum; but this we are told did not occur.

In so far as the evidence will permit of an opinion we think the facts point more to a toxic origin for the deplorable accident, though at the very outset we encounter an obstacle to the establishment of this belief. If it is possible for the horse that supplied the serum to have been suffering from tetanus in its incipient unrecognizable stages on August 24, when the serum in question was drawn, then the solution of the whole problem is simple, but we do not know whether this could have been the case or not. Little is known of the real period of incubation of tetanus. In human beings it is usually regarded as something less than fifteen days; we occasionally hear of latent, delayed or chronic tetanus; we know that experimentally the period varies in different animals, varies with different doses, and with different cultures employed; it does not seem therefore beyond the realm of possibility for the horse, which developed unmistakable signs of tetanus on October 2nd, to have had the disease in its early stages on August 24, (about five weeks before) when he was bled. If there is anything in this assumption, the serum contained at the time of bleeding not only diphtheria antitoxin but tetanus toxin in small quantities as well. But why then did not the animals on which the antidiphtheritic strength of the serum was tested give evidence of tetanus intoxication and thereby direct attention to the horse? I think this is best answered by some of the conditions under which these tests are made. In the standardization of serum for its antidiphtheritic strength the method commonly employed is, roughly stated, to mix with a fixed quantity of diphtheria toxin of known toxicity varying amounts of the antitoxin serum under consideration until a point is reached at which the amount of serum just exactly neutralizes the toxin employed, that is to say, prevents the toxin from killing the animal (guinea pig) into which the mixture is injected. In the case of strong sera, i. e., those rich in antitoxin, the quantity needed for neutralizing the toxin may be very small indeed, often as low as 0.005 to 0.01 c. c. While these antidiphtheritic sera contain usually only diphtheria antitoxin, for which the test is being made, they may under very exceptional circumstances, as I believe to have been the case in St. Louis, contain also other, undesirable, bodies such as toxins, referable to accidental, intercurrent or antecedent infections, but in amounts not sufficient to cause, at the time of bleeding, symptoms in the animal that would attract attention. When, therefore, the serum being standardized is employed in such very small amounts as those noted above, it is possible for the quantity of undesirable toxin that it may contain to be too small to evince its intoxicating properties,

even in the very susceptible guinea pig on which the test is made; but when this tiny dose of serum is multiplied up to a point at which it becomes a useful therapeutic agent for the treatment of diphtheria in human beings, i. e., from one thousand to two thousand times, this trace of dangerous toxin assumes thereby very much more significant proportions, and might indeed be sufficient to cause acute intoxication with, in some cases, lethal termination.

The vulnerable point in this argument is plainly the assumption that a horse may have tetanus toxin in his blood for a month or six weeks prior to the time that he evinces the characteristic signs and symptoms of tetanus, but until we know that this cannot be the case we must regard it as a remote possibility against which all precautions should be taken.

In so far as tetanus bacilli or their toxins are concerned, their detection in such animal products as antitoxic sera is fortunately a matter of comparative simplicity, and after the experience in St. Louis I do not regard one is justified in distributing these products until all doubt in the matter is cleared away. This I believe can always be done in several ways, namely, by the very careful observation of the horses under treatment; by the occasional prophylactic use of tetanus antitoxin upon such horses; by the keeping of serum for a reasonable length of time after it is prepared and before it is distributed throughout the community, the object of this interval being to keep the horse from whom the serum came under observation; and finally by a special test directed to this point, a test in which there is injected into a highly susceptible animal, the guinea pig, not the fraction of the dose of the serum that is to be used on human beings, but the full human dose. If after this the animals exhibit no signs of tetanus, one is justified in assuming that the serum is free from anything capable of causing the disease.

The question has arisen as to the probable influence that the St. Louis accident will have upon the employment of antitoxic sera in general. Doubtless some will be for a while intimidated, but that this will be wide-spread or lasting I think unlikely. When we consider the thousands and thousands of injections of these sera that are annually administered, with undesirable results so infrequent that they may practically be ignored, in so far as they are referable to the serum, it is evident that this deplorable incident must be regarded simply as an unavoidable accident of exceptional rarity, and if my interpretation of it is correct, as an accident that could not have been foreseen and that might have fallen to the lot of any of us.

To say that I experience the deepest sympathy for the man on whose shoulders the weight of this burden must fall will be to express my feelings but mildly; and I trust, as I believe, that the outcome of the investigations that are now being made of the incident by those competent to undertake it, will fully exonerate him from any personal responsibility for the accident.

THE PRESENT STATUS OF THE BOTTINI OPERATION
AS A METHOD OF TREATMENT IN OBSTRUCTIVE
HYPERTROPHY OF THE PROSTATE GLAND, DERIVED FROM A SUMMARY OF EIGHT HUNDRED
AND EIGHTY-EIGHT OPERATIONS BY FORTY-
EIGHT OPERATORS.By ORVILLE HORWITZ, B. S., M. D.,
of Philadelphia.

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College; Surgeon to the Philadelphia Hospital, Jefferson Medical College Hospital and State Hospital for the Insane.

It is generally believed that with few exception, prostatic hypertrophy usually begins in individuals who are over fifty years of age. White and Martin state: "extensive tabulation demonstrates, that enlargement of the prostate begins exceptionally under the age of fifty or after seventy." This is the received view, but I am of the opinion that the morbid condition commences much earlier than is commonly supposed. At least one eminent authority concurs with me in this belief. Dr. L. Bolton Bangs, writing recently on this subject (*Journal of Dermatology and Genito-Urinary Diseases*, March, 1901), says: "In my opinion enlargement of the prostate gland is not a senile condition; its effects may not show themselves until midlife or later, but it really begins in early life."

Obstructive symptoms due to prostatic enlargement usually make their appearance between 50 and 65 years of age, when on examination it will be found that the growth has obtained considerable size. Hypertrophy of the prostate gland is not only a very slow but essentially a chronic process; it naturally follows that probably several years elapse after the gland first begins to enlarge before any considerable increase in the dimensions of the organ takes place, and indications make themselves fully manifest; which would account for the symptoms occurring late in life, the gland being usually markedly enlarged at the time they first make their appearance. This view appears to me to have been verified from numerous cystoscopic examinations, strengthened by the improved methods of examining the urethra, prostate and bladder, which have led me frequently to discover a beginning retundity of one or more lobes of the prostate; abnormal in men between 40 and 50 years of age, there being no symptoms referable to the change going on in the gland, the condition being unsuspected by the patient, and discovered by the surgeon accidentally. I am convinced that if the future of these patients could be watched, it would be found that, in many instances, by the time they had attained the age of 60, the prostate would be found to have enlarged sufficiently to give rise to unmistakable symptoms.

Individuals in whom prostatic hypertrophy takes place may be divided into three groups:

1. Those in whom the enlargement does not produce obstruction; or where the urinary symptoms are so slight as to attract little or no attention, the patient being unaware that the morbid growth has taken place, and goes through life with few or no symptoms referable to the prostatic enlargement.

These individuals, of course, require no treatment.

2. Those in whom there is residual urine associated with a disturbance in the function of urination and are dependent on catheterism for relief; who nevertheless live to old age in comparative comfort, requiring no other treatment than the use of the catheter. Under this head may be ranked a large number of prostatitis.

3. Those who sooner or later suffer from what is known as "the break-down in catheter life." The catheter being inserted with difficulty, with pain becoming more and more intense both day and night; these persons are certain in the course of time to suffer from very grave secondary complications, their resisting power becoming lowered and worn out by pain and loss of sleep. It is in this group of cases that either a radical or palliative operation becomes necessary as time goes on; and the sooner the profession realizes the truth of the statement that those individuals in whom the "break-down in catheter life" is imminent should early receive surgical aid, the better for the unfortunate sufferers. Delay in these cases is fraught with danger to the patient and often prevents the surgeon from doing anything more than palliate the disease. The importance of early recognizing these cases of prostatic hypertrophy cannot be too strongly urged upon the profession, when, if deferred, ultimately surgical interference becomes a necessity. Experience has demonstrated conclusively that the safety and comfort of these individuals demand that an operation be performed as soon as it becomes evident that the time is approaching when the catheter cannot be depended upon as a means of treatment. Early operation means small mortality, with quick convalescence and a radical cure; whilst an attempt to postpone the inevitable betokens operating upon a patient worn out with suffering and loss of sleep, whose resisting power is at its lowest ebb, often associated with some grave secondary complication, adding very materially to the risk of surgical procedure. When this condition exists, any mechanical interference is fraught with danger, and a radical operation being often out of the question, some palliative measure becomes necessary, which at least is but a makeshift; extremely unsatisfactory alike to patient and surgeon. Frequently in cases of advanced prostatic obstruction attempted radical operations, if successfully performed, are unsatisfactory in their results and prove to be only palliative. In several instances, in cases of hypertrophy of the prostate gland of long standing, when I have performed complete prostatectomy and entirely removed all obstruction, the bladder has remained permanently crippled by disease, and has never fully regained its vigor. Other operators report a similar experience. The general health of these patients often improved; the catheter, however, has to be frequently employed, although the instrument can be inserted without difficulty or pain. The cystitis is mitigated, but though these patients are benefited, they are far from cured, the operation being only a palliative measure. It is this class of patients that teaches the necessity for early action.

I believe that the day is past when the physician

is justified in standing by and seeing these unfortunate people drift along month after month into a situation of permanent invalidism with the discomfort, pain and misery attendant on their unfortunate condition, allowing valuable time to be lost by delaying until the urgency of the symptoms demand immediate surgical interference. The opportunity to perform a radical operation, with comparative safety and almost certain of success, goes by and in its stead one of the unsatisfactory palliative measures in vogue is resorted to, which, owing to the generally poor physical condition of the patient, is usually fraught with great danger.

The sooner the profession learns to recognize the cases in which the catheter cannot be relied upon to relieve symptoms caused by the obstructing hypertrophied prostate, and that they are suitable cases for surgical interference and should be referred to the surgeon, the better for suffering humanity. Not only will life be prolonged, but much unnecessary misery will be spared; we will cease to hear of prostatic surgery for the relief of hypertrophy being attended by such great mortality and of the results being so uncertain, and in many instances unsatisfactory. Early operation under these circumstances is absolutely essential, as in any other condition in which prompt surgical aid is indicated.

Operations for the relief of prostatic hypertrophy are divided into the palliative and radical, to which I take the liberty of adding, since the introduction of the Bottini operation, the *prophylactic*. Perineal prostatotomy, vasectomy, angioneurectomy and ligation of the internal iliac arteries have all had their advocates and have been given a fair trial by numerous surgeons throughout the world; the universal testimony as to their efficacy is unfavorable, and they have practically been abandoned as a means of treatment. Orchidectomy has proved to be of value in some instances, where the prostatic growth is of a purely glandular type; a rare form of hypertrophy which is almost impossible to distinguish from that of other varieties. This operation is not applicable in the early stages of the enlargement, whilst the sexual vigor is still preserved, as a consequence the sphere of its usefulness is so restricted as to be of but little practical value. The palliative operations consist of vasectomy, in conjunction with daily catheterism, or permanent suprapubic drainage. Whilst the radical measures are either a partial or complete prostatectomy or a prostatotomy, by means of the galvano-caustic incisor. The latter method of treatment being capable of being employed as either a prophylactic, palliative or a radical procedure, depending on the character of the growth, the length of time it has existed, the complications which attend it, together with the physical condition of the patient.

The operation of prostatectomy will always be applicable in certain forms of prostatic hypertrophy. The indication for its employment is much restricted since the introduction of the Bottini operation. Partial suprapubic prostatectomy is to be performed in cases of obstruction due to interurethral growths, in some instances where residual urine is caused by hypertrophy of the lateral lobe, or where it is due to a valve-like formation that acts

as a barrier to the free egress of the urine. Complete prostatectomy is indicated, provided the patient's physical condition is suitable, where all three lobes are enlarged, especially if associated with tumor formation, where the vesical outlet is well elevated above the base of the bladder, having a pouch formation either above or below the enlarged gland, with probably a stenosis of the urethra. Prostatectomy, to be safe and effective, must be resorted to early, before serious complicated conditions have supervened.

In 1875, Bottini, of Pavia, performed his first operation for the relief of prostatic hypertrophy by the method that he devised, employing an instrument especially designed for the purpose known as a "prostatic incisor." In spite of the good results that he claimed for his method of treatment, the profession paid but little attention to the subject until the instrument was remodelled, and perfected, by Freudenberg, of Berlin, who not only verified the statements made by Bottini in cases of enlargement of the prostate gland, but strongly advocated its employment. (*Berliner Klinische Wochenschrift*, Feb. 15, 1897.)

It was not, however, until the operation was performed for the first time in the United States by Willy Meyer, in the autumn of 1897, that the interest of the American surgeon in this mode of treating senile hypertrophy of the prostate was aroused; since then it has attracted general attention and has been almost universally accepted throughout the country. The views of the majority of surgeons, whose experience has been extensive, agree in the opinion that the galvano-caustic operation of Bottini, for hypertrophy of the prostate, is the safest and most satisfactory, and at the same time more generally applicable to the different forms of prostatic enlargement than any other method of treatment hitherto devised. It is difficult to understand how so brilliant an operation, attended by such excellent results, and such low mortality, should have been allowed to lie dormant for twenty years before it was appreciated, or before it was generally employed.

The accumulated testimony derived from numerous surgeons throughout the world, representing a large number of operations, showing that the method advocated by Bottini is the most successful, being attended by the greatest number of symptomatic cures, and the lowest mortality of any radical measure that is employed at the present time for the relief of prostatic hypertrophy, the mortality is estimated to be between 4 $\frac{1}{4}$ and 7 per cent. I venture to assert that as soon as the practitioner recognizes the fact that early operation in his prostatic cases, by means of the Bottini method, means cure with quick recovery, we will find that the death rate following this form of prostatotomy will be still further reduced. Freudenberg analyzed 753 operations and found that good results may be looked for in 86.63 per cent, failure in 7.66 per cent. Various writers have taken exception to the Bottini operation on the ground that it is uncertain in its results; that it is dangerous to perform, as the work is done entirely by the sense of touch; that relief is but temporary; the beneficial results obtain-

ed being due to rest and the drainage by means of continuous catheterism; and that finally in a certain percentage of cases stenosis of the vesical outlet is apt to supervene. The recorded experience of numerous surgeons whose positions and reputations are sufficient guarantee for any statement emanating from such trustworthy sources, is sufficient to refute the charges that this operation is "uncertain, dangerous and the results obtained are temporary in character." It is true that the surgeon must rely on his sense of touch for a successful performance of the operation, and in that sense it is a "blind operation," but by no means as much so as the bloody and dangerous procedure of tearing out the entire prostate gland through a small incision made in its capsule, the organ being reached either through an opening into the bladder or perineum, and so working, by sense of touch, at the bottom of a dark cavity. When we reflect that the prostate gland is supplied by large nerves derived from the hypogastric plexus of the sympathetic nerves, the sacral plexus of the spinal nerve, and through the lower sacral trunk with the lumbar plexus; as a result of this free interchange of fibres between the sympathetic and the cerebro-spinal system of nerves, the conclusion is readily reached that the prostate is in intimate connection not only with the component parts of the genitalia, but, through the agency of the spinal cord, with remote regions as well. Furthermore, the organ is surrounded by important structures which are liable to injury during its extraction, so that the operation of complete prostatectomy is a much more formidable undertaking than that of the Bottini, is fraught with greater danger to the patient, and is only to be attempted in rare instances.

Surgeons who decry the Bottini operation on the ground that it is a "blind procedure," the operator having to rely upon his sense of touch, must necessarily condemn the more modern method of treating vesical calculus by litholapaxy, an operation which is dependent entirely on the sense of touch for its success and which must be highly cultivated in order to perform it properly. Yet all authorities agree that in the hands of a skilled and experienced operator the crushing of stone is the most satisfactory and the least dangerous method of treating the majority of cases of this description.

It is worthy of note that the writers who object to the Bottini operation on theoretical grounds are those who have had the least practice with this method of treatment; their knowledge being limited to a few isolated cases, whilst on the contrary those who have performed it repeatedly become more fully impressed with its efficacy as their experience expands, when they become convinced that excellent results are obtained in the majority of cases, that there is comparative small risk attending it, and that it can be successfully employed in prostatic enlargements of various configuration and size. In order to perform the Bottini operation properly, the requirements are similar to those which enable the surgeon to crush a stone in a bladder successfully. It is essential that the patient should be properly prepared for the ordeal, the employment of faultless instruments, the observance

of a careful technique, requisite skill, and an educated touch which is only to be acquired by long experience with the use of genito-urinary instruments. In inexperienced hands the operation is of course attended by the same danger, though no greater than litholapaxy, when attempted by one who has had but little practice in urethral work. To those practiced in urethral instrumentation, prostatotomy, by the Bottini method, is not a "blind" procedure." If previous to the operation the urethra has been examined, its length determined, the size and contour of the prostate defined by means of the stone-searcher and a cystoscopic examination, together with rectal investigation, and a knowledge of the condition and capacity of the bladder, the operator has data to guide him which make the procedure one of exactness. He may feel certain of making an accurate cut of the length required in the desired location.

The question has been broached as to the permanency of the relief afforded by the operation. A few observers have reported a small percentage of cases where there was a tendency to recurrence within the year. Of the thirty-six cases that came under my control there was a tendency to recurrence of the obstructive symptoms in but three instances, making a second operation necessary. In each of the cases there was marked improvement in the physical condition of the patient. At the second operation a local anesthetic was employed, and the results were very satisfactory. In the light of a more extended experience I am inclined to believe that in the three cases referred to the cuts were not made of sufficient length at the time of the first operation. This, however, is a good fault, as the operation is easily repeated, and it is far better to do too little than too much. That the advantage derived from the operation is not due to rest and continuous catheterism is shown by the fact that these means were employed as a preparatory method of treatment where the individuals were suffering from the effects of a long-standing cystitis with temporary beneficial results. In a small number of cases the catheter was allowed to remain in situ for two weeks after the operation; in the majority the instrument was inserted only when required.

It has been suggested that contraction of the vesical outlet of the bladder might follow this method of treatment, necessarily giving rise to obstruction.

Three years have elapsed since my first operation; in all the cases under my charge no complication of any kind has resulted. In one instance I had an opportunity to perform a suprapubic cystotomy on a patient who had submitted to the Bottini operation seven months previously. I found that all obstruction had been removed and that a deep furrow existed in the middle line of the median lobe. At the meeting of the American Association of Genito-Urinary Surgeons, in May last, Dr. L. Bolton Bangs showed a post-mortem specimen of a prostate gland removed from an individual upon whom he had performed a Bottini operation six months previous to his death. The patient having died from an ailment not in any way connected with his prostatic trouble. The furrow that had been

cut through the prostatic tissues some months previously was found to be as well defined as if it had been freshly made, all obstruction to urination had been removed by the operation. It would appear as if the fear of constriction of the neck of the bladder following this operation is to be but little apprehended.

In an article that appeared in the *Medical Record* March 9, 1901, Dr. Bangs showed that there was a marked difference between the action of the galvano-cautery and the Paquelin cautery. The former leaves a fine, delicate scar, whilst that resulting from the latter is thick and leathery. Pyelitis is not a contraindication to the performance of this operation, it necessarily adds greatly to the danger and the prognosis in such cases should be guarded. I have operated upon four cases in which this form of complication existed. No injurious consequences followed; one was cured, the others were much improved. This result accords with that of Willy Meyer, who, in the *Medical News*, April 28, 1900, says: "I do not share the view expressed by various authors that the Bottini operation is absolutely contraindicated in the presence of a pyelitis. Among my twenty-four cases there were certainly at least two in which a marked degree of uni- or bilateral pyelitis was present. Both patients stood the operation very nicely, the one being absolutely cured, the other much improved." He then sounds a note of warning regarding the initial risk incurred when operating upon those in whom this complication is present. Age is not a bar to the employment of this method of treatment. In the series of cases operated upon by me, the youngest was 49 and the oldest 85 years of age. Successful operations have been reported in individuals who were in the nineties. It is hardly necessary to add that the younger the patient the better his physical condition; the greater his resisting power the lower is the mortality attending the operation. The operation should only be performed on the aged when the obstruction is such that something must be done for immediate relief.

Good as well as bad results have been reported by many surgeons operating upon the hard, soft and mixed varieties of prostate hypertrophy, from which it is to be inferred that the character of the growth has but little influence upon the result. Success or failure will follow the operation regardless of the character of the growth. If there be any distinction, it will be found to be in favor of the fibrous form. For reasons set forth in the previous paper (*Philadelphia Medical Journal*, June 22, 1901) I do not believe that a preliminary suprapubic cystotomy should be resorted to in order to expedite the employment of the galvano-caustic incisor. Experience has taught me that in many cases of incurable suprapubic fistula following suprapubic cystotomy, associated with hypertrophy of the prostate gland, the removal of the obstruction caused by the glandular enlargement, by means of the Bottini operation, will not infrequently be followed by a permanent cure of the fistulous tract. A typical case illustrating the truth of this assertion will be given later on.

(To be Continued.)

BOVINE TUBERCULOSIS AND MILK SUPPLIES.*

By H. L. RUSSELL, Ph. D.,

of Madison, Wisconsin

Professor of Bacteriology, University of Wisconsin

The importance of any phase of investigation relating to tuberculosis and its relation to milk is unquestioned in these latter days when the general public is beginning to appreciate, for the first time, the magnitude of the problem that confronts them in attempting to lessen the ravages of the "great white scourge" of the human race.

In considering this subject, it may be approached from two points of view:

1. From the standpoint of animal industry.
2. From that of public health.

Bovine Tuberculosis and Animal Industry.

The rapid extension of the disease among cattle within the last few decades has forced upon breeders and dairymen the necessity of considering this subject whether they desire it or not. It is customary in many quarters, even yet, to deem all consideration of this matter as unnecessary, inexpedient and harmful to the dairy interests. But, as is too frequently the case, the motive for such action rests upon a financial foundation, and many breeders are averse to a calm, judicious discussion of the matter simply because it may mean a financial loss to them.

Since the introduction of the tuberculin test as an aid in the diagnosis of the disease in cattle, it has been positively determined that the malady, at least in its incipient form, is very much wider spread than was formerly supposed, but it by no means follows that all animals that react to the tuberculin test are actually in a condition in which they or their products are dangerous to man and beast.

The slow, insidious nature of the disease that characterizes it in the human is also to be found in cattle, and not infrequently an animal may be infected with the seeds of disease for a considerable time—even a year or so—without showing in any degree physical symptoms that are manifest to even the animal expert. Such animals are not diseased in the ordinary meaning of the term, i. e., they are not capable of transmitting the disease, either directly or indirectly, through their milk supply or meat. The affection in such cases is latent, generally confined to various lymphatic glands, but animals so affected are, however, potentially dangerous, for the latency of the disease may be overcome through the operation of various factors, and the chronic type may thus be awakened into an acute phase. It is in this way that the disease spreads slowly and unperceived through a herd. Before it has made such inroads as to cause actual death of any considerable number of animals, many more have acquired the trouble, at least in the earlier phases. Necessity of controlling its spread and eradicating it is evident for the sake of the herd itself, if from no other point of view. Successful animal industry, especially with cattle, requires that herds shall be kept free from all taint of this disease.

Bovine Tuberculosis and Public Health.

But the other phase of the question, viz., the re-

* Read before the Canadian Medical Association at its meeting in Winnipeg Aug. 29, 1901.

lation of bovine tuberculosis to the public health is undoubtedly of more interest to an audience of medical men than a consideration of the question from the viewpoint of the breeder and the stock-raiser.

The fact that both the human and bovine types of this disease have been shown to be causally related to the tubercle bacillus might, on the face of the matter, be taken to indicate that they were produced by the same identical organism, and yet every bacteriologist recognizes that, while the causative organisms found in this disease in man and animals show many common characteristics, there are also to be noted differential characters that serve to indicate that the respective organisms belong at least to different types or varieties rather than the same identical form, as in the case of anthrax in man and animals.

Special interest concerning the very practical question as to the transmissibility of the bovine type of the tubercle bacillus to the human and vice versa has been very recently awakened. Certainly, the practical importance of this problem is such as to demand most careful scrutiny. If there is any danger of transmissibility, it is needless to emphasize its importance to public health interests. On the other hand, if no such danger does exist, it certainly works a hardship on animal industry to expend so much time and energy on precautionary measures that have for their aim the elimination or at least the diminution of the reputed danger to the narrowest possible limits.

But, if the question of bovine tuberculosis is considered merely from the viewpoint of animal husbandry, restrictive regulations are still necessary; and if these must be maintained, it would seem the part of a sound public health policy also to continue the enforcement of such restrictive measures as are designed to safeguard human life, until it can be shown beyond all doubt that such measures are needlessly severe.

One fact should be borne in mind, and that is, that the virulence of the bovine type is much greater than the human variety of the organism. The conclusive researches of Theobald Smith* and others in this country, as well as a number of European investigators, indicate that the susceptibility of cattle to inoculation of tuberculous human sputum is relatively slight in comparison with similar inoculations with material of bovine origin. This in itself would indicate that the danger of cattle acquiring the disease from human sources would be so slight as to be practically negligible. Furthermore, comparative experiments made on various animals in which both types of bacilli were employed show uniformly that the bovine type is much more virulent than the human.

Pending the accumulation of sufficient observations relating to accidental infection to prove conclusively what could be quickly demonstrated beyond cavil, if it were possible to study this subject experimentally, it seems fair to consider that the danger of infection from bovine to the human would be greater than from the human to the bovine. It

will take some years at best to collect the data that from the very nature of the case must be derived largely from observations, before we will be in a condition to consider the evidence as absolutely conclusive either one way or the other.

In the meantime, it is desirable that restrictive measures should be maintained with sufficient rigor to ensure freedom from all possible danger, even though such measures may be found in the future to be to onerous. One might with equal propriety decry periods of quarantine that were enforced with rigidity during the middle ages, but such are now known to have been unnecessarily severe. At the present time, when our knowledge relating to the ways in which contagia are disseminated is much more complete, it is true that such rigid lengthy quarantine and complete isolation measures are not necessary; but in cases, even yet, where exact data are lacking, it is a correct principle for public health officials to insist upon such measures as are known to safeguard public health interests, even though it may become necessary to modify them subsequently as the actual conditions become more completely known. These restrictive measures should, however, not be unnecessarily severe and must, of necessity, be revised frequently as knowledge becomes more accurate.

Possible Danger from Tuberculous Cattle.

The main sources that may serve directly in the dissemination of tubercle bacilli from animal to man are the meat and milk. It is true that indirectly the possibility exists of inhaling tubercle organisms of bovine origin as these are thrown out from the respiratory passages of animals. Not only may they be ejected forcibly, as in the act of coughing, but in a dried form, they exist in the barn on surfaces with which the animal has come in contact. Not infrequently does this indirect method of transmission serve to introduce the disease into a perfectly healthy herd, if the same is brought into infected quarters, in a manner entirely comparable to that which exists in the tenement districts of the cities, where certain houses become so saturated with the virus of the disease that it is practically epidemic.

Infection from Meat.

The first direct source of infection referred to, viz., the use of tuberculous meat, is fraught with much less danger than that which arises from the use of milk. In the first place, the fact that meat is almost always consumed in a cooked condition diminishes the danger in a great measure, as ordinary cooking destroys the vitality of the organism, except where meats are done "rare." Again, it is also to be noted that by far the larger proportion of animals that are adjudged tubercular, on the basis of the tuberculin test, are affected to such a slight extent that the muscular parts used as food do not contain the seeds of the disease. Generally speaking, tuberculosis is a disease of the visceral organs and serous surfaces. Normally, it is not disseminated in the body by means of the vascular circulation, and consequently, in the earlier phases in any event, the muscular parts are not invaded.

* Journal of Experimental Medicine, 1898, Vol. I, 45.

With generalized and advanced stages this condition may be different, so that it becomes possible to transmit the disease by ingestion of the meat. To condemn and destroy all flesh of animals simply because of a positive tuberculin reaction is to follow a course needlessly severe and expensive. Much of the meat is just as good as any that could be purchased. In actinomycosis it is no longer considered necessary to sacrifice the entire animal, if the disease affects the jaw or some portion of the head. Such should be the case with animals in good condition that react to the tuberculin test where post mortem examination reveals a localized state of disease. It naturally follows that such a course ought only to be permitted under strict veterinary inspection. This method of disposal is practiced in various European countries, and if as large a percentage of our stock was affected, as is found in some of these countries, some such measures would of necessity have to be adopted here.

Infection from Milk.

With reference to the danger from milk the conditions are far different. This food is so generally consumed in a raw state that if tubercle bacilli are present, the opportunity for intestinal infection is much greater. The relative susceptibility of the intestinal tract, especially with children, is a question of magnitude in this connection, but here proof must rest on statistical evidence concerning which there is, unfortunately, considerable difference of opinion in interpretation. I shall therefore leave this question open and consider next the question as to how frequently the tubercle bacilli are to be found in market milk.

Prevalence of Tubercle Bacilli in Milk.

It is unfortunate that American data are so meagre on this point. The work of Ernst, Rabinowitsch and others has shown that the organism is to be found under our conditions, but it is impossible for us to apply the data gathered abroad, especially in Germany, for the reason that bovine tuberculosis is a very much wider spread disease in these countries than in our own. It would, therefore, be manifestly unfair to compare conditions in Denmark or portions of Germany, where from 25 to 40 per cent. of cattle are found to react to the test, with regions here that do not contain at most more than a few per cent. (2 to 4).

It must be borne in mind that although an animal may react to the tuberculin test, yet it may deliver milk, even for a long time to come, that contains absolutely no trace of tubercle bacilli. The important question as to just when the milk of a reacting animal becomes infectious is not susceptible of exact answer. Unquestionably, if the udder itself is affected, the milk is almost sure to contain tubercle organisms, but this condition does not occur so that the organ becomes visibly affected except in a relatively small percentage of cases. It more frequently happens, however, that less marked lesions may exist in the udder that would even escape close examination, and in such cases the tubercle bacillus is not infrequently found.

On the other hand, of the animals that react to the tuberculin test, but show no physical symptoms of the disease, either generalized through the sys-

tem or localized in the udder, the larger part of these does not contain the seeds of this disease. This fact has been determined as a result of experimental inoculation on laboratory animals, and has also been abundantly confirmed by tests upon young cattle and hogs.

There is ample evidence, though, that milk may possess infectious properties for animals and still be derived from cows that show no apparent symptoms of disease, but when one recalls that very frequently an animal may be in good flesh and apparently healthy, and yet the disease has made extensive progress in the internal organs, becoming well generalized, it is not surprising that tubercle bacilli are to be found in the milk supply. We need, however, many additional data as to the prevalence of the tubercle organism in milk, before the relative distribution of the germ can be at all accurately determined. In this work for accuracy animal experiments should take precedence over microscopic examination, for it is frequently possible to produce positive infections in guinea pigs by intraperitoneal injections where the microscope fails to reveal the specific organism.

Tubercle Bacilli in Milk Products.

If tubercle bacilli are at all numerous in milk it follows of necessity that milk products as cheese and butter must contain them. It seems quite improbable, though, that the danger from these products can approximate that of infected milk, for the reasons that a considerable number of the organisms must be eliminated in the process of manufacture, and also that these food products are consumed in less quantities than milk, and therefore the amount of simultaneous infection must be reduced. The conclusions derived from earlier experimental evidence on the subject of tubercle bacilli in butter have been rendered less satisfactory of late years by the discovery of organisms in this food that simulate the morphology of the tubercle germ and to a less degree in some cases even the pathogenic properties of the organism. Just how much the data previously accepted are vitiated by these findings can only be known by a thorough retest of the question.

Control of Tuberculous Milk.

But what shall be done with the products of animals reacting to the tuberculin test? While it can be readily demonstrated that a large proportion of animals responding to the test actually deliver tubercle free milk, still the impossibility of telling just when an animal may pass from the harmless into the dangerous stage necessitates the proper treatment of all milk.

Exclusion of Tubercle Bacilli by Means of Tuberculin Test.

This question has been solved in two ways, either of which accomplish the desired end in a perfectly practical manner. These methods are exclusion and destruction. By applying the tuberculin test to a dairy herd—especially one that is concerned in the production of milk for direct consumption—and excluding all animals that react to the test, it is easily possible to avoid all semblance of danger. This course has much to recommend it, especially in milk

supply herds, for not only does it insure a tubercle-free milk but it eliminates one of the greatest dangers to the continued well-being of the herd, for experience shows that bovine tuberculosis is a more serious menace to dairy herds than beef herds, because usually they are more closely housed, thereby increasing the danger of infection.

This method is very frequently followed in herds that produce extra fine milk, where the enhanced keeping quality is secured by exercising great care as to the milking conditions and to the manner in which the milk is subsequently handled. The bacteria associated with the ordinary fermentations of milk, such as souring, can be practically eliminated by keeping out all dust and dirt, invisible as well as the visible filth, but these methods of cleanliness have no effect on the bacteria derived directly from the cow. It therefore becomes necessary to rely on veterinary inspection to eliminate the animals unfit for milk production, and with reference to tuberculosis, the tuberculin test enables this to be done much more accurately than physical examination.

Destruction of Tubercle Bacilli by Heat.

The remaining method of treatment is to destroy any possible tubercle organisms (as well as any other pathogenic forms) by heat. The two methods of applying heat that have been the most successful are known respectively as pasteurization and sterilization, the essential difference in these two processes, as doubtless all of you know, being that the pasteurizing treatment aims to kill only the vegetating, growing bacteria, while the sterilizing process, at approximately if not reaching the boiling point, destroys also most of the spore bearing forms. As a rule, over 99 per cent. of the organisms contained in milk are in a growing vegetable condition. Therefore, so far as keeping quality is concerned, the pasteurizing method is almost as good as the more stringent treatment.

I need not enter into the relative merits of these two processes for the preparation of milk for infants or invalids. The standpoint that we are considering is that of the general consumer and from this point of view, the first method is more applicable. It is cheaper, more easily performed, changes the normal characterization of the milk to a less degree, and so far as destroying the pathogenic bacteria, is fully as satisfactory when properly done. It is true, pasteurized milk will not keep as long as sterilized, but this is of little consequence to the general user, for if the milk keeps perfectly sweet for even 24 hours longer than is usually the case with raw milk, it is sufficient to meet his needs.

With reference to the conditions in pasteurizing that are necessary to destroy the tubercle bacillus, our knowledge is much more exact at the present time than it was two years ago. Until very recently it has generally been considered that the tubercle bacillus ought to be taken as the standard test organism in pasteurizing, because this organism was considered the most resistant of any pathogenic germ that was likely to be found in milk.

Thermal Death Point of the Tubercle Bacillus.

De Man, working in Forster's laboratory, formulated a scale as to the time required to destroy this

organism at varying temperatures. His standard was as follows:

55	degrees	C.—	4	hours.
60	"	"	— 1	"
65	"	"	— 15	minutes.
70	"	"	— 10	"
80	"	"	— 5	"
90	"	"	— 2	"
95	"	"	— 1	"

Inasmuch as in pasteurized milk it is desirable to avoid the cooked flavor which appears when milk is heated to 70 degrees C. or above, the standard gradually adopted for pasteurizing was the requisite time to kill the tubercle bacillus at temperatures slightly below this point.

The more thorough work of Theobald Smith within the last two years has shown that the tubercle bacillus is not endowed with greater powers of resistance than that possessed by many other organisms. His experiments carried out under laboratory conditions at 60 degrees C. (140 degrees F.) showed that this species was totally destroyed in 15 minutes at this temperature. The great majority of the bacteria were killed in five or ten minutes. This result was obtained whether he exposed the culture of the tubercle in distilled water, dilute salt solution (0.60 per cent.), bouillon, and under certain conditions in milk, the thermal death point was no higher than with other media; where the medium was exposed to the air, the organisms were not killed, the protection in this case being associated, as he thought, with the scalded layer that forms on the surface of milk when this liquid is heated.

The practical significance of these investigations led us to retest these experiments, under commercial rather than laboratory conditions. This was done by pasteurizing milk infected with tubercle cultures in a closed rotating commercial pasteurizer. Guinea pigs were used to test the vitality of the heated bacteria, intraperitoneal injections being made in each case. The quantity of tubercle organisms thus inoculated was much greater than would ordinarily be found in even a badly infected naturally tuberculous milk. The results of these tests confirmed the data presented by Smith, and showed that even a ten-minute exposure at 60 degrees C. was sufficient to destroy the vitality of the tubercle organism so thoroughly that no trace of disease developed in any case. Where the milk was heated for five minutes disease was produced, although even in these cases the course of the same was much less rapid than in the control pigs which were inoculated with unheated milk and which died invariably within 13 to 19 days.

Relation of Thermal Death Point to "Scalded Layer" on Milk.

These experiments were still further continued in order to test the thermal death point in milk pasteurized in an open vessel in a quiescent state with that treated in a commercial pasteurizer. In domestic pasteurization, milk is frequently heated in vessels where its surface is exposed to the air. Under these conditions the surface pellicle forms readily. When such milk was infected with tubercle bacilli and pasteurized at 60 degrees C., the con-

tained bacteria in the milk exposed in the closed commercial pasteurizer were always killed in a ten-minute exposure, while that exposed in a quiescent condition in open bottles was not destroyed in a considerably longer period of time. The exact limit was not determined in these cases, but in an exposure for fifteen minutes the vitality of the contained organisms was not impaired. In Smith's experiments the organism retained its vitality heated in cotton stoppered tubes in one case for an hour.

To determine with certainty whether this increased resistance in open vessels was due to the surface pellicle or not, further experiments have been made at the Wisconsin Experiment Station this season. These have not yet been reported in full, but the results obtained are briefly as follows:

Samples of milk were inoculated with a peculiarly resistant coccus form that we have found in milk that has a normal thermal death point at 75 degrees C. (practically 15 to 18 degrees C. higher than that possessed by ordinary bacteria). Under these temperature conditions, the surface film forms very quickly. After an exposure of the milk for ten minutes at various temperatures varying from 70 to 85 degrees C. the surface pellicle was removed, and planted in an agar culture, care being taken to spread out the membrane as much as possible. Even where the temperature was raised to 82 degrees C., colonies of the inoculated organism developed quite abundantly in the membrane while the milk exposed in sealed tubes became sterile when a temperature of 76 degrees C. was reached.

To show that this increased resistance was not due to a lower temperature at the surface, the experiment was made by removing the membrane a few minutes after it had formed and immersing the same in a bath of sterile water. In this medium the membrane sank quickly to the bottom and even under these conditions the organism tested lived longer in the submerged membrane than it did where the milk was heated in a closed vessel. This throws the explanation of the phenomenon back on to the nature of the membrane itself. This surface pellicle is made up largely of dried casein, due to the fact that evaporation takes place at the surface faster than convection currents can occur in so viscous a liquid as milk, and the result is that the surface of the liquid dries out to some extent. Any bacteria, tubercle or otherwise, that are caught in this layer are thus artificially protected by being encapsuled in the more or less dried casein.

It is evident from these investigations that the conditions necessary for the destruction of the tubercle organism in milk are not simply to heat the milk to a certain temperature, but it is necessary to so protect the liquid as to prevent the formation of this surface film.

Advantages of Low Temperature Pasteurization.

One great advantage arising from the pasteurization of milk at this relatively low temperature (60 degrees C.) is that the consistency of the liquid is not changed. The chief objection that has hitherto been urged against the more common use of pasteurized products in general milk supplies is that the action of the heat destroys the creaming power

of the milk and so renders it apparently thinner in "body," due to the fact that the cream line does not form on the surface. It has been previously shown at the Wisconsin Experiment Station by Babcock and the writer* that this diminished viscosity is due to the separation of the characteristic fat globule clusters found in normal milk into the constituent isolated globules. This physical change occurs at about 60 degrees C., and therefore, if milk is heated at this temperature or below, even though the exposure be continued for a long period of time, the milk does not lose its creaming power. If, then, it is possible to destroy the tubercle bacillus with certainty at this temperature, where the physical condition of the milk is not changed, one may be assured that such milk is perfectly safe so far as pathogenic bacteria are concerned, and at the same time the use of pasteurized products is thereby removed. This method has now been in practical operation at the University of Wisconsin Dairy School for two years and has been thoroughly tested under commercial conditions. The keeping quality of such milk is satisfactory, retaining its sweetness for several days, where the product is kept with any ordinary degree of care. The introduction of this process into general milk supplies has been quite rapid during the past year, and there are now quite a number of plants in the larger cities in the States that pasteurize a very considerable proportion of their output under these conditions.

SOME POINTS ON INTRACRANIAL NEOPLASMS CONSIDERED FROM THE NEURONIC STANDPOINT.**

By F. SAVARY PEARCE, M. D.

of Philadelphia.

Professor of Nervous and Mental Diseases in the Medico-Chirurgical College of Philadelphia, and Neurologist to the Philadelphia Hospital.

History of Brain Tumor.—This subject is an important one to the general practitioner as well as to the neurologist, on account of the relative frequency of this disease as compared with other organic diseases not only in adults but also in children. Cerebral neoplasm is also of vital import in medicine, because of the possibility of its treatment by surgical procedures, if a diagnosis can be made early. It is the purpose of the present contribution, based on careful observation of this disease, to point out the possible reason in the neuronie theory so-called, for the great difficulty of determining the site and extent of lesion. Considering that the history of brain tumor dates back but a score of years, when Bernhardt first wrote upon the subject, the wonderfully rapid scientific development of this branch of medicine, through the study of anatomy and physiology of the central nervous system, is forcibly brought to our attention and we are indebted for this advance of knowledge to the line of workers represented by such authors as Steffan, Bramwell, Jacoby, Mills and Lloyd, Starr, Knapp and others. From the knowledge thus gained as shown in the final summary of 600 cases reported by Starr, at least 7% of tumors can be removed. This is en-

* 13th Rept. Wisconsin Expt. Station, 1896, p. 73.

**Read by invitation before the Section of Medicine, New York Academy of Medicine, May 21, 1901.

couraging as regards surgical technique, but shows a lack, withal, of ability to cope with this one of the most serious diseases; existing, as it does, in the highest structure of the body.

As early diagnosis and location is the essential point for successful treatment, therefore it is with the hope of advancing some reasons for inability to determine by the ordinary methods of cerebral localization, some cause for disturbances manifesting themselves in aberrations of function which are at variance with all anatomical and physiological knowledge. The history of the development of the neuron theory is naturally followed by the hope of explaining some diseases by this fascinating speculation. The writer has attempted explanations of epileptic seizures with this hypothesis in a paper on "Epilepsy," read before the Philadelphia County Medical Society in 1896.

Bechterew, Forel, His, and Cajal abroad, and Dercum, in this country, should receive the grateful thanks of the scientific mind for presenting this acumen of thought, although the materialistic, and therefore grosser, bases for nerve cell action and life may never be brought in accord by any determination of even anatomical changes as seen by the microscope. I say this discharge theory is most fascinating, if difficult to apply in all cases.

Physiological chemistry no doubt plays an important rôle in the determination of the toxic causes of brain symptomatology, much as in hemi-anesthesias of Bright's disease; still a certain number of phenomena remain as yet unexplained, but by the theory of neuron separation and sequent perversion of neural energy.

The phenomenon of hypnotism also comes forward in proof of the realism of the neuron theory.

Etiology of Brain Tumor.—The heredity of a tendency to cell degeneration and overgrowth in the form of neoplasms is a most intricate study; but we feel sure, with extending experience, that the cellular theory of Virchow must be considered tenable in the light of developing scientific truths in neurology as shown in the recent scientific researches. For example, as to intracranial neoplasms, a case seen in consultation with Dr. Dubbs, diagnosis of cerebellar tumor in a young lad, was fortified by the fact that the mother had died from the same condition. Traumatism also is a predisposing cause to tumor of the brain; though we are here again in want of actual proof of this, yet not of the fact that a cerebral neoplasm is frequently increased in growth by an injury to the head, as in one case seen in the Philadelphia Hospital this winter, in a man, 45, who had been in a *mêlée*, showing bruises about the head and chest, and suffering with aberrant symptoms of concussion of the brain with left hemiparesis. The case finally came to autopsy, when a tumor of the right parietal lobe was discovered. It had evidently been latent up to this time.

Or, again, the intoxication as of alcohol, lead or of specific disease, as syphilis or influenza, may be the precipitating cause of symptoms; much masked first by the said intoxications to which is frequently added a hysterical element. Finally, the resultant symptom of brain tumor alone will explain the fundamental cause of the disease. I take it here, that we have a most difficult problem to solve; but it is

likely in some cases, aside from mere disturbance of circulation cutting off proper neuron inhibition of nervous impulses, we have resident in the aforesaid exciting causes, the insult to the disturbed nerve function in the neurons alone, or which are working at a point near the "breaking strain." Then it is the association of impulses, at least, is ruptured and symptoms of brain tumor will present. The nature of the pathological growth in these obscurely developing cases, irritating cell contraction will much modify the method of onset of symptomatology; since the integrity of the association fibers will be more or less jeopardized by the essentially destructive nature of the disease, *per se*. Thus a soft simple-round-cell-sarcoma, a psammoma, or an extravasation cyst of slow development may exist without producing localized or general symptoms in proportion to the apparent injury to the cerebral neurons; whereas, a minute dense tumor, as a fibroma or endothelioma, when developing from within the encephalon, would, by destruction, produce more widespread symptomatology and more localizing special symptoms of the neoplasm. Pressure growths are also less symptomatic therefore.

With an increasing experience in observing my own failures, as well as those of others, to diagnose some of these cases, I am convinced more and more that underlying the anatomical basis of symptomatology, as it were, there is an individual element of resistance to nerve impulses in different sorts of protoplasm in this highest type of tissue—the neuron. So that scientific as we may be and great as its importance, there must be the general *ensemble* of abnormal physiology to reckon with, which still leaves this most difficult branch of medicine, in major part, within the realm of high art.

Special Symptomatology.—As we know to-day, the symptoms of cerebral neoplasm which change or modify the efferent impulses from disease within the brain mass, are the principal ones we most rely upon to diagnose brain tumor and allied conditions. Thus the hyperesthesias, paresthesias or anesthetics, depending upon irritation or destruction respectively in some part of the sensory tract, and depending also upon its localization, will be valuable signs in determining the situation of the tumor, in the typical case. On the other hand, the muscle rigidity, increase of reflexes, superficial and deep, convulsions sequent to such condition more or less transient, finally permanent paralysis of the part involved, will be important diagnostic signs of a neoplasm in the motor tract. Still it must be remembered that we have microscopic changes where the remaining neurons in immediate contact will carry on vicarious function for some time; and this is as yet undetermined by our want of knowledge of the physiological point of extreme tension; and where the symptoms of neurasthenia or hysteria may gradually grow to paramount place; finally, degeneration progressing, and symptoms of organic disease present when "too late to mend." This is a point in proof, it seems to me, of the neuron theory still tenaciously maintained in America by my colleague, Dr. Dercum. *Per contra*, as showing that anesthesia can also exist without organic lesion; and therefore in support of the neuron theory

ory, in separation of contact of one neuron with another, it would seem a recent case coming to a careful necropsy in my own wards in the Philadelphia Hospital, demonstrates pretty clearly. The case had been diagnosed one of hysterical anesthesia by Dr. C. K. Mills, involving the left face and arm down to the wrist and upon the left trunk as far down as the eleventh rib in the axillary line, below this point there being a hemi-hyperesthesia of the remaining left trunk, extending to the lower extremity. The anesthesia in the face came to the mid-line pretty accurately and obtunded sensation but little in the left cornea. The man died of lobar pneumonia involving the right lung. On careful examination of the brain by the pathologist, Dr. Joseph McFarland, and myself, there was found absolutely no change in the brain structure, every part of which was minutely investigated. Here, then, we have a proof of hysterical, if you please, lessening and absence of sensation on one side of the body accurately defined, and yet no lesion determined. It seems here a missing link is certainly found, albeit in a negative way, in support of the neuron theory of accounting for modification of nerve impulses in functional disease.

General Symptoms of Brain Tumor and the Neuron Theory.—Among general symptoms of brain tumor, headache is a most characteristic one. Since the ramifications of the fifth nerve are confined particularly to the dura within the cerebral cavity, the pain of brain tumor is necessarily the result of irritation of these fibers. This symptom may be extreme, however, even in cases where the growth is deep within the encephalon. I am not willing to believe that in every case, it is excess of intracranial pressure from the neoplasm that causes head pain in these deep-lying tumors, and I am therefore more free to feel that possibly irritation of the neuron produces an irregular flow of nerve impulse, which gives evidence as *head distress*, by the mere fact of such a perversion of function of nerve force, whatever that may be (*perhaps electricity*). Assuming this origin for pain in cerebral tumor, it would be somewhat likened to the less intense and more vacillating "helmet-like" distress of neurasthenia, in cases of which disease I have observed head pain not to be distinguished from that positively known to be of cerebral tumor origin. So that aside from evident cortical growth irritation and pressure symptoms as a cause of pain in cerebral tumor, it would seem plausible to add that head distress is due in part to irregular neuron activity and sequent disturbance of the proper distribution of nerve impulse, which can in some measure be accounted for by neuron separation within the brain mass. Headache due to galvanism of scalp is a point in favor of the theory of neuron activity, the energy of which may here indeed be well assumed to be electric force.

Cerebral or Reflex Vomiting.—The usually accepted view of cerebral vomiting being due to pressure of the growth, therefore causing irritation of the vagi and the resultant emesis, can also be explained to my mind (in the cases where there is no excess of intracranial pressure), by assuming an irregular discharge of nerve force through these particular nerves as the result of neuron irregularity of func-

tion; the discharge being but an exit to a stored up excess. That in some cases on taking food into the stomach, vomiting does occur at times in brain tumor, is another point in favor of the fact that the afferent impulse is carried to the brain, there to be reinforced by the irritability of the brain mass; then, being reinforced, is transmitted to the gastric walls through the vagi. This certainly could not be explained by a pressure, *per se*, even though we admit the pressure is the cause of irritability.

Stupor.—Mental obtundity in brain tumor cannot be entirely explained away, it seems to us, by assuming destructive lesion only; since in many of the cases with greatest amount of stupor (and not necessarily in the frontal lobes lesion), we have no other marked somatic evidence of irritability or palsy. So that slight irritation of a growth may be sufficient to produce retraction of the dendrites (or by excess of the intercellular serum pressure may thus separate one neuron from another), and preventing by this breach of contact, the abeyance of thought which is the most delicate action of the brain that would present, as is so in brain tumor, long before physical disabilities are "en evidence." The neuron theory is apparently tenable here. In judging of this theory, I reiterate, we recognize the impossibility of proof; but reasoning from analogy with other physical mechanisms, the evidence of such activity seems fairly conclusive.

Special Symptoms.—Subjective sensations as of tinnitus aurium may be due to irritation of the cells of the nuclei of the acoustic nerves, just as the pain of locomotor ataxia must be due to irritation of the posterior roots of the spinal cord; and how better can you explain this latter than by the assumption of an overflow of nerve impulse caused by irritation of the neurons, and perhaps through movements produced by irregular throwing off of energy from an overcharged system? So it would be with cerebral neoplasm concerning the other special senses from this neuron standpoint; which need not be detailed here.

Motor Phenomena.—Convulsions of the precedent tumor, and choreiform movements may be entirely due to excitation of the neurons through over-activity of the movement of them. This seems convincing to me, since specimens I have seen of tumor of the brain of large size which did not produce any convulsions whatever until very late in the disease, could in this way be accounted for, *viz.*: That immunity to excitation occurred in such gradually growing growths; and that finally, vicarious function being carried on well up to a certain period, a breach of function suddenly occurred, explosive impulses followed, and the patient is suddenly carried off. This happened in a case of my own recently, where there was no evidence of intracranial pressure, the patient finally going into convulsion and dying in this status from exhaustion. There was no toxic causal factor made out in this case.

Recent experiments by Charpentier, published in the *Revue Scientifique*, tend to prove an electric theory of nerve force. This electric theory was also upheld in a paper read by Dr. O'Brien before the Medical Society of the State of Pennsylvania in 1900, in which he ingeniously compares the finer electrical

apparatuses with the mechanism of the nervous system. And to my mind, it would seem that the neuronie theory also explains away the mechanism of nerve-force action in the human body. But I do not wish to weary you!

Conclusions.—From the evidence gotten in the symptomatology and pathological findings in cases of cerebral neoplasm, as well as in functional disease of the nervous system in particular, it would seem that there is ground for believing in the domination of electric energy as a cause of a continuance of life processes after birth, which from a theoretical point of view, as stated, would seem likely to be a form of electricity.

While appreciating the value of anatomical and, therefore, regular physiological perversions as most exact causes for determining the general and special symptoms of tumor within the brain, still the limitations of knowledge even of the said anatomico-physiological abnormalities produced by growths will not entirely explain our inability to diagnose tumors in a large minority of instances of this disease. Some evidence is here proposed to account for this inability to determine a cerebral neoplasm, through assuming perversion of functionation by disturbed neuron physiology; and with this neuron theory of separation of dendrites, we may account for otherwise unexplained symptoms.

The more we study life processes, the more it seems to me that protoplasmic life being established, electricity is the governing motor force. And following this line of thought, it must be that the mechanism of the central nervous system which contains the nerve force or electricity, if you please, should have some mode of action in the control of this vital energy—and that the neuronie theory best subserves explanation of the phenomenon.

A case coming to my attention at the last moment in the preparation of this paper, is "en evidence." A physically healthy woman in the insane department of the Philadelphia Hospital, subject to petit mal, died suddenly without any known cause. At the autopsy on May 9th, 1901, there was found absolutely no pathological condition to explain the cause of her death. In this case, an over discharge of nerve force to the inhibition of the heart through the vagi will alone explain the death; the normal heart being found in firm systole at the necropsy. The neuronie theory will partially explain this case.

My position certainly seems tenable as a cause of expression for nerve impulses that are *not normal*. This seems to me the more probable, as we seek more and more the intricacies of life processes which are styled normal and abnormal.

A quotation from Prof. Ranney's writings can be well given here to elucidate the normal action of the nervous system. "All day long, and every day, multitudinous apparent impulses from eye, and ear, and skin, and muscle, and other tissues and organs, are streaming into our nervous system, and did each afferent impulse issue as its correlative motor impulse, our life would be a prolonged convulsion.

"As it is by checks and counterchecks of cerebral and spinal activities, all these impulses are drilled and marshalled and kept on hand in orderly array till a movement is called for; and thus we are able

to execute at will the most complex bodily maneuvers, knowing only *why*, and unconscious or but dimly conscious how we carry them out."

NEURASTHENIA.*

By JAY G. ROBERTS, M. D.,

of Hastings, Neb.

It has been said, and not without reason, that the American people are fast becoming a race of neurasthenics. If this be true, then a consideration of this condition will not be amiss. It may be that this affection is not more common than heretofore, but that a varied number of symptoms and manifestations now known to be neurasthenic were formerly looked upon as symptoms of an undiscoverable organic lesion. Be that as it may, the fact remains that while, but a few years since, neurasthenia was a term scarcely known to the average practitioner, it has now come to rival hysteria in prevalence and popularity. One error formerly committed and often persisted in at this time is the confounding of neurasthenia with hysteria. Nothing could be more wrong, for while it is true that neurasthenia and hysteria often coexist, they are two distinct entities, hysteria being a disease with well marked stigmata of perhaps a doubtful or not well understood pathology, while neurasthenia is merely a condition, a condition of nervous exhaustion, pathological fatigue or, as Prof. Brower used very aptly to say, a condition of nervous bankruptcy wherein the expenditure of nervous energy has exceeded the supply.

The amount of nervous energy in store not being sufficient for the performance of the ordinary mental occupations and for the supply also of the various vital organs in the performance of their functions, they are both but poorly accomplished. The various functions of the body, which are but little or not at all under the control of that master, the will, are not forced to do their duty as is the mind, and therefore suffer first from lack of the necessary capital with which to do business. Impaired function with its train of evils is the result. Indigestion, mal-assimilation, auto-intoxication, impaired metabolism and failure to supply proper material and nourishment to replace the depleted store of nervous energy form a vicious circle which runs on with ever increasing intensity unless broken by proper management.

Osler (1) has characterized this condition as the physical counterpart of insanity, the essential feature of which is the abnormal response to stimuli from within or without upon the higher centre presiding over the mind; so in neurasthenia the inhibitory nerves, through exhaustion, lose control over the various functions of the body which then respond to stimuli and impulses which would otherwise pass unheeded, thus causing waste of energy and a further depletion of the already exhausted nervous system.

Eskridge (2) speaks of a primary neurasthenia in which an exhaustion and irritability of the nervous system constitute the chief derangement, and a secondary neurasthenia following organic lesions or acute disease. Such a division is, however, hardly

*Read before the Nebraska State Medical Society, May 8, 1901.

indicated, as neurasthenia is always secondary, whether to excessive mental effort, worry, fear, etc., or to exhausting disease. The various disorders of function, however, may be the result of disease or other extraneous causes, thus preceding the exhausted condition of the nervous system, or be secondary to the exhaustion which may have been, as stated above, the consequence of excessive mental effort or other nervous strain.

Etiology.—Hereditry is always given first place in the etiological consideration of neurasthenia, though, of course, it is evident that the condition itself is not transmitted but rather a predisposition in the form of an unstable nervous equilibrium, ambition, impaired physical organization, or a disposition to worry, discontent, etc.

Education is a potent cause not only in the senseless irrational methods of cramming, educating the mind at the expense of the body, indulged in by our public schools, but also in the home where displays of temper, worry, discontent, and fretfulness soon produce a demoralizing effect upon the younger generation. As stated by de Merritt (3), neurotic parents being in a constant state of irritability themselves, scold and nag their children incessantly but have not will power to enforce real discipline, thus destroying what little mental equilibrium their offspring may have been born with. Among the factors, which in the parent tend to the transmission of such a predisposition to the child, may be mentioned hysteria, neuroses, sexual and other excesses, overwork, excitement, emotions, gout, rheumatism, syphilis, tuberculosis, etc. Anything which lowers the resistance and vitality of the parent, likewise tends to lower the resistance and render unstable the mental equilibrium of the offspring and thus predisposes to neurasthenia.

Of the exciting causes not already mentioned, the struggle for existence in this age of fierce and unequal competition, entailing worry, excitement, overwork and disappointment, is a potent factor.

Psychic shock or insult of whatever origin, drug habits and eye-strain are frequent causes, as are also sexual excesses, or indiscretions, masturbation, gonorrhea, syphilis, or more frequently syphilophobia, the acute infectious diseases, especially influenza, for there is no acute disease in which the resulting nervous depression is so out of proportion to the severity of the illness as it is in grip. As a consequence we may expect to meet with an unusually large number of cases of neurasthenia after each succeeding epidemic of influenza.

Injury or trauma is credited with being among the most frequent causes of neurasthenia, but, as pointed out by me in my article read before you last year (5), it is undoubtedly the result of the psychic shock or insult rather than the injury itself, which is often so trivial as to be disregarded.

Pelvic disorders in women are important factors in the etiology, for though Peterson (4) holds that "the pelvic organs themselves play but a small rôle, the influence of exhausting pain in these organs being no greater than similar exhausting pain elsewhere," there are few, indeed, who agree with him. The intimate relation existing between the female generative organs and the nervous system is too well known to need mention, as is also the fact that

the nervous depression attending injury or disease of these organs is out of all proportion to the pain caused by them.

Excessive child-bearing and lacerations of the cervix or perineum are factors of some moment, also the disturbances occurring at puberty and the menopause. Another element in this connection which is usually disregarded is that of autointoxication from deficient menstruation. The disturbances following upon impaired or insufficient menstruation are so like the manifestations of autointoxication of other origin as to leave little doubt as to their practical identity. As it is probable that autointoxication is the fundamental cause of the majority of cases of neurasthenia, the nervous system being first to suffer from any toxic substance accumulating in the blood, it is readily understood how important is any form of intoxication. Indeed, too much stress cannot be laid upon this factor in the etiology of neurasthenia, for it is always present, and whether it is a primary cause or a result, the condition once established, it forms the main link in the vicious circle which keeps up the disorder.

Age and sex are of but little importance, though it may be said that cases of an hereditary predisposition usually occur at that trying period of life, puberty, or between the ages of 15 and 20, while the acquired form occurs more frequently during that period in which the trials of business and family affairs weigh most heavily, the period between the ages of 30 and 45. In women puberty and the menopause are the most critical times. As to sex, men are more frequently affected than women, which may be accounted for by the greater prevalence of hysteria in women.

Pathology.—Until recently very little was known of the pathology of this disorder owing, no doubt, to the infrequency of death, which was not the result of some intercurrent disorder, and to the little value of observations made in such cases. The researches of Hodge, Barker, Mann and others have all tended to demonstrate that the primary morbid change is not in the nervous system but in the entire organism.

Hodge has noted an actual loss of substance in the cells, especially in the nucleus. This loss of substance necessarily causes impaired function of the individual cells and of the organs which they go to make up. Impaired metabolism and impaired excretion of waste products, always the result of activity physical or mental, and the consequent accumulation of such products in the blood, give us an autointoxication.

The influence of such intoxication is first felt by the neurons and the nervous system. The depressing effects of the accumulation of the products of activity are well shown, as stated by Eskridge (2), in the experiment of stimulating a muscle to exhaustion by means of the electric current. After washing out the products of muscular activity, the reaction to electrical stimulus returns, showing the evil influence of such products when allowed to accumulate in the organism.

It would seem then, that the keynote of this condition is autointoxication, and upon this basis can be readily understood the influence of the toxins of the various infectious diseases in the production of

the condition and its frequency following the infectious diseases.

Symptomatology.—From the very nature of the affection, the most important symptom is fatigue which is frequently so intense as to be actually painful. Many, however, though to all appearances a picture of exhaustion, will insist that they are not tired. This lack of appreciation of weariness is a troublesome factor in many cases. Usually, however, patients complain that the slightest exertion either mental or physical "uses them all up," that they are unable to concentrate their mind, and forget easily, attempts at concentration being followed often by headache, vertigo, and tinnitus.

Mental Symptoms.—Fretfulness, irritability, a disposition to worry over trifles either real or imaginary, frequent attacks of the blues, and hypochondria are common. Patients are often morbid and depressed, sometimes bordering on melancholia, are introspective and believe themselves possessed of all manner of diseases. In advanced cases the disposition becomes entirely changed, a person often becoming envious, jealous, tyrannical, cruel, suspicious of friends and family. Will power is lost. The subject is easily provoked to laughter or tears, delusions and illusions occur. Indeed so pronounced do these symptoms oftentimes become as to lead to the suspicion of some mental aberration. Insomnia is one of the most pronounced and aggravating features, being complete for long periods or only partial, the patient being unable to get more than a few hours sleep in a night, which may be broken by dreams, nightmares, or night-sweats.

Sensory Symptoms.—Headache is one of the most constant symptoms and may be located in almost any part of the head, being usually however frontal or coronal. Backache is also a frequent source of complaint especially in women. It is usually located in the lumbar region, but may occur anywhere from the cervical to the sacral region. Coccygodynia may occur in women and there may be localized areas of tenderness over the spine. Pain in the legs is next in frequency, occurring in the knees or calves usually, and may be so pronounced as to suggest rheumatism. It is often present after exertion, as walking or climbing stairs, and may be so severe as to keep the patient awake nights.

The skin may be dry and harsh or damp and clammy. There may be hyperesthesia, formication, and sensations of numbness, but not anesthesia. Flushes of heat or localized areas of heat or cold are often complained of. Single localized pains in various parts of the body as the heart or stomach occur and are termed by Blocq (6) "topoalgias."

Special Senses.—Of the special senses vision is most frequently affected, a common symptom being an aching or weariness of the eyeballs upon reading. There may be flashes of light, narrowing of the field, difference of the pupils which is usually temporary and unilateral, or ptosis, all expressive of exhaustion of the visual apparatus. Hearing is sometimes disturbed, less frequently taste and smell.

Motor Symptoms.—The various motor functions display disturbances indicative of physical exhaustion.

Muscular power is deficient. Though it may be

extremely good for short exercises, upon prolonged exertion the muscular fatigue may become so great as to be actually painful. Tremor is sometimes present. The reflexes are usually unchanged, though the deep reflexes may be increased. There may be unsteadiness of gait due rather to dizziness or vertigo than to incoordination. It is especially marked when the patient is near a stairway or other open space. There may be short spasmodic contractions of isolated groups of muscular fibres, sometimes in the facial muscles closely simulating chorea.

Circulatory Symptoms. Palpitation and irregular heart action are usually present, while rapid heart action and decreased vascular tone, as shown by Webber (8), are of prognostic value. Throbbing of the arteries and capillary pulsation may be present and at the same time the extremities may be cold. There may be precordial distress or rarely false angina.

Gastric Symptoms. So important are these as to give rise to the term gastric neurasthenia, which is but a form of the disorder in which the gastric phenomena predominate. There may be all grades of gastric indigestion, chronic gastric catarrh with acid and gaseous eructations and heartburn. The gaseous distention often interferes with the heart's action, causing precordial distress and palpitation. There may be a condition of atonic dyspepsia in which the food lies a long time in the stomach, giving rise to fermentation and eructations. This fermenting and partially digested mass passed on into the intestines causes autointoxication and constipation, sometimes alternating with diarrhea. Actual hyperesthesia and the gastric topoalgia of Blocq are often present.

Genito Urinary Symptoms. The urine, according to Fleury (7), was diminished in 66 per cent. of cases, normal in 20 per cent., and increased in 14 per cent. The specific gravity was increased in 59 per cent., decreased in 11 per cent., and normal in 30 per cent. Acidity increased in 59 per cent., decreased in 12 per cent., normal in 29 per cent. Uric acid increased in 61 per cent. Urea decreased in 57 per cent. of the cases. The phosphates were decreased in 43 per cent. and normal in 31 per cent. Indican and skatol were present in 73 per cent. of cases.

There may be present a condition of lithemia, the so-called "lithemic neurasthenia."

Albumin is sometimes present, "neurotic albuminuria" (Barley 10), especially after exertion, and does not necessarily indicate a grave a lesion of the kidneys. Transient glycosuria is also noted. An irritable condition of the prostate is usually to be found, and perverted sexual function is nearly always present.

There may be spermatorrhea, nocturnal emissions with erotic dreams, impairment or actual loss of sexual power, and great depression after intercourse.

Hyperesthesia is often present, giving rise in the male to premature or painful ejaculations, and in the female to vaginismus. In the female there may

also occur erotic dreams, sexual excitement, and orgasm during sleep.

Diagnosis.—There is rarely any difficulty encountered in the diagnosis of an uncomplicated case.

Cases, however, complicated with organic lesions or hysteria, are sometimes puzzling and, as Osler says, it is not always possible to make a diagnosis.

A careful search should always be made for any organic disorder which might have a causative effect in the production of the neurasthenic condition.

Hysteria. The absence of the various stigmata of hysteria, the globus hystericus, faucial anesthesia, clonus, crises, and contractures, serves to exclude hysteria.

Locomotor ataxia. The preataxic may cause some confusion, but the Argyll-Robertson pupil and loss of reflexes do not occur in neurasthenia. The reflexes usually being increased if at all changed.

Exophthalmic goiter. Tremor, rapid pulse, nervousness and irritability are symptoms common to both affections, but it is only in cases without exophthalmos that there can be any difficulty in diagnosis. In such cases the occurrence of Von Graefe's sign, which is often present before exophthalmos, will enable one to make a diagnosis.

General Paresis. In the early stages this affection presents some symptoms in common with neurasthenia, such as tremor, impaired articulation, change in handwriting and inequality of pupils, all of which in neurasthenia are due to fatigue or exhaustion and disappear upon rest. In general paresis there are impairment of intellect and diminished mental activity, while in neurasthenia there is increased mental activity, and whatever impairment there may be, is due to exhaustion and is not present after rest. The defective articulation as is the handwriting is due to diminished will power and can usually be overcome by an effort, which in paresis only increases the difficulty.

Prognosis.—The prognosis under proper treatment is almost always good, unless organic changes have already occurred in the kidneys or other organs. Lapses are frequent, however, especially in those of a neurotic temperament, so the physician must ever be on his guard for manifestations of the old difficulty after a cure has been established.

The vascular tension is of considerable prognostic value as shown by Webber (9). The prognosis being good in cases in which the vascular tone is normal and in those in which there is a decided loss of vascular tone, but which regain a normal tone under treatment, while there is little hope of any permanent benefit in those cases in which the vascular tone is very much below normal and in which under treatment it may vary but makes no substantial gain.

In well marked "juvenile neurasthenia" and cases occurring after middle life, the prognosis should be guarded, as it should also in cases of profound neurotic tendencies or complicated with hysteria.

Treatment.—This being a condition of exhaustion or pathological fatigue, it necessarily follows that rest should be the first and most important requisite in its treatment—not only in the treatment of the condition already developed, but as a prophylactic measure, a proper amount of rest and relaxation in

time being sufficient to prevent the majority of cases.

In our efforts to secure this much needed rest, both mental and physical, great care must be exercised to avoid greater expense of nervous energy over the details of treatment and the worry incidental to a change from an active business life to one of idleness, than would result from the cares of the business itself.

Therefore, absolute rest is very seldom indicated and in many cases is actually harmful. Some advanced cases may require the Weir Mitchell rest treatment, but the majority of cases which come under our management will be most benefited by a short vacation followed by shorter hours of work, an hour or two rest in the middle of the day, regular meal hours and early retiring. Isolation is necessary in cases placed upon the Weir Mitchell treatment, but care should be used and the presence of a trusted attendant is imperative.

Isolation in other cases is often detrimental, as it encourages introspection and exaggeration of symptoms. One should beware of the wheel-chair or hammock, for, as Loveland (9) says, these patients easily become dependent upon props.

In connection with rest, proper attention should be given to exercise. In cases placed upon the absolute rest treatment, this must be replaced by massage, but for cases able to be about, outdoor exercise of a light and pleasurable nature is best. Here again care must be used to prevent overindulgence, which will undo all the good which may have been accomplished.

Of outdoor exercise there is none that can compare with golf. It takes one out into the open air, away from the noise and bustle of the busy streets, does not require great mental effort and is not apt to be overdone. Bicycling is another form of exercise which is of value, but is not to be compared with golf, requiring greater mental effort and is more likely to be carried too far. There is always a temptation to a sprint or a race which is hard to resist. Horseback riding is also of value. The great difficulty to be met in these cases in regard to exercise is the same as is with their work, they seem to have no appreciation of the limits of their ability and overplay as they overwork.

Diet. Next in importance to rest and properly regulated exercise is diet. When we consider that nearly every digestive disturbance which by failure to provide proper nourishment for the exhausted organism, together with the resulting autotoxemia, becomes one of the most important factors in the causation of the disorder, we can appreciate the importance of giving due attention to diet. The carbohydrates, as giving rise to fermentation and interfering with the digestion and assimilation of nitrogenous foods, should be avoided as much as possible. According to Brower (11) beef, mutton and eggs should form the basis of the dietary, in addition to milk, malted milk or a combination of the two may be used advantageously. It will sometimes be necessary to resort to predigested foods until the digestive organs have regained their tone somewhat. Tea and coffee should be avoided entirely, not only because of their detrimental influence upon the nervous system, but because of their

interference with digestion. Fluids in any quantity dilute the digestive juices and impair their action and should therefore be taken at other than meal times, preferably upon rising in the morning and an hour before meals. Hot water being best, to which may be added to advantage in some cases a teaspoonful of Carlsbad salts.

Bathing is of great value as increasing elimination and for its tonic effect upon the nervous system. The cold shower or sponge bath upon rising has in most cases an excellent effect. The hot bath and hot air bath furnish excellent means of overcoming insomnia, but should not be used except for that purpose, because of their depressing effect upon the nervous system.

Drug treatment. As in all treatment of this condition the first object to be gained is increased elimination. To this end the salts of lithia are of service. Vichy or Hunyadi water may be used in some cases.

Constipation should be overcome by the use of phosphate of soda or cascara sagrada, either alone or in combination with aloin, strychnia and belladonna, always where possible depending upon the cascara alone.

Of tonics the phosphorus-containing compounds are our mainstays, zinc phosphide, the hypophosphites and the glycerophosphates. I have obtained excellent results from a testicular extract, made from young bulls, these results being due probably to the lecithin and spermin.

Strychnia is of value in some instances, but it is a whip and must be used with care. I can conceive of nothing more irrational than the goading of an already exhausted nervous system to further effort with strychnia. Like alcohol in acute diseases it may be used to advantage to tide a patient over an emergency, but its continued use for any length of time is very likely to result disastrously. Alcohol should be studiously avoided, as should, as far as possible, the various hypnotics and sedatives, resort being had to the hot bath, the pack, gentle exercise or massage to overcome nervousness or insomnia.

A great deal can oftentimes be accomplished by suggestion or psychotherapy, and here the personality of the physician becomes a marked factor for good or evil, as the case may be.

As a last word, "Don't" use morphine. Morphine should only be used for insufferable pain, and that is not what we are dealing with here. God only knows how many of these poor unfortunates with their weakened will power and diminished resistance have received their passport hellwards in the shape of a dose of morphine, "Just to quiet them."

ARCHIVES DE MEDICINE DES ENFANTS.

July, 1901. (Volume IV, No. 7).

1. The Contagiousness of Nodular Erythema. ANDRE MOUSSOUS.
2. The Galactogenous Action of Milk. VILDERMANN.
3. Weaning: Its Time and Preparation. DELOBEL.
4. Traumatic Herpes Zoster. R. MILLON.

1.—Moussous reports a case of nodular erythema with fever which persisted after the eruption had disappeared. The child left the hospital well, a month after admission. After this child had been in the ward ten days, another girl developed fever, followed by the appearance of nodular erythema. She also recovered without any complications. This was the second time that Moussous has seen a child, who has been long in a ward, develop nodular erythema from another who has just come into the hospital. He reviews the literature, finding other apparent instances of the contagiousness of nodular erythema. Though unable to explain it, Moussous believes that it must not be forgotten. [M. O.]

2.—Vildermann experimented upon nursing mothers, giving them from one to two quarts of milk daily. In all, nine women received the milk, with the result that their milk secretion increased, though in two cases this only lasted two weeks. The case-histories of five out of these seven patients are given in full. The condition of the infant improved in all cases, whether the mother was anemic or in good health. The women themselves noticed the relief afforded by the milk. He reports two more cases, in one of which the milk did the infant no good, in the other the results in both mother and child were excellent. Vildermann advises milk for nursing mothers, especially when the child is not well, on account of its galactogenous action. [M. O.]

3.—From the seventh month in a bottle-fed baby, from the ninth month in a breast-fed baby, starches may be included in the diet. After the first 12 or 16 teeth are through, the time of weaning comes. Sudden weaning is only justifiable when the mother is taken ill. The infant should be weaned during the spring or autumn months; never during the hot summer. As a rule the child can be weaned any time between the tenth and eighteenth month, better nearer the eighteenth month, if the mother keeps in good condition. After the sixth month the cereal can be given in place of the breast once in 24 hours; after 7 months, this can be given twice; from 8 to 9 months, soup may be given once a day; at 10 months the child should cease nursing during the night, and may have soup thrice daily. At the age of one year, chicken and meat may be added. The breast must gradually be decreased so that at 18 months it is given perhaps twice a day. Cow's milk should be given regularly, at all meals. Vegetables can only be begun later. Thus by gradual increase in the food and gradual decrease in the nursing, the child is weaned. [M. O.]

4.—Millon reports two cases of herpes zoster in girls which appeared two or three days after knocks. There were no general symptoms in either case, and both recovered quickly. The vesicles appeared upon the elbows hurt, on the arm and chest, distinctly localized to the distribution of the nerves injured. These cases are very rare. [M. O.]

A Case of Purulent Cerebrospinal Meningitis with Recovery.—Bolnet and Raybaud report the case of an Algerian, aged 19, with cerebrospinal meningitis. (*Bulletins et Memoires de la Société Médicale des Hôpitaux de Paris*, June 6, 1901). He often had attacks of malaria. From the age of 6, he has always used alcohol and tobacco in excess. He caught cold, followed by slight fever, three weeks ago. He had two chills during this time, and took quinine. On admission he seemed well. The next day a chill occurred with violent headache. All the signs of meningitis then appeared. Lumbar puncture showed a great number of polymuclear leukocytes, and diplococci, mainly intracellular, in the cerebrospinal fluid. Under warm bathing, ice to the head, and calomel, he recovered in a month. Then an epileptic attack occurred, lasting two days. Since that time he has kept perfectly well. [M. O.]

THE SURGERY OF PULMONARY ABSCESS, GANGRENE AND BRONCHIECTASES FOLLOWING PNEUMONIA, BY DANIEL N. EISENDRATH, A.B., M.D., of Chicago

TABLE I.
SIMPLE ACUTE ABSCESES.

Author	Age and Sex	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Results of Autopsy
Korte.	Male, 1 yrs.	Broncho - pneumonia after measles, 6 weeks before.	Marked dullness from 4th rib down. Above it large moist rales.	Present.	Exploratory puncture, 7th intercostal space, showed pus.	Yes.			
Korte.	Male, 37.	Pneumonia, left lower lobe, 3 weeks previously.	Dullness from angle of scapula down, with weak bronchial breathing, and many rales.	Yes.	Pneumotomy, found cavity in left lower lobe, admitting two fingers. Recovery after 8 weeks. Second operation one month later, to relieve accompanying empyema.	Recovery after 8 weeks.			
Korte.	Male, 3½ years old.	Influenza. Pneumonia two weeks previously.	Dullness posteriorly from angle of scapula downward, left side.	Yes.	1st operation, opened an empyema. 2nd operation performed 1 week, eight weeks later on account of pain to left of precordium. Abscess in left upper lobe opened.	Recovery in eight weeks.			
Korte.		Pneumonia four days previously.	Extensive dullness, anteriorly to third rib, posteriorly to spine of scapula.	Yes.	Thoracotomy: circumscribed empyema opened. Dullness continued. Fever and sputum like that of an abscess. Second operation: Opened encapsulated abscess of lung.	Recovery in three months.			
Edward Martin, (Philadelphia). Unpublished.	9 years.	Pneumonia.	Faint dullness, left of cardiac dullness, and merging into it.	Yes.	Pneumotomy: Half ounce of pus evacuated.	Recovery.			
George E. Brewer, (New York). Unpublished.		Acute septic pneumonia of right lung.	Patient almost moribund; very septic.	Yes.	Resection. Fifth rib in front.	Recovery.			
R. Matas, (Unpublished).	Male, 22.	Pneumonia.	Well defined area of dullness over base of right lung; bronchial breathing; hectic fever.	Yes.	Resected eighth rib and evacuated nearly a pint of pus, no odor; cavity had rigid, rough wall. Iodoform gauze packing.	Recovery.			
Bushnell, American Journal Medical Sciences, Oct., 1896.	Male, 30.	Croupous pneumonia. Left lower lobe, one month before.	Vesiculo-tympanic resonance and broncho-vesicular breathing anteriorly over left side chest. Axilla flat, no respiratory or voice sounds.	None.	Exploratory puncture in 6th space showed pus. Thoracotomy: Found empyema and abscess cavity in lower lobe.	Recovery.			
W. J. & C. H. Mayo, Rochester, Minn. St. Mary's Hosp. Report, 1901.	Female, 10	Grippe. Pneumonia four weeks previously.	Physical signs: Located abscess in left lung. X-Ray not of material aid.	Yes.	First operation failed to find abscess. Second operation, two weeks later, opened abscess in front of previous opening.	Recovery.			
H. Alexejew, (Archiv. f. Kinderheilkunde, Vol. 31, p. 278.)	Male 8.	Eight days, broncho-pneumonia.	Below right scapula, marked dullness and decreased respiratory murmur. Exploratory puncture showed thick pus. At first there were fine moist rales. High fever.	Yes.	Resection 7th rib, 3 cm. deep; in lung found cavity, which has perforated posteriorly, so that it communicated with an encapsulated empyema between diaphragm and lung.	Recovery in 8 weeks.			
H. Jablonsky, (Archiv. f. Kinderheilkunde, Vol. 31, p. 278.)	Male, 10.	Grippe. Pneumonia 5 weeks previously, of right lower lobe.	Dullness from 3rd rib in front, from angle of scapula behind, and spreading axillary regions. Increased respiratory murmur and fremitus and moist rales. A tumor appeared, 1 by 6 cm., over the 11th to 6th ribs. On coughing frothy mucus-pus came from wound.	Yes.	Evacuated four ounces of bloody pus from tumor. From incision could palpate cavity in lung (size of an egg).				Fever, etc. fell rapidly by 1st day. Still present.
Greene, Lancet, Jan. 24, 1901, p. 198.	Female, 6.	Pneumonia of entire left lung four weeks before.	Bulging and tenderness over 11th rib (axillary line). Large quantity purulent expectoration and dullness, tubular breathing and decreased fremitus.	Yes.	Opened abscess in lung with trocar as guide. Drained.	Yes, in a few weeks.			

TABLE I (Continued.)

SIMPLE ACUTE ABSCESSES.

Author	Age and Sex.	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Results of Autopsy
Massachusetts General Hospital.									
Runbeck, Deutsches Archiv f. Klin. Med., Vol. 41, 1887.	36 m. Female.	Pneumonia, 3 weeks.	One week after, fluid was found in chest. About a half-cup cranial fluid drawn off. Since then considerable pain in right side. Cough, with white, frothy expectoration. Shortness of breath. A distinct bulging in axillary region of the side.	None.	Either given. A portion of fifth rib removed, opening made in right lung. Considerable hemorrhage, and 1½ pints of pus evacuated. Patient also coughed up considerable pus and blood.	Recovery. Three weeks.			
De Jong, Nederl. Tijdschr., No. 13, 1889.	Male, 33.	Pneumonia, 4 weeks before. No crisis. Physical signs cleared up, but fever again began (remittent type).	Dullness from midaxillary line to spine of scapula.	Yes.	Exploratory puncture in sixth intercostal space showed pus. Resected rib (6th). Entered cavity in lung with soft walls, and evacuated pus. Drained. Temperature fell at once.	Yes, in four months.			
Greene, Lancet, 1886, I, 233.	Male, 6.	Traumatic pneumonia, 2 weeks before.	Signs of cavity in left lower lobe.	?	Puncture with aspiration. Repeated in fourteen days.	After a few weeks.			
Huber, Trans. Am. Med. Ass'n, Vol. 3, 1892.	Male, 1.	Croupous pneumonia, 5 weeks before.	Consolidation of left lower lobe.	Yes.	Puncture, later pneumotomy and drainage.	In 12 days.			
Quinke, Berl. Klin. W., 1888, No. 19.	Male, 24.	Pleuro-pneumonia, 1 month before.	High temp. and respiration rapid. Bronchial breathing.	Yes.	Exploratory puncture showed pus. Drained.	Eight months later.			
Rochester, Medical News, Jan. 29, 1891.	Male, 38.	Left lower lobe pneumonia, 3 months before.	Dullness behind as high as 5th dorsal spine. Vocal fremitus absent and respiratory murmur decreased. Very fetid expectoration; marked fever.	None.	After application of zinc chloride, resected rib. No cavity found.	Two months later.			
Sewerin, Botkin's Hosp. Zeitung, 1896, No. 11.	Female, 22.	Pneumonia of right middle and lower lobes. Tympany in inter- and infra-three weeks before first operation.	Elastic fibers found in sputum. Tympany in inter- and infra-scapular regions, with amphoric breathing and voice. Dullness below it.	Yes.	Resected 5th rib and drained. No relief, followed by pyemic symptoms. Three months later more extensive resection; cavity packed.	Recovered, three months after second operation.			
Karewski, Deut. Med. W., 1899, No. 13.	Female, 69.	Soon after an attack of croupous pneumonia signs of cavity.	Signs of cavity in axillary region.	Probably.	Incised and evacuated 350 c. c. pus, with necrotic lung masses.	Yes.			
Vereins Beilage.	Female, 69.	Double croupous pneumonia three weeks before. Right resolved in three weeks.	Over left lung behind dullness. Vocal fremitus and bronchial breathing. But little expectoration. High fever.	Yes.	Withdrew 30 c. cm. pus 3 weeks after onset from left lower lobe, with potan apparatus. Diagnosis then was made of empyema. Resected 9th rib and evacuated 2 ounces greenish pus from cavity in lung, followed by expectoration of considerable quantity of bloody pus.	Recovery in 3 weeks after operation.			
Arnold Edwards, Lancet, Dec. 18, 1897.	Female, 21.	Pleuro-pneumonia nine weeks before. Daily expectoration of pint of purulent pus, and high fever.	Dullness over right lower lobe laterally and behind; coarse, gurgling rales under right scapula and bronchial breathing.	Adhesions present with encapsulated serous exudate.	Chloroform. Exploratory puncture showed pus. Resected rib and found irregular cavity, of large size.	Recovery in 2 months.			
Elsner, Medical News, March 25, 1899.	Male, 34.	Severe pneumonia, eleven days before.	On eleventh day symptoms of pus accumulation in middle lobe of right lung. Localization very difficult.	Yes.	Lung incised and drained. Incision followed by considerable hemorrhage. Found pneumococci and staphylococci.	Yes.			
Elsner, Medical News, March 25, 1899.	Male, 20.	Pneumonia middle and lower lobes of right lung with delirium tremens, just preceding operation.	Crisis followed by intense pain below scapula and in axilla, and fever. Dullness and amphoric breathing.	Few adhesions	Exploratory puncture showed pus. Resected rib and opened on abscess in lung, just beneath pleura, containing half a pint of pus. Local anesthesia.	Recovery 2½ months after operation.			
Crerar, British Med. Journal, May 20, 1900.	Male, 9.	Right-sided pneumonia just before (1 weeks.)	Four weeks after crisis had passing cough, but no sputum. Marked emaciation, temperature, dull area toward axilla and from 5th dorsal spine down. Vocal resonance lost. Diagnosis of empyema made.	Yes; adhesions at upper part.	Could not find abscess at first, until several ribs resected. Opened cavity size of small orange in lung, with soft ragged walls. Gauze packing.	Healed in two months after operation.			

TABLE II.
ACUTE GANGRENOUS ABSCESES.

Author	Age and Sex	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Results of Autopsy
Korte.	41.	Pneumonia, 1 month previously.	Marked dullness over lower and lateral aspects of left lung. Putrid sputum and odor.	Yes.	Circumscribed empyema opened communicating with abscess in lung. Iodoform gauze drain.	In 7 weeks.			
Korte.	Male, 34.	Septic pneumonia, 1 month previously.	1 Dullness from 2nd rib down, on right side, with moist rales. Puncture in 6th interspace revealed fetid pus.	Yes.	Pneumotomy; opened cavity in right lower lobe which was gangrenous.	Recovery in 7 weeks.			
Korte.	Male, 56.	Pneumonia, 4 weeks before.	Dullness over right lower lobe laterally. Decreased respiratory murmur and fremitus. Puncture in 6th interspace showed thick putrid pus.	Yes.	Pneumotomy; large irregular cavity in right lower lobe opened.	Recovery in 6 weeks.			
Edward Martin, (Philadelphia.)	Female, 14.	Pneumonia.	Profuse and offensive expectoration, following subsidence of physical signs. Dullness over area size of hand at base of right lung, with large bubbling rales.	Yes.	Circumscribed empyema found under ninth rib, which was resected. Opening into pulmonary cavity found and enlarged, and drained.	Complete, but slow recovery.			
Edward Martin, (Philadelphia.) Unpublished Case.	Child, age and sex not given.	Pneumonia followed by symptoms of profound septic poisoning and fetid expectoration.	All pointed to abscess cavity in right lower lobe.	Yes.	Two ribs resected and whole right lower lobe found in a condition of acute gangrene.			Death in 24 hours.	
James H. Dunn, Minneapolis. Unpublished Case.	Female, 35.	Pneumonia, left lower lobe, 2 weeks before.	Chills, expectorations of fetid pus. Signs of cavity.	Yes.	Resection of 6th and 7th ribs in posterior axillary line. Exploring needle showed pus. Cavity opened and drained.	Complete in 9 weeks.			
W. L. Rodman, Am. Practitioner and News, Sept., 1891.	Male, 28.	Septic pneumonia following fracture of ribs.	Signs of cavity.	None.	Gangrenous abscess cavity opened. Packed with iodoform gauze.	Recovery.			
Chas. A. Morton, British Medical Journal, Feb. 17, 1890.		Acute pneumonia 4 days previously.	Dullness from angle of scapula down. Tubular breathing.	None. Held up lung with forceps.	Sutured parax and evacuated pus. No infection of pleura resulted.	Recovery in 4 months.			
W. J. and C. H. Mayo, St. Mary's Hosp. Report 1901.	Female, 42.	Pneumonia 3 months before.	Physical signs and X-Ray not of marked aid in localizing cavity.	None.	Suture of visceral to parietal pleura. Second operation five days later, abscess drained; gangrene of lung.	Recovery.			
Quincke, Mittheilungen aus den Grenzgebieten, 1896; also Berl. Klin. W., 1888, No. 18.	Male, 32.	Atypical pleuro-pneumonia, 10 weeks before.	Those of abscess in right lower lobe. Fever and putrid sputum.	None.	Zn Cl ₂ paste used to produce adhesions. Twelve days later pneumotomy.	Recovery in 4 months.			
Quincke, Mittheilungen aus den Grenzgebieten, 1896.	Male, 33.	Pneumonia 2½ yrs before. Fresh pneumonia probably cause of abscess.	Putrid sputum, containing elastic fibres, behind on right side of abdomen from 6th dorsal spine down dullness, bronchial breathing and metallic rales.	Yes. Shown by lack of mobility and respiratory ribs resected in scapular line. Three days later gangrenous cavity opened and drained.	Exploratory puncture in 7th space showed pus. Eighth, ninth and tenth ribs resected in scapular line. Three days later gangrenous cavity opened and drained.	Recovery in 6 weeks.			

TABLE II (Continued.)

ACUTE GANGRENOUS ABSCESES.

Author	Age and Sex	Etiology and Duration	Physical signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Result of Autopsy
H. C. Smith, Lancet, July 29, 1889	Female, 30.	Atypical pneumonia 9 weeks before.	Cavity symptoms at angle of right scapula. Putrid sputum.	Yes.	Exploratory puncture below angle of scapula negative. Pneumotomy with blunt dilatation of small cavities		Yes. Putrid odor disappeared.		
H. Jablonski, Archiv. f. Kinderheil- kunde, Vol. 31, p. 27.	Male, 10.	Probable pneumonia 3 weeks before.	Extensive dullness over right lower lobe with fine moist rales and bronchial breathing. High fever, rapid breathing and marked fetid breath.	Yes.	Resected 7th rib in axillary line; entered cavity filled with putrid fluid and fine lung detritus. Removed a 3 cm. piece of gangrenous (sequestrum) lung. Greatly improved, yet fever and expectoration continued. Opened 3 cavities one month later by resecting rest of seventh rib.			Five months later of mani- extensive adhesion of tion, although right lung. Around general condi- wound of operation tion had great- many pus cavities fill- ly improved. ed with gangrenous particles, and commu- nicating with several bronchi.	
H. B. Meakin, British Medical Jour- nal, 1883, Vol. II, p. 717.	Male, 31 Insane.	Pneumonia, base of right lung. May 20, 1891.	Three days after beginning of disease area of dullness increased, and noticed fetid breath. Dullness to clavicle and to left of sternum. No expectoration. High fever.	None.	Schleich anesthesia Exploratory puncture, obtained one ounce of fetid thick fluid. Sixth and seventh ribs resected. On opening pleura large quantity of fetid fluid escaped. No collapse of lung. Opened gangrenous cavity of lung, and drained.	Yes.			
Openshowski, Zeit. f. Klin. Med., Band 16, 1886	Male, 20	Pneumonia, 3 weeks before, followed by sud- den expectoration of a large amount of fetid pus (150-350 cm.) daily.	Decreased resonance over right upper lobe in front from a third rib down. Dullness further down with bronchial breathing and middle-sized moist rales. Later tympany, amphoric respiration and metallic rales in axilla.	Yes	Resected 5th and 6th right ribs, opened lung with cautery, and entered cavity communicating with bronchus.	Recovery in 8 months.			
Fenger, Centralb. f. Chir., 1885, p. 269.	Male, 30.	Croupous pneumonia 6 weeks before, fol- lowed by circumscribed area of gangrene in right lower lobe.	Cavity signs below nipple (right). Exploratory puncture showed gangreous pus.	Yes.	Inserted trocar after resection of fifth rib, and used cautery, opening cavity.		Small fistula left commu- n- cating with bronchus.		
Cavley and Gould, Medico-Chir., Trans., Vol. 67, 1884, p. 289.	Female, 18	Septic pneumonia in left upper lobe, followed in one week by symptoms of cavity and gangrenous expectoration.	Cavity signs.	Yes.	Exploratory puncture showed pus (fetid), at level of 8th spine (dorsal). Trocar inserted and used as drain.	In 6 weeks.			
S. C. Smith, Lancet 1889, Jan. 17, p. 81.	Male, 60.	Pneumonia (right lung), 11 days before.	Sudden fetid expectoration on 13th day after beginning of pneumonia. Tubular resp. around spine of scapula and below nipple. Diagnosed cavity of middle lobe.	Yes.	Opened cavity by incising between ribs and inserting tube. But little relief from toxic condition.			1 day's later.	
Hofmaki, Wiener Med. Presse, Vol. 32, Nov. 27, 1892.	Male, 32.	Pneumonia some years before. Fresh attack previous (11 days) to operation, followed by gangreous sputum.	On right side behind, dullness, and large moist rales.	Yes.	Resected 7th rib at angle of scapula. Pleura looked grey and lung felt firm. Made 3 negative exploratory punctures. The 4th penetrated 2½ inches into lung and showed small amount of putrid pus.	In 3 months.			

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended November 8, 1901.

JOURNAL DE CHIRURGIE.

June-July, 1901. (No. 6).

1. The Treatment of Joint Injuries. V. VAN HASSEL.
2. Umbilical Hernia in Infancy and Childhood. A. WALRAVENS.
3. Systematic Resection of the Omentum in the Radical Cure for Hernia. F. DEJARDIN.

1.—Van Hassel divides injuries of the joints into three classes, those without cutaneous lesions, those with wounds of the joint, and those due to the diathetic diseases. In the first division, the affections of the joints without skin lesions, he places arthritis, treated by puncture, irrigation, incision, and finally arthrotoomy; contusions with luxation, treated by reduction, massage, hydrotherapy, and electricity; contusions with torn tendons, treated by suture; and contusions with fracture, treated by immobilization and massage, or if ankylosis occurs, by arthrectomy. The wounds of the joints may be large or penetrating, when incision, irrigation, or finally arthrotoomy, may be necessary; or the wound may be complicated by bony fragments, when arthrectomy, resection, or rarely amputation, must be done. The two diseases in which joint symptoms appear are syphilis and tuberculosis; in the former specific treatment also being carried out. To illustrate these various joint conditions, van Hassel reports the case-histories of 40 patients observed by him.

[M. O.]

2.—Walravens divides umbilical hernias of infants into

those due to a malformation, embryonal in character, and the true umbilical herniae, due to a failure of consolidation in the umbilical tissue. The former may be of two kinds, funicular, which are small, and those due to an absence of the abdominal wall, which may be large. Both varieties may contain liver and intestines, and other anomalies are generally found with the hernia. Therefore the diagnosis is easy. These herniae are lined by peritoneum. The treatment should be laparotomy, with radical cure for the hernia, as soon as possible. A table of 78 cases follows. The true umbilical herniae may rarely be fetal, i. e., congenital, yet with all the symptoms of true umbilical hernia. Phimosi seems to influence the production of umbilical hernia. During childhood an umbilical hernia has a tendency to heal spontaneously, decreasing as the child grows older. Yet radical cure is advised in all cases, as soon as possible. Only among the rich, where the infant receives the best care, should the operation be postponed. A table of 50 cases follows. The technique of the operation for the radical cure of umbilical hernia is given, with illustrations. [M. O.]

3.—Dejardin, who reports in detail the histories of seven cases of resection of the omentum in the radical cure for hernia, concludes that systematic resection of the omentum in the radical cure for hernia, should be abandoned because it is useless; it does away with a useful organ, and it is dangerous, as it may cause pain, hemorrhage, infection, and the formation of adhesions. He also reviews the literature of the subject. [M. O.]

ZEITSCHRIFT FUER HEILKUNDE.

June, 1901 (22 Jahrgang, Volume VI. No. 2).

1. The Bacteria Found in Aseptic Wounds. FERDINAND SCHENK and ERNST LICHTENSTERN.
2. The Pathogenesis of Pancreatic Cysts. PAUL LAZARUS.

1.—After a detailed review of the experiments of different investigators since the time of Lister's discovery of antiseptics in 1867, performed to show the presence of bacteria in aseptic wounds, Schenk and Lichtenstern report their own experiments in this direction. They used sterilized silk threads, two thirds of which were left in the wound after operation. These were removed and placed in bouillon. Laparotomy was performed in every case, and healing followed by first intention in all but four cases where small stitch abscesses developed. There is no doubt that bacteria exist in the secretion of wounds which heal by first intention. The temperature charts and pulse curves are given, with abbreviated notes, in 43 cases. Only in exceptional cases was the wound sterile. In 7 patients. The staphylococcus pyogenes albus was most commonly found, in 39 cases. Streptococci were never seen. In but one case were the bacteria found to be pathogenic. Bacteria are most frequent on the second day after operation and disappear after the fifth day, as a rule. They conclude that surgical fever with aseptic wounds is due to the absorption of organic matter and of the products of bacterial assimilation; and that it is impossible to tell how much the fever is due to the organic or bacterial toxins. In the preparation for operation, Saenger's sand-soap was used in 22 cases, in 16 of which the skin was found sterile. In the 16 cases operated without sand-soap preparation, the skin in only 9 was sterile. Thus in 13 out of 38 cases, bacteria were found in the skin, the staphylococcus albus twelve times. They conclude that the bacteria in the wound secretion come from the skin of the patient or the hands of the operator.

[M. O.]

2.—Will be abstracted when concluded.

An Interesting Case of Extra-genital Infection, with Soft Chancre.—Blansch de la Rosch (*Voenno-Medicinski Journal*, May, 1901; *Frutch*, vol. xxii, No. 22) reports the case of a young man who developed a soft chancre on the penis on the second day after his marriage. The young bride was found to have a number of soft chancres on the vulva. In looking for the origin of the infection the author examined the servants, and discovered that the chambermaid was afflicted with a soft chancre. She admitted that, upon seeing her mistress wash her external genitals with a sponge, she used the same sponge for a similar purpose.

NOVEMBER 23, 1901

\$3.00 PER ANNUM

The Bacteriology of Smallpox.—The recent epidemic of smallpox in Philadelphia and other cities of the United States naturally forces upon us a closer scrutiny of the disease which has assumed at present more than a theoretical aspect. The first question that arises in the mind of the inquirer is, What is the specific cause of this dreadful malady? Unfortunately, the answer to this query is far from satisfactory, and, briefly stated, may be summarized by the negation "we do not know." Our ignorance, however, is not due to a want of effort on the part of the bacteriologists. On the contrary, there is hardly another disease on the etiology of which so much untiring labor has been spent, but there seems to be something subtle about the smallpox germ which baffles all efforts at detection. It is both curious and instructive to glance through the long list of various "specific" germs discovered from time to time only to be cast into oblivion, or else to be classified among the accidental contaminations of the lymph. The desire to unearth the hidden foe seems to have been master to cool and dispassionate judgment, and as a result hasty conclusions were drawn from insufficient data. Thus in 1809 Sacco claimed to have found granules in vaccine lymph which he considered specific. His observation was confirmed by Beale in 1863 and again by Hallier, Zurn and Keber in 1867-68. In 1872 Cohn described a coccus (*micrococcus vaccinia* or *variola*) found by him in lymph and considered as the specific agent in the causation of the disease. In 1873 Klebs found a micrococcus in lymph, which occurred in the form of tetrads. This organism was looked upon as specific and received the name of *tetracoccus vaccinae*. In 1882 Koch placed on the list another "specific" micrococcus observed by him in the vaccine vesicle of a child. In 1883 Cornil and Babes described another "specific" micrococcus. In 1884 Voigt isolated from gelatin plate cultures a coccus which, when inoculated on calves, rendered them immune to subsequent vaccination. *Vaccinococcus* was the pretentious name given to this organism. In 1886 a coccus was described by Marotta, who regarded the organism as specific. In 1887 Carmichael presented his claims for the discovery of a "specific" micrococ-

cus. In the same year Garre reported successful animal experiments which established to his own satisfaction the specific nature of a coccus isolated by him from vaccine lymph. In 1889 Grigorieu described a micrococcus (*micrococcus vaccinia*) which he regarded as specific. This organism produced a papular eruption on a calf, affording immunity to subsequent vaccination. In 1893 a "specific" bacillus was cultivated by Besser. In the same year Maljean described a coccus which was capable of producing a vaccine eruption on a calf. About the same time Klein and Copeman, independently of each other, described a minute bacillus occurring constantly in the vesicle and the epidermis surrounding it. Klein failed in his attempts to cultivate this organism, while Copeman, on the other hand, was more fortunate, having selected the hen's egg as his culture medium. At a later date he succeeded, in conjunction with Blaxal, in growing the bacillus on agar. This organism, deserving as it does more consideration than the other "discoveries," is still forming the subject of a thorough study. Quite recently Kent (*The Lancet*, 1898) reported successful experiments with the diplo-bacillus. He succeeded in cultivating it on glycerin-albumin, milk and sterile lymph, and by inoculations on calves produced typical vaccine vesicles. However, we must suspend final judgment until further evidences are brought forward. In 1894 a "specific" micrococcus was brought forward by Ruete. However, experiments on human beings failed to establish his claims. A short thin bacillus was claimed as the specific organism by Martin and Ernst in 1895.

To the long list of "specific" micrococci and bacilli might be added a no less lengthy one of "specific" protozoa. These were observed by Renault, Van der Loeff, Hlava and Pfeiffer and others. However, there is little experimental proof either of their pathogenic relations, or of their identity. It is quite probable, as Copeman suggests, that "they are nothing more or less than the fragments of ameboid leukocytes which had originally invaded the peripheral circulation and, in turn, the particular tissue affected, under the influence of chemiotaxis." The protozoa of Guarnieri (*cytocytes vaccinia*) de-

scribed by him in 1892 has received considerable attention, having been observed also by Monti, Ruffer and Plimmer, Pfeiffer, von Sicherer and Clarke. On the other hand, the specificity of the parasite, if it is one, is questioned by Massari, Ferroni, Salmon and Huckel.

The many conflicting results noted above would appear inexplicable, were it not for the fact that the various investigators dealt with a tissue ordinarily swarming with pathogenic and saprophytic organisms, especially the pus-forming cocci. It is quite possible that in some of the cases of successful animal inoculations minute particles of the lymph were carried along with the isolated organisms, thus imparting to the latter specific properties. It is also conceivable that in a few instances a mixed culture was obtained, the smallpox germ remaining undetected until lost by successive cultivations of its visible neighbors. In this connection one recalls the appropriate passage in one of Koch's earlier publications (*On the Investigation of Pathogenic Organisms*, 1881). Saye he: "To mistake the granules of granular corpuscles for micrococci is much more excusable, especially of those bodies termed by Ehrlich plasma cells (*Mastzellen*). The granules in many of these corpuscles appear to be loosely held together, the corpuscles are easily destroyed in spreading out the material on the cover glass, the granules become freed, and to the unpracticed eye simulate micrococci either single or arranged in groups. Similar corpuscles of essentially large size and regularly developed occur in the blood, and especially in the spleen and lungs of white rats, less frequently in white mice, and I have seen preparations from the above-mentioned organs in which deeply stained masses of granules from the crushed corpuscles lay distributed in broad streaks in such quantities that the sight would have elicited a cry of joy from an enthusiastic micrococcus hunter."

Applying the well known postulates formulated by Koch to any and all of the microorganisms observed in connection with smallpox or vaccinia, we find them wanting in one or more (usually more) points, and therefore conclude that none of them could be considered as the specific germ, which is still awaiting discovery.

The Municipal Control of Smallpox.—When smallpox appears in a community, one of the first things to be done, in order to arrest the spread of the disease, is to select a suitable site on which to erect an isolation hospital for the treatment of those who become infected with the malady. In locating this hospital, its effect on the dissemination of the disease should not be overlooked. At the present time it appears that the contagion of smallpox is

air-borne, and it seems that the presence of such a center of infection as a smallpox hospital influences the number of cases of the disease in its neighborhood. When the bacteriology of smallpox is known, it may be shown that the air has little or no effect in carrying the contagion, just as a knowledge of the bacteriology of malaria and yellow fever has destroyed the theory of infection through the air in these diseases. At present, however, it has been shown by Blyth, quoted by Moore in the *Twentieth Century Practice of Medicine*, that the influence of the hospital, in the Sheffield epidemic of 1887-88, extended four thousand feet, and Evans showed that at Bradford, in 1894, the influence of the hospital was felt within a radius of one mile.

Formities must be disinfected, and the rooms or public conveyances which the patient has occupied or traveled in, must be fumigated in order to lessen the likelihood of spreading the disease. Power, Herberden, Watson, Hewitt, Osler and Buck have shown that contact with convalescent patients and with fomites is responsible for the spread of the disease. The period of infectiousness probably lasts until the last scab has disappeared, and until desquamation is complete. In order to control the disinfection of houses and of articles that have come in contact with the sufferer, notification of the disease is an essential. The true control of smallpox, however, depends upon thorough vaccination and revaccination.

The mortality of smallpox is 50% in the unvaccinated and 2.3% among the efficiently vaccinated. Before the introduction of vaccination the death-rate in England and Wales was three thousand per million of population. In April, 1890, there were only 15 deaths from this disease, about one-seventieth the former death-rate. In 1890, the year in which the eleventh census was taken, there were only 398 deaths from smallpox in the United States. The statistics of the German Army should be familiar to every one. During the present year, owing to the fact that the immunity conferred by vaccination is gradually being exhausted, several municipalities have seen the beginnings of smallpox epidemics. The one way for these communities to control this pest is by insisting that every individual who has not been successfully vaccinated within the past five years shall submit himself to vaccination at once.

Vaccination Statistics.—Immermann states that, long before Jenner introduced vaccination, it was known that cowpox was communicable to man (*Nothnagel's Specielle Pathologie und Therapie*, Band IV, Heft 2). In 1763 Heim had noted that the accidental inoculation of individuals with cowpox was followed by immunity to smallpox. Von Hum-

boldt, in the account of his travels published in 1803, spoke of this immunity among the natives of Mexico, and Brun noticed it in Beludschistan. Sutton and Fewster attempted vaccination in 1778, but were unsuccessful. Pesty, however, had successfully vaccinated his wife and children in 1774. The results of Jenner's investigations, begun in 1796, were published in articles which appeared in 1799 and 1800. In spite of the manifold objections at once raised against vaccination, the practice became widespread.

Upon the continent Bavaria was the first to adopt laws making vaccination compulsory, in 1807. This example was followed by Baden, Württemberg, Oldenburg, Saxony, Gotha, Meiningen and Brunswick, from 1815 to 1832. Prussia had some vaccination laws as early as 1810, and in 1816 it was made indirectly obligatory. Following the severe epidemic of 1870, vaccination became compulsory throughout the German Empire in 1874. It is now necessary for every German child to be vaccinated in its first year, and to be revaccinated in its twelfth year. Some children elude vaccination for a year or two, but they are sure to be vaccinated eventually, so thorough are the laws. Proust states that in 1874, 1,374,436 children should have been vaccinated for the first time, yet 179,469 escaped vaccination, from absence, illness, or other causes. (*La Tribune Medicale*, September 11, 1901.) In Austria, where vaccination was practiced as early as 1801, compulsory vaccination only became a law in 1886. Vaccination, which was voluntary in Sweden, Denmark and Norway from 1801, became compulsory in 1816. In Italy the doctrine of vaccination was well advocated by Sacco in 1799. About the same time the practice was made optional in the Netherlands. Nor has vaccination ever become compulsory in Holland, Belgium or France. In Russia voluntary vaccination was the practice in 1801; in France, Spain and Portugal in 1809. Vaccination began in Strassburg in 1810. From 1797 to 1810 there had been 117 deaths from smallpox out of 50,000 people; from 1811 to 1875 15 deaths occurred out of 70,000; while from 1875 to 1884, with obligatory vaccination, out of 90,000 inhabitants there were but two deaths. Switzerland, where vaccination had early been compulsory, suspended the law in 1883. While there had been 15 deaths from smallpox during the three previous years, 11 deaths occurred in 1884, 52 in 1885, and 85 in 1886.

England made vaccination compulsory as late as 1867, Ireland in 1868, and Scotland in 1864. In England, however, certain amendments were passed by Parliament in 1871, which provided a loophole for escaping vaccination. Then again, in 1890, the fa-

mous "conscience clause" was inserted, by which vaccination was no longer made obligatory, should parents fear that it might prove prejudicial to the health of their child. While the deaths in England from variola in 1889 numbered 23, and in 1890 16, in 1891 there were 49, in 1892 431, and in 1893 1,456 deaths from smallpox. These figures, with these laws, make more striking the fact that vaccination was discovered in England. The United States attempted optional vaccination in 1800, but in spite of frequent epidemics, not one State has made vaccination compulsory. The only laws existing refer to school children, who must have been vaccinated before they are allowed to enter the public schools. No laws concerning revaccination exist in any country but Germany. All this leads to one inevitable conclusion, that, to completely stamp out smallpox, there is but one method available, compulsory vaccination.

The Diagnosis of Smallpox.—The diagnosis of smallpox is in the great majority of cases comparatively easy, but the few exceptions which prove this rule are of vast importance to determine precisely, for there are few diseases in which a mistaken diagnosis causes more discomfort to the patient, and anxiety to his friends than in smallpox. Its ravages and the dangers of an epidemic have led to the present legislation by which the State endeavors, by isolation and strict quarantine, to safeguard the interests of the community. In a typical case there are several factors which aid in the diagnosis. The prominent initial symptoms in the adult are a severe chill or repeated chills during the first day, and in children a convulsion or a series of convulsions. Vomiting, agonizing frontal headache, excruciating pain in the lumbar region and in the limbs, are so much more severe in this disease than in the other exanthemata, that they should at once put the physician on his guard. The fever is present very early, the temperature reaching 103° to 104° or perhaps higher on the first day. The pulse is rapid, full and strong, but not often dicrotic. If the pyrexia is extreme, delirium, sometimes very violent, may be present. On the second day of the disease as a rule, the initial rashes make their appearance, and it is in this stage that a mistaken diagnosis is most frequently made. These rashes are of two forms: The diffuse and scarlatinous in character, and the macular and measly forms. Petechiae in a few instances are present. The rashes may be general, but as a rule they are limited to the inner surface of the thighs, to the axilla and the lateral regions of the chest. Occasionally, as Osler has pointed out, they may be present on the extensor surface, particularly in the neighbor-

hood of the knees and elbows. It is not until the fourth day that the distinctively smallpox eruption occurs. This is at first felt, rather than seen, as a shot-like papule under the skin. It appears usually on the forehead and wrists at first, but is soon nearly universal. Only one crop of papules appears in contradistinction to varicella. On the fifth or possibly the sixth day the nodule contains a clear or slightly cloudy serum, and at this point umbilication of the vesicle is noted. About the eighth day the vesicles change into pustules, the umbilication disappears and the contents become purulent in character. Surrounding the pustules there is an injected area, and the skin between the pustules is swollen. With the early appearance of the papules the fever falls and the patient feels greatly relieved. At the pustular stage the fever again rises, and this usually lasts until the tenth or eleventh day, when convalescence sets in. It may be said that the most likely of the eruptive fevers with which smallpox is confounded, are varicella, scarlet fever and measles. In making the diagnosis the presence of an epidemic is to be remembered, as well as the especial characteristics of the diseases named. The rash of varicella appears within twenty-four hours, is not confined to any one locality, and frequently occurs in successive crops. It consists of clear vesicles without umbilication, but, in occasional cases, this may occur. In scarlet fever the rash appears within forty-eight hours, sore throat is present, and the rash appears first on the chest to spread rapidly over the trunk, the face and the limbs. It is bright, lobster-red in color and disappears on pressure except in the malignant cases, and it is followed by large, flaky desquamation, which is peculiar in that it continues longest on the hands and feet. The rash of measles appears on the fourth day, first on the forehead than the limbs, and soon spreads to the trunk. It has a characteristic crescentic appearance with healthy areas of skin between. The eruption is mottled and does not disappear absolutely on pressure. The vesicles are small and bran-like. It has been pointed out by clinicians that while these are the diseases which are usually mistaken for smallpox, or smallpox mistaken for them, more rarely relapsing fever has been diagnosed smallpox and cerebrospinal fever has been mistaken for the hemorrhagic form of smallpox. The pustular syphilitic eruptions as well as certain drug eruptions may also raise some doubt as to diagnosis, but it is to be remembered that the syphilides rarely cause pyrexia. It is only in the initial stages that relapsing fever would suggest smallpox, especially in the occurrence of intense

muscular pains in the back present in the two conditions, but the eruption in smallpox will remove all doubt. Authorities are agreed that the diagnosis of smallpox should not be positively made during those days in which either scarlet fever, measles or other exanthemata are to be regarded as a possibility, but the patient should be isolated and carefully watched until the certainty of the diagnosis is without question.

Teachers Must Be Vaccinated.—In the Court of Common Pleas in this city last week, Presiding Judge Arnold refused to grant an injunction in the proceedings begun by a teacher in the Public Schools against the Board of Public Education, restraining them from discharging her for refusing to comply with the order to show a certificate of vaccination. The teacher in question was dismissed from her position by order of the Committee of Hygiene of the Girls' High School, and she applied for the aforesaid injunction, which has now been denied her.

We understand that this teacher maintains that vaccination would be injurious to her health, and that the Board of Education had no right under the law to dismiss her. Judge Arnold very properly discusses the subject from, and bases his opinion upon, the legal aspect entirely. He disclaims any right or intention to discuss the merits of vaccination as a preventive of smallpox, and he holds that the law applying to cases of this kind is the ordinary law of master and servant. If the servant disobeys the reasonable orders of his master, the master may suspend or discharge him. The Judge thinks that in this case the plaintiff is "too self-opinionated," and that she has refused to comply with the rules of the Board of Education and is therefore subject to dismissal. It seems to us that the whole case is thus properly stated in a nutshell. The question involved is not a medical, but a legal one. It is evidently within the province of the Board of Education to decide what constitutes disobedience to its orders, and like all other employers it has a right to dispense with the services of an employé if that employé has disobeyed its reasonable commands. It seems to us that from her own standpoint the plaintiff in this case made a sad mistake in trying to sustain her prejudice against vaccination by seeking a vindication in the Courts. From the purely medical standpoint, which especially interests us here, it is evident that teachers as well as scholars must be under the one law. Certainly the teacher is just as capable of carrying the infection with her as a pupil, and the whole object of the law would be nullified if a contumacious teacher were to be allowed to have her own way in such an emergency as has been threatening this city.

The Accidents of Vaccination.—The varied nature of the casualties attributed to vaccination strongly suggests that sequence and consequence have too often been confounded. It is but in the nature of things that amongst the thousands of people who are vaccinated each year, we should hear of various morbid phenomena following immediately or remotely upon the performance of vaccination. The *post hoc propter hoc* is a judicial weakness of the medical as well as of the lay mind. We may rest assured that many accidents which are attributed to vaccination bear no relation to it save a chronological one. To prove that vaccination is the cause of any untoward manifestation, the latter must occur with a sufficient degree of frequency to preclude its being a mere coincidence. There are, however, certain accidents which, in an inconsiderable percentage of cases, follow upon the performance of vaccination. The manner of their production will be the more easily comprehended, if vaccinia be regarded as an acute exanthematous disease plus a local wound. It is claimed that various diseases of the skin occur after vaccination. It is true that eczema, psoriasis, urticaria and pemphigoid eruptions have been recorded as having developed for the first time after vaccination. Authorities are pretty well agreed that in such cases vaccination only determines the outbreak in individuals predisposed to these disorders. A casual relationship could equally well be established with measles, scarlet fever, etc.

The true vaccine eruptions are usually of trivial import and of short duration. The measles-like eruption known as **roseola vaccinosa**, which is not infrequently seen about the 8th or 10th day after vaccination, appears to be the result of absorption of the specific virus and has its analogue in the **roseola variolosa** which occasionally appears just before the outbreak of the papules of smallpox. A vesicular and papular eruption designated respectively **vaccine miliaria** and **vaccine lichen**, may accompany the vaccine process. Generalized vaccinia, which appears to be rarer now than in former days, may occur through the blood, or more commonly through early auto-inoculation. Among the eruptions produced by the vaccine virus plus something else, may be included **impetigo contagiosa**. This may be engrafted upon vaccinia by infection of the wound at the time of vaccination or subsequent to it. Quite a number of recurrent **bulbous eruptions** resembling pemphigus and dermatitis herpetiformis, have within late years been recorded following vaccination. It is probable that these are due to some superadded infection through the vaccine ulceration. **Dermato cellulitis** characterized by redness, swelling, tension, heat and pain, occurring around the vaccine wound and sometimes spreading over a considerable portion

of the inoculated member is, since the general employment of bovine lymph, not at all uncommon. In rare cases **gangrenous ulceration** may occur at the site of vaccination. **True erysipelas** is much rarer than it was in former years when less care was paid to asepsis. Erysipelas has in years gone by been responsible for most of the fatalities of vaccination. **Pyemia** is at the present day an extremely rare complication. From time to time deaths from **tetanus** have been reported after vaccination. There is no reason to believe that tetanus occurs any more frequently after the wound of vaccination than it does after any other wound. Many of the accidents above referred to are preventable; improvement in technique and further perfection in the collection and preservation of the virus will doubtless eliminate most of them. Considering the inestimable benefits conferred upon humanity by vaccination and the trifling incidence of complications among the multitudes of vaccinated, no one should hesitate to avail himself of the great protection against smallpox afforded by Jenner's immortal discovery.

Vaccination and Tetanus.—The occurrence of tetanus in some children during the course of vaccination in a neighboring city has probably led to a great deal of unnecessary alarm in reference to the accidental dangers of vaccination. In a careful search of statistics in reference to the previously mentioned condition, it is found that almost invariably is tetanus an accidental complication and in no wise due to the virus itself. Tetanus is liable to occur in the vaccine poek, as it is liable to occur in any open wound by admixture of dirt and filth and similar material. We doubt whether there is a well authenticated case on record in which it has been proven that the occurrence of tetanus during the course of vaccination has been due directly or indirectly to the virus used in vaccinating. This same also holds true of cancer and tuberculosis. Careless vaccinating, dirty hands, dirty instruments, failure to wash the skin upon which vaccination is to be performed, handling of the wound by the patient, such as scratching, etc., are all causes for the occurrence of tetanus in a vaccinated person. The operation of vaccination, while it is a simple one, must nevertheless be carried out with extraordinary care. The instruments should be scrupulously clean, and the part upon which vaccination is to be performed should be carefully washed with soap, water and alcohol. It is not wise to use the ordinary antiseptic solutions, as they are liable to destroy the efficacy of the virus. We are certain that the prophylaxis which will effectually prevent the occurrence of tetanus in vaccination is cleanliness.

The Ocular Complications of Variola.—Since the introduction of vaccination there has naturally been an extensive decrease of blindness. Indeed, we need no more forcible reminder of this fact than the statistics of Carron du Villard (*Guide pratique des maladies des yeux*, Paris, 1838) which show that out of every one hundred cases of blindness during prevaccinal times, thirty-five were due to variola. However, these statistics must be considered in a relative sense, especially since the introduction of vaccination, there being no prophylactic treatment for the eyes during the disease except the employment of usual antiseptic measures like bichloride of mercury solution and even methylene blue. The ocular involvements in variola may vary from the conjunctivitis, which is always present, to destruction of the whole globe, blindness and phthisis bulbi. In favorable cases there may be but a chronicity of the conjunctivitis, with possibly a few isolated eruptions on the ocular conjunctiva, not unlike those seen in phlyctenular conjunctivitis. During the stage of eruption, corneal involvement is usually due to an extension of the process from the conjunctiva, but during the period of decrustation, and especially in the confluent variety, the cornea often becomes the seat of primary involvement, consisting of deep infiltration, perforation and hypopyon. Iritis and choroiditis have been observed, but are comparatively rare, while, with the exception in the hemorrhagic varieties of smallpox, there is rarely, if ever, retinal involvement, unless during the destructive process of a panophthalmitis. In the hemorrhagic varieties there occur not only subconjunctival ecchymoses, but hemorrhages into the anterior chamber, and from the retina. The lids may participate in the eruption to such an extent, that grave deformities ensue. Pustules situated near the ciliary margins may eventually give rise to ectropion, symblepharon and even ankyloblepharon. Adler, in a treatise on this subject, published in Vienna in 1875, states that the skin of the lids is affected in 20 per cent. of the cases. Dufour, in the *Annales d'Oculistique* of May, 1901, quotes the statistics of Landesberg which show the following, as obtained from a study of 270 cases: Affections of the conjunctiva, 57.78%; affections of the lachrymal apparatus, 5.55%; affections of the lids, 1.11%; affections of the cornea, 30.00%; affections of the iris, 2.96%; affections of the uveal tract, 1.48%. Transmission to the lid, of virus from vaccine vesicles, has been observed by Schirmer, Schweigger and others. Finally, cicatricial deformities of the lids may prevent them from closing properly, thus exposing the eye to subsequent injury and infection. The present epidemic of variola is an ex-

cellent opportunity for ophthalmologists to observe, if they will, the ocular involvements of variola. For an organ like the eye, which represents such a composite histological structure, cannot remain exempt from the ravages of smallpox, and for this reason the manner of invasion and the sequelæ closely resemble those in other portions of the body, from the eruption on the mucous membrane of the lids and eyeballs to the suppurative destruction of the whole globe. Nevertheless, if we consider, that blindness may result from a single pustule on the cornea, or from an extension of a suppurative process from the lids or conjunctivæ, we cannot overestimate the necessity for expert treatment of the eyes in smallpox.

Venereal Diseases in the Army.—The report of the Surgeon-General contains some significant figures on this subject—figures that should be cogitated by the hygienist as well as by the moral statistician. Vice always looks unusually hideous in the aggregate, but physicians must not close their eyes to its effects on health and are obliged to face it with particular earnestness when it sends in its official reports. The Surgeon-General's figures throw some curious lights on some of the effects of "imperialism" in dark corners. We know not whether they will be made the text for still further philippics against foreign conquest—and this question does not concern us here—but we are deeply interested in the medical problems involved.

The admission rate for venereal diseases for the whole army for the year 1900 was 133.97 per thousand of strength. For 1899 the rate had been practically the same, 133, while the mean annual rate for the decade, 1889-98 had been only 71.45. These figures seem to show—what, we believe, has usually been observed—that active service among troops increases the prevalence of the venereal diseases.

But an analysis of the figures seems to reveal that it is the soldier in foreign service who is especially vulnerable. A creditable exception, however, is found in the volunteer troops serving in the Philippines, among whom the rate was only 70.94, while the regular troops in those islands maintained the high rate of 138.88, as against a still higher rate, 155.39 among the home troops. In China the admissions rose to 173.60. In Cuba the rate reached 190.68, and in Porto Rico it rose to the excessive height of 367.88. The latest reports, not yet tabulated, show that the venereal diseases are increasing materially in the Philippines. In April of the present year they constituted 20.42% of the total sickness as compared with 8.97 in the preceding April. This apparently discouraging increase is in part explained, however, by the fact that the

troops are now more critically inspected than formerly for the symptoms of these diseases.

Efforts are being made also to control prostitution in Manila, but by what methods and with what success the report does not fully show. It is an old and a difficult problem—probably as old as the race, and certainly as difficult as continence seems to be among soldiers.

Surgeons Versus Hematologists.—The problem of the examination of the blood for clinical purposes has been approached from two standpoints. One of these is that of the hematologist, the other that of the clinician; and curiously enough—or perhaps the matter is not so very curious, because on almost every question of methods this same result has ensued—there has been a considerable lack of agreement between the two parties, the clinician arguing that the results are too indefinite to enable him to diagnose his cases with accuracy; the hematologist, that the clinician—insufficiently familiar with the technique employed—is incapable of interpreting the results accurately.

As a matter of fact, we believe that in this dispute the fault lies largely with the hematologist, for if his results are not sufficiently precise and conclusive to enable the clinician to use them in his actual practical work, they are, from the clinical standpoint, of minimal value. Furthermore, if his reports are returned to the clinician so late that the latter is compelled to act upon the ordinary symptoms and signs of disease before receiving them, their value can be regarded as nil. On the other hand, the clinician, as the man upon whom the responsibility for action is placed, has the right to demand precise, definite reports, returned in the briefest possible space of time, and when such reports are not forthcoming, his criticisms and complaints are fully justified.

Dr. John B. Deaver, of this city, is undoubtedly a man whose clinical experience in surgery has qualified him to speak upon the question of surgical diagnosis; and as a man employing, or having employed for him, all methods of the ward or laboratory to confirm his diagnosis, he is qualified to express an opinion upon such methods that is worthy of the most respectful consideration. Recently he has called forth the protests of certain hematologists by his criticism of the value of blood examinations in surgical conditions, and in his most recent article, published in this number, as a sort of reply to these protests, he has reviewed the entire subject of blood examinations. The one point concerning which there has been the greatest amount of dispute is the value of leukocytosis as a symptom of disease. Now leukocytosis, it must be admitted, is a sign

of certain general states, and practically never a distinguishing sign of a particular local lesion; and when Dr. Deaver argues that it is insufficient to establish a differential diagnosis between tubal suppuration and appendicitis, he assumes a position that is absolutely unassailable. We think that on the whole his standpoint is a good one; that leukocytosis is not to be regarded as a final arbiter in questions of operative interference, but that it is simply a contributory symptom of considerable value, not yet as thoroughly understood as it might be, but never to be entirely neglected in any case.

Dr. William F. Norris.—In the death of Dr. William Fisher Norris the medical profession in general and the ophthalmic fraternity in particular lose one of their most distinguished members. Early in his career, which began with distinction as a surgeon in the Civil War, Dr. Norris devoted his energies to ophthalmology, and by virtue of his scientific labors and his skilful practice, soon took a foremost place in that group of men who thirty years ago gave the impetus to American ophthalmic work, which has secured for it the high and honorable position it now holds. As a clinician, a teacher and an operator, Dr. Norris's work was characterized by accuracy and thoroughness. It was a privilege to watch his examination of a patient, so perfectly conscientious and searching were his methods. It was more than a privilege—it was a profit, as the many men who have followed his teachings and his practice know. He was not a specialist; he was a liberally educated physician who had added to his knowledge an intimate acquaintance with the principles and practice of one of medicine's greatest specialties. The medical world can ill afford to part with this honest, earnest, scholarly gentleman, whose impress fortunately remains as a lasting heritage.

The Department for the Insane, Philadelphia Hospital, now has a population of 1485, a number far in excess of its healthy capacity. It is to be hoped the City Councils will quickly respond to the urgent recommendations of the Directors of the Bureau of Charities for funds to build a modern insane hospital in a suburban locality. This humane need has been too long delayed. The medical management of the Hospital has the confidence of the community, both professional and lay, and those who conduct it are deserving of praise for the results obtained under so very many unfavorable conditions.

Current Comment.

MONKEY AND MAN.

A despatch published recently in the daily press on the authority of a Paris newspaper asserts that Prof. Haeckel, the well known evolutionist, has revised his belief that man is descended from an ape-like ancestor. The story goes that Professor Haeckel, while traveling in Java re-

cently in search of the "missing link," discovered striking evidence that monkeys are descended from man, and not man from monkeys; also, that children lost in the woods adopt monkey habits. This tale is regarded by scientific men as due chiefly to the lively imagination of some Parisian reporter. Professor Haeckel has not been heard from directly, but in his latest published statement, made originally before the Zoological Congress, he says that "the direct descent of man from some extinct ape-like form is now beyond doubt, and admits of being traced much more clearly than the origin of many another mammalian order." That he has discovered new evidence that would warrant the rejection of this belief is not likely, although it may be that he has found instances of degeneration from the human species to something resembling an ape-like form.

WOMAN AND HER DELUSIONS.

We have only to let the mind follow the procession of believers in every 'ism and 'ology and 'osophy under the sun, from those who gave heed to the utterances that crept from under the poke-bonnet of the early Shaker Ann, to those who hung on the words of wisdom issuing from the yellow turbaned monks of the Orient, to know that the long ranks are largely feminine, not in numbers only but in loyalty and in zeal * * * * *

It would be foolish to deny that extreme phases of religious teaching have always found many devoted followers among women. In every abnormal movement they not only outnumber men, but outrank them in advocacy and outdo them in sacrifice for whatever cause has won their allegiance * * * * *

Is it best that way? Who knows? There's something lost and something gained. We do not judge; we only know that because women cannot always find the "old things good enough for them" they plunge quite too often into something infinitely worse.

—*Mary Loue Dickinson, in Christian Work.*

THE FRUIT CURE.

The curative value of fruit is becoming more and more insisted upon by those who make a study of dietetics. Grapes are recommended for the dyspeptic, the consumptive, the anemic, and for those with a tendency to gout and liver troubles. Plums, also, are said to be a cure for gouty and rheumatic tendencies. The acid fruits, especially lemons and oranges, are particularly good for stomach troubles and rheumatism.

It is not sufficient, say the advocates of the fruit cure, to eat a small quantity at breakfast or dinner. One should eat from two to eight pounds of grapes a day, or, if oranges are the curative agency, the number to be eaten in a day may vary from three to six.

A healthy condition of the body depends upon a perfect balance of foods taken. There are many other factors entering into the question, but this feature must not be forgotten. Few people there are who can keep healthy without fruit.—*The Syracuse Clinic.*

EXHIBIT OF THE MEDICAL DEPARTMENT AT THE PAN-AMERICAN EXPOSITION.

The exhibit, which was in charge of Captain E. L. Munson, assistant surgeon, U. S. Army, consisted of a brigade field hospital of 100 beds, and was excellently located on a plot of ground immediately south of the Government Building, very accessible to visitors and of sufficient size not only to contain the hospital tentage without crowding, but also to furnish an adjoining space suitable for drill purposes. The hospital was fully equipped in all its details according to the provisions of the latest supply table; the purpose being to leave nothing to the imagination of visitors, the majority of whom would be unfamiliar with military matters, but to demonstrate the equipment of the Medical Department, in respect to the brigade hospital unit, in quality, size and capacity as well as in form, variety and quality.

The number of visitors who have inspected the field hos-

pital and witnessed the exhibition drills of the hospital corps is very great, and my expectation that this exhibit would prove an attractive and interesting as well as instructive feature of the Exposition has been amply justified. The character of the exhibit is such as would naturally attract military and medical men, and in addition, the recent war with Spain and hostilities in the Philippines and in China have aroused a general interest in military matters. A large proportion of visitors at the Exposition have had relatives or friends in the regular or volunteer forces and these, particularly the women visitors, have shown much interest in the methods and appliances by which sick and wounded soldiers are cared for by this Department in the field. As a means of educating the popular mind with respect to the efficiency of the Medical Department, this exhibit has thus been of very great value.

Reviews.

A Text Book of Physiological Chemistry for Students of Medicine and Physicians. By Charles E. Simon, M. D. 8 Vo. 430 pages and Index. Lea Bros. and Company, Philadelphia.

The accumulation of facts in the domain of physiological chemistry goes on in increasing ratio, yet so far from solving the problem of life, progress seems only to add new difficulties. "Hills peep o'er hills, and Alps on Alps arise." The work before us is a finely printed volume containing a large amount of valuable matter, and will be a useful addition to the literature in this field. The main object is to serve as a text-book for students who have had sufficient instruction in general chemistry to understand the structural formulae and to carry out the experimental work when described in moderate detail. The first section of the book gives an account of the three main classes of food stuffs. The enzymes, digestive secretions and processes of digestion and resorption and chemistry of important secretions are then considered. The concluding one hundred and thirty-five pages comprise the chemistry of the principal tissues and organs.

The theoretical chemistry is presented in much detail, structural formulae being freely used, indeed, some may think that they are too liberally used, for although such formulae aid chemistry very much, they are discouraging to many students and to most practicing physicians. Still, it is best to err in this respect on the side of fullness than of deficiency. Among the many tests given, we note that the author favors the phenylhydrazine test for sugar and Folin's modification of Hopkin's method for uric acid. The literary quality of the book is high and the descriptions and directions are clear and concise. We would be more pleased if the chemical nomenclature was more rigidly framed for while, as a rule, the expressions conform to approved forms, we note lapses into antiquated terms. Among instances of the latter, attention must be especially called to the use of the word "glucose" for "dextrose." It is true that "glucose" is the term by which the dextrose of urine is usually designated by clinicians, but a scientific work of this standing should explain the error of this use and employ the proper term. A reader who is intelligent to comprehend the structural formulae given on page 89, for example, will surely be able to comprehend the approved nomenclature in this field. The only reference we find to dextrose is in the otherwise good index, in which the exasperating "see glucose" occurs. Under the monosaccharides, levulose, galactose and glucose are enumerated. One incidental objection to this method of nomenclature is that many clinicians may be led to think that commercial glucose is identical with the carbohydrate of the urine.

The general execution of the work—proof reading, press work and paper—is very satisfactory. On page 33 the specific rotatory power of albumins is given without the minus sign; this may have been deemed necessary in view of the statement in the text that they are all levorotatory, but it would be better to follow strictly the accepted

method. The work will undoubtedly find a wide field of usefulness. It is not illustrated, except with an uncolored plate of absorption spectra. [H. L.]

Eczema, With an Analysis of Eight Thousand Cases of the Disease, by L. Duncan Bulkley, A. M.; M. D., Physician to the New York Skin and Cancer Hospital, etc. Third Edition of "Eczema and its Management." Students' Manual Series on Diseases of the Skin. G. P. Putnam's Sons, New York and London, 1901.

In this volume Dr. Bulkley has gone thoroughly, but concisely, into a consideration of the subject of eczema, especially as regards the underlying, exciting and contributory causes, and the measures and medical management necessary for its treatment. After some general considerations the author takes up a brief analytical study of the 8000 cases, discusses the frequency and nature of the malady, and presents in succinct form the etiological factors which experience has shown have a bearing of variable import in provoking an outbreak. The various lesion forms are then discussed and types as regards acute, subacute and chronic character of the morbid processes described. Brief consideration is then given to the differential diagnostic points from twenty-seven diseases. A large part of the book is given to the practical subject of treatment. Dr. Bulkley has always contended, and rightly, too, that while the value and necessity of external treatment cannot be too highly appreciated, the proper constitutional management of the disease must receive full consideration and its importance recognized. And no better introduction to the latter can be given than his statement, "The first fact to be remembered in the treatment of the disease is that there is not, and never can be any specific for eczema, as the practice of some would seem to indicate; indeed, in many cases it is useless and unnecessary, and in many others it does actual harm."

After general consideration of the subject, regional eczema is taken up. Diet and other like subjects are discussed, and the work ends by the addition of a series of formulae most commonly employed.

The book can be recommended for its good, sound sense, its careful and explicit, though brief directions, and if properly perused will be of practical use to the general practitioner and consequently to his patients, keeping both him and his cases from the pitfalls of the proprietary and semi-quack cure-all ointments, to the employment of which seductive advertisements, and his lack of knowledge of the subject might lead. [H. W. S.]

Illinois State Board of Health. Report of Sanitary Investigation of the Illinois River and its Tributaries. 8 Vo. 204 pages, index and map. Phillips Bros. State Printers. Springfield, Ill.

The establishment of the Chicago main drainage canal has not only aroused interest as an engineering operation, but has awakened much alarm among those who depend for drinking water upon the stream into which the enormous volume of sewage enters. The present volume is a special report giving chemical and bacteriological results of extended investigations of the streams likely to be involved in this pollution, as well as of tributary streams, with a view of establishing comparisons. The general question of self-purification of streams is discussed by Dr. Egan, Secretary of the Board. We need not present here a detailed study of the chemical and bacteriological statistics. They are all made by the most approved processes, and it is claimed that the investigation shows that the sewage of Chicago is not likely to cause injury to those using water below the mouth of the Illinois river. As a matter of fact such investigations as these have little more than academic interest. No observant sanitarian will believe that the introduction of the sewage of a large and very filthy city into a running stream will do otherwise than render that stream more unsafe as drinking water than before. The practical issue is, however, complicated by the fact that these streams are in all probability unsafe in their original

condition. The small streams flowing through flat cultivated or populated land are sure to become polluted, and the addition of Chicago sewage will increase the danger, not create it. The best remedy is the restriction of water-waste in the main city, and the efficient filtration of all surface waters by the towns below the point of pollution. [H. L.]

Anatomy, Descriptive and Surgical; by Henry Gray, F. R. S. Edited by T. Pickering Pick, F. R. C. S., and Robert Howden, M. A.; M. B., C. M. A Revised American, from the Fifteenth English Edition. With 780 Illustrations, many of which are new. Published by Lea Brothers & Co. Philadelphia and New York.

We know of no medical text book in continuous use that can hold the record with "Gray's Anatomy." It has now reached a revised American edition, which is a reprint from the fifteenth English edition. The editors are Mr. Pickering Pick and Mr. Howden, and they announce that the entire work has undergone a careful revision. The section on embryology, especially, has been amplified, and some 60 illustrations have been added. Throughout the rest of the work many new diagrams also have been added, and some of the old ones redrawn. As the publishers announce, this work has held the front place in works on anatomy for forty-five years, and its merits are only brightened by the numerous works which have endeavored to contest its supremacy. It hardly calls for an extensive review, as the work is too familiar both to the student and the practitioner to need more than a notice. In this present edition it retains its old familiar lineaments, and we doubt not that it will continue to be an indispensable handbook to every practitioner in every department of medical and surgical work. [J. H. L.]

A Case of Rupture of the Uterus.—In the (*Revue Médicale de l'Est*, 1901, No. 10) Dr. A. Herrgott reports the case of a woman of 33, who was pregnant for the seventh time. Her former confinements had been normal. Three days before admission to the hospital the amniotic sac had broken. Labor had already lasted 48 hours. The fetal heart-beat was not audible, and the abdomen was tender. The vulva was much congested, the left arm of the fetus protruding, the shoulder being caught in the external orifice. An anesthetic was given and embryotomy done with much difficulty. After some time, delivery of the body followed normally. As there was hemorrhage, Herrgott suspected rupture of the uterus. This was found upon examination, along the left side of the cervix, continued at a right angle. The rupture was complete, through the peritoneum. As there was subcutaneous emphysema, Herrgott performed laparotomy, and removed the uterus. The patient died. Herrgott shows how dangerous may be premature rupture of the membranes in transverse presentations. [M. O.]

Quantitative Determination of Methylene Blue in Urine.—Ivanoff (*Medicinskoje Obozrenie*, May, 1901) finds that the determination of methylene blue in the urine, after the injection of the substance for the diagnosis of renal insufficiency, is best accomplished in the following manner: A number of filters are prepared by immersing them for 15 minutes in a 2.5% solution of tannin heated to 50-70°C. They are then dried and again immersed in a 1.5% solution of tartar emetic at a temperature not exceeding 20°C., for 15 minutes. The filters are finally washed in water and dried. Several of these are employed for the purpose of making a color-scale. A quantity of methylene blue is dried to a constant weight in a hot air oven; solutions of various strength, as 1:50,000, 1:100,000, 1:200,000, are prepared and 10 cc. of each passed through the filter several times, until the filtrate is entirely free from color. Thus a series of colored filters is obtained, corresponding to definite amounts of methylene blue. To determine the methylene blue in the urine, 10 cc. of the latter are passed repeatedly through one of the specially prepared filters until the disappearance of the least trace of blue from the filtrate. The colored filter is then compared with the standard. The author claims for this method accuracy as well as convenience. [A. R.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Death of Dr. Norris.—Early on the morning of November 18, Dr. William F. Norris died at his home in Philadelphia, the best known ophthalmologist in America, the most renowned American not only in Europe, but throughout the entire world, in his especial line of work. While it was generally known that Dr. Norris had been suffering from pneumonia for several weeks past, he was considered convalescent, so that the news of his death came as a shock to those who were accustomed to seeing him daily, up to a few weeks ago, at the University Hospital. A member of one of Philadelphia's oldest families, born January 6, 1839, the son of Dr. George W. Norris, William Fisher Norris was graduated from the University of

DR. WILLIAM FISHER NORRIS.

Pennsylvania in 1857, receiving his A. M. degree in 1860 and his M. D. in 1861. Two years later Dr. Norris entered the United States Army, holding the position of assistant surgeon during the Civil War. In 1864 he had charge of the Douglas General Hospital in Washington. Then Dr. Norris passed some years in Europe, at work upon ophthalmology. While in Vienna he met and married Fräulein Rosa Clara Huchmann, who was the mother of his sons.

Dr. Norris held many prominent positions: Professor of ophthalmology in the University of Pennsylvania from 1876 up to the time of his death; president of the American Ophthalmological Society from 1885 to 1889; fellow of the College of Physicians of Philadelphia, and president of the Section on Ophthalmology in 1894; visiting surgeon to the Wills' Eye Hospital for thirty years, having only resigned this fall, when he became consulting surgeon; companion in the military order of the Loyal Legion; manager of the Mutual Assurance Company; vice-president of the Pathological Society of Philadelphia; member of the Academy of Natural Sciences; member of the American Philosophical Society; and one of the founders and president of the Board of Managers of the University Hospital.

Though in his sixty-third year, Dr. Norris still possessed a certain shyness, modesty, or diffidence of bearing, which was most noticeable when among strangers. Yet this was soon forgotten when one heard him talk, so well did he impress upon his audience the fact that he thoroughly knew his subject. Nor was his delivery at all dramatic.

His spare time was passed at his beautiful country place, "Woodburne," near Montrose, Susquehanna County, Pennsylvania. After having been an invalid for several years, Mrs. Norris died about five years ago. Dr. Norris later married Miss Annetta Culp Earnshaw, of Gettysburg, who survives him. He also leaves two sons, Dr. George William Norris, resident physician at the Pennsylvania Hospital, and William Felix Norris, a student at the University of Pennsylvania Law School. Dr. Norris was the author of many widely known books, pamphlets, and papers upon ophthalmological subjects. Among the more prominent of these may be mentioned his work in Pepper's "System of Medicine," "Medical Ophthalmology," "Versuche über Hornhaut Entzündung," written in conjunction with Professor Stricker, "A Contribution to the Anatomy of the Retina," written with Dr. James Wallace, and several large works, in editing which he was assisted by Dr. Charles A. Oliver, a "Text-book of Ophthalmology" and a "System of the Diseases of the Eye," by American, British, French, Dutch, and Spanish authors. This comprehensive work, in four large volumes, the greatest of its kind in the world, appeared between the years 1897 and 1900.

His genial manner, his straightforward way of doing just what he considered his duty, endeared him, not only to his patients, but also to those of his students who had the opportunity of knowing him. Thus it was that many scientific positions which he held during his life came to him unasked, the simple reward of merit. Great as is the loss in the death of Dr. Norris to the University of Pennsylvania, the University Hospital, Philadelphia, and the medical profession, his works will live long after him as the best ophthalmological books of reference in the English language.

Smallpox in Philadelphia.—During the week ending November 16th, but 50 new cases were reported, with 12 deaths. A church has been closed and disinfected in Frankford, where services were held by a clergyman still in the period of smallpox invasion. Up to the present time fourteen schools have been closed for forty-eight hours each, for fumigating purposes, and orders have been given to have all schools properly disinfected. There are now eight schools temporarily shut up, so that they may be fumigated and disinfected. Dr. William Welch, of the Municipal Hospital, speaking of the efficacy of vaccination as a preventive in smallpox, said that of the fifty men and fifteen women employed in the hospital all were vaccinated except one, and that one had caught smallpox. Over 4000 patients and 300 employés in the Philadelphia Hospital have been vaccinated. One death from tetanus is reported, in an imbecile who, after being vaccinated successfully, scratched the wound. He was employed in the yard hanging clothes from the laundry. Three weeks after vaccination, the wound became infected, lymphangitis followed, and symptoms of tetanus developed on the 5th day. In 52 hours death in convulsions resulted, in spite of the serum treatment, morphine, stimulants and sterilization of the wound.

Smallpox in Pennsylvania.—Outside of Philadelphia many cases of smallpox are reported. These seem most frequent near this city. Norristown has fifteen houses now under strict quarantine, and fifteen cases are under care at the hospital which has been established in the old hotel building at Oakview Park, which itself is isolated. A doctor and two nurses from the Municipal Hospital in Philadelphia are there in charge. The disease was imported into the town from Philadelphia, and since then only twenty-one cases have developed, all of which were properly quarantined. They have been scattered through the town. There are a few cases reported in Pottsville, some in Chester, and some near Wilkesbarre. The epidemic of smallpox in Plymouth, which was not thoroughly stamped out in the summer, when it was rather severe, has manifested itself again, and is once more becoming serious. Four new cases have been reported since Sunday, and several houses are quarantined and are being closely watched.

Society Meetings Next Week.—The following societies will hold meetings at the College of Physicians, next week,

at 8.15 P. M.: Monday, November 25, Neurological Society; Wednesday, November 27, County Medical Society; and Thursday, November 28, Pathological Society.

Berks County Medical Society.—At the November meeting of the Berks County Medical Society, Dr. Kaiser read a paper upon cerebral disease. Vaccination was discussed, and the following resolution was passed unanimously: "In view of the alarming increase of smallpox in Philadelphia and this vicinity, the Berks County Medical Society urges the general public to observe the recommendation of the Board of Health and protect themselves against this disease by resorting to vaccination."

Emergency Hospitals in Coal Mines.—The mining department of the Lackawanna Railroad is teaching its employes to give first aid to the injured in case of accidents. Medical men are engaged instructing the foremen of the various mines in attending the injured pending the arrival of a qualified surgeon. A room will be fitted up in each mine, to be used as an emergency hospital.

National Academy of Sciences.—The American National Academy of Sciences met at Hutton Hall, University of Pennsylvania, November 12 to 14th. Among the papers by medical men was one on "Snake Venom in Relation to Hemolysis Bacteriolysis and Toxicity," read by Drs. S. Weir Mitchell and Simon Flexner, and one "On the Vaso-Motor Supply of the Lungs," read by Dr. Horatio C. Wood, Jr. Dr. Noguchi, of the Pathological Department of the University of Pennsylvania, discussed the first paper.

The Woodward Fellowship in Physiological Chemistry.—Dr. George Woodward has given the trustees of the University of Pennsylvania \$20,000 to establish the "Woodward Fellowship in Physiological Chemistry" in the Pepper Laboratory. The incumbent of that position is supposed to devote himself entirely to original work in the field of physiological chemistry. The character of the work will be varied and will consist of chemical investigations of diseases. Dr. Alfred C. Croftan, the incumbent, is a physician who has made a specialty of chemistry as applied to medicine. Dr. George Woodward, the donor, was graduated from the University Medical Department in 1891.

The Germ of Dysentery.—Investigations carried out during the past summer by the Department of Pathology of the University of Pennsylvania have discovered the occurrence of the specific bacillus of dysentery in the disease prevailing in the United States. Several epidemics of dysentery occurring in different parts of the country were studied, and in all the same germ was obtained. The results of the investigation, the expenses of which were borne by the Rockefeller Institute of Preventive Medicine, go to show that the dysenteries of tropical and temperate climates are identical.

Physicians' Rights.—A woman called on a physician last March for the purpose of having him visit her sister, who was suffering with a sprained ankle. She testified in court last week that he not only refused to listen to her story, but ejected her from his office without any provocation on her part. The physician, however, testified that the prosecutrix became so abusive that he was obliged to eject her, after she had refused to leave voluntarily. He insisted, however, that he used no more force than was necessary. The defendant, the Judge said, had the right to eject the prosecutrix if her conduct was objectionable, even to the extent of using force.

Municipal Hospital Site.—Councils' Sub-Committee to consider the removal of the Municipal Hospital at Twenty-second street and Lehigh avenue, met last week. Two sites for a new Municipal Hospital, in case Councils decide to remove the present buildings, were considered, a tract of land in the Thirty-third ward, adjoining properties of the Greenmount Cemetery, New Cathedral Cemetery and the Philadelphia and Newtown Railroad, described as being ninety-eight feet above tide water, containing 53¼ acres, obtainable for \$140,000; and a plot of ground on the Delaware river front above Venango street, 1000 feet front, extending westwardly 3500 feet to Richmond street, to cost \$200,000.

New Clinical Laboratory.—The Philadelphia Clinical Laboratory, Incorporated, has been opened for the analysis of urine, gastric contents, milk, calculi, etc., the examination of blood, sputum, pus and tissues, and other bacteriological, histological and chemical work at moderate prices. The president is Mary Pennington, Ph.D., director of the chemical laboratory in the Women's Medi-

cal College, while Elizabeth Atkinson, Ph.D., is secretary.

Resignation.—Dr. Ralph F. Sommerkamp has resigned the position of assistant physician in the Insane Department of the Philadelphia Hospital.

Death of Dr. Samuel Ashhurst.—News has been received of the sudden death of Dr. Samuel Ashhurst from asthma, November 12, in London. Dr. Ashhurst, who was a graduate of Amherst College and the University of Pennsylvania Medical School, was 61 years old, a widower without children. He had been connected with the Children's Hospital for many years, and was always a great favorite among children. He was a first cousin of the late Dr. John Ashhurst, Jr.

NEW YORK AND NEW JERSEY.

New Hospital for Convalescents.—New York is to have a new hospital for convalescents, according to the plans of St. John's Guild. The trustees of the Guild have decided to establish a hospital on the Guild property at New Dorp, S. I., to be open the year round, for the care of women and children during convalescence. Tentative plans have already been prepared.

Tubercle Bacilli in Milk.—That tuberculosis in cattle is transmitted in milk to human kind, though only rarely; that children can and do drink infected milk with only a remote chance of becoming victims of the disease, and that 20 per cent., roughly speaking, of a city's milk supply contains tubercle bacilli, were some of the points in the paper read before the section on pediatrics at the New York Academy of Medicine by Dr. David Bovaird, Jr., November 14th. Dr. Bovaird also briefly touched upon the point that, with the exception of very rare cases, the eating of meat from tuberculous animals will not transmit tuberculosis.

The New York State Railway Surgeons began their eleventh annual meeting on November 18th. Dr. W. R. Townsend presided. Papers were read by Dr. G. P. Conn, of Concord, New Hampshire; Dr. N. H. Hartey, of Indiana; Dr. M. J. Rosenau, of Washington, D. C.; Dr. William H. Park, of New York, and L. J. Gilbert, of Pittsburg.

Purveyor of Degrees.—John W. Norton-Smith, M. D., Ph. D., LL. D., president of the Central University of Medicine and Science, in Jersey City, who offered to sell honorary degrees at cut rates, was in court in Jersey City, November 16, on a charge of obtaining money under false pretences. The charge was based on a letter received by the police from Dr. D. H. Harrison, of Swanville, Texas, to whom Norton-Smith had offered a diploma for \$10. The false pretence consisted in a presentation made in the letter that the Central University was incorporated under the laws of New Jersey. It was incorporated two years ago, but, in July last complaint was made to the police that Norton-Smith was conducting an illegal business, selling diplomas to anyone who was willing to pay \$10. It is said he offered to cancel his act of incorporation, if the authorities would drop the prosecution. This was agreed to, and the certificate was cancelled. Subsequent developments show that he resumed business immediately.

Passaic Fears Smallpox.—The Board of Health of Passaic, N. J., issued orders that all employes of local mills be vaccinated within ten days, or else the work will be done at the expense of the city. Though only one case of smallpox has been discovered there, the authorities fear that others may develop.

Tetanus Following Vaccination.—Six deaths from tetanus following the infection of the vaccination wound have occurred in Camden, N. J. Almost all cases clearly show the secondary infection in the history. The physicians are now taking great care to observe cleanliness. There was a special meeting of the Board of Health, November 18th, to consider the question of tetanus following vaccination. While the majority of the physicians present did not believe that vaccination produced tetanus, they did believe that the air was so full of tetanus germs that any scratch, whether for the purpose of inoculation or otherwise, became dangerous. Resolutions were therefore passed that children be received in the schools, though never vaccinated, and that physicians for the present discontinue vaccination.

To Report Malarial Fever.—In New York the Board of Health is to require the physicians in public institutions, hospitals and asylums to report all cases of malarial fever

coming to their notice. All the other physicians of the city are requested also to make such reports. Presumably, if the results warrant it, such reports will be made generally compulsory later.

Medical Inspection of Schools has been inaugurated in three of the smaller cities during the month past—Syracuse, N. Y.; Orange, N. J., and Newark, N. J.

Dr. Albert L. Gihon Dead.—Dr. Albert Leary Gihon, medical director of the United States Navy, retired with the rank of commodore, in charge of the Naval Hospital for four years, died from apoplexy in Roosevelt Hospital, New York, November 17. He served during the Civil War, and was well known as a writer on medical subjects, many of his works being in use as text books. Born in Philadelphia sixty-nine years ago, Dr. Gihon received his education there and at Princeton. He was professor of chemistry and toxicology in the Philadelphia College of Medicine and Surgery in 1853. He entered the navy in 1855. "The Annual of Universal Medical Science," "Handbook of the Medical Sciences" and "Twentieth Century Practice of Medicine" are the titles of some of the books in which the did editorial work. He was the author of nearly thirty volumes on medical subjects.

NEW ENGLAND.

Great Man Honored.—On November 11th a distinguished gathering in Tremont Temple, presided over by Senator George F. Hoar, did honor to Samuel Gridley Howe, on the occasion of the 100th anniversary of his birth. His widow, Julia Ward Howe, formed the most conspicuous figure in the platform group. An excellent picture of Dr. Howe fronted the chancel, while in the galleries sat some thirty pupils from the Perkins Institution and Massachusetts School for the Blind. The band of the Perkins Institution was also present, and helped to provide a musical programme. A souvenir in raised letters, containing a poem by Whittier, with an event in the life of Dr. Howe, was given each person attending the meeting. Dr. Hale finally read a letter from Helen Keller. Mr. Richard C. Humphreys reminded the audience of Dr. Howe's connection with the Massachusetts School for the Feeble-Minded, incorporated in 1850. To define Dr. Howe's connection with it would be simply to say that it was his school, organized and conducted almost alone in addition to his work for the blind. Dr. Howe was a truly great philanthropist. He was born in Boston, November 10, 1801, taught in the public schools and graduated at Brown University in 1821. It was through Dr. Howe's influence also that the New York Institution was started. Several other speakers eulogized Dr. Howe.

Smallpox in Boston.—The number of smallpox cases reported to the board last week is 28, with three deaths. This makes the total number for the current year 159. A careful examination of the medical records of the 217 cases of smallpox, which have appeared in Massachusetts since June 6, shows that only half a dozen of the patients had been vaccinated within a month prior to contracting the disease; 118 had never been vaccinated at all; 65 persons of mature age had not taken the treatment for at least ten years—most of them not since infancy—and 25 who claimed to have been vaccinated, and are so reported, showed no scars. Thus it appears that 143 of the 217 were absolutely without vaccine protection, inasmuch as the operation was performed so long ago as to have lost its value. Consequently only 34 of the 217 patients can be credited with having taken due precautions against the disease. But in some of these cases the records are incomplete and in others it is just ten years since the operation was performed, while in the remaining few the time varies between nine years and five days. It is safe to state that not more than 20 of the 217 Massachusetts people who have been suffering from the dreaded disorder since last summer, had taken the precautions that the ordinary physician would advise. Some cases were reported in Hyde Park last week, also.

Dr. Weldon Awarded \$6750.—A verdict of \$6750 for the plaintiff in the case of Dr. John Weldon of Willimantic,

Conn., vs. Otis Clapp & Sons was last week returned in the United States Circuit Court before Judge Lowell. The action was brought to recover damages for breach of an alleged warranty of a static X-ray machine, which the plaintiff bought of the defendants, to the effect that it would not burn. The plaintiff was burned severely by the machine, so that his leg is still lame. The defendants denied that the warranty was made, and claimed that the machine was harmless when properly used. The doctor had sued for \$20,000 damages.

Diphtheria Epidemic in Lowell, Mass.—Owing to an epidemic of diphtheria, an order was introduced in the board of aldermen, November 12, appropriating \$30,000 for a contagious hospital. At present there are about 90 cases of diphtheria in Lowell. The local board of health has called upon the state board for advice and Dr. Morse has been in the city making investigation as to the causes.

Gives Morse Hospital \$15,000.—The trustees of the Morse Hospital, Natick, Mass., have received from Hollis H. Hunnewell, Sr., a gift of \$15,000 in C., B. & Q. R. R. 4 per cent. bonds, there being no restrictions as to how the money shall be used. This is the largest donation made for the benefit of the institution since its establishment.

Bequests.—The will of Alfred Henry Hersey, of Hingham, Mass., probated at Plymouth, makes bequests of \$5000 each to the Massachusetts General Hospital and the Perkins Institute for the Blind; \$3000 to the Massachusetts Eye and Ear Infirmary; \$2000 each to the Carney Hospital, Kindergarten for the Blind, Channing Home and Boston Home for Incurables; and \$1000 for the Free Hospital for Women.

WESTERN STATES.

Tetanus in St. Louis.—The St. Louis Health Department was on November 18 found by the coroner to be negligent on account of the preparation of diphtheria antitoxin, from the administration of which seven children died of tetanus. The antitoxin had been prepared and issued by the St. Louis Board of Health in bottles bearing the dates of August 24th and September 30th. The Coroner's verdict is based upon the testimony of physicians who attended the lockjaw cases, the inquest, and the report of the bacteriologists employed by the city to make tests of the infected serum and ascertain the responsibility for it.

Insanity Among Teachers.—Statistics of the Illinois State Hospital for the Insane at Elgin, in the last biennial report, show that out of 660 persons admitted to the institution in the last two years ten were women school teachers. At the same time was elcted a report of Professor Zimmer, of Berlin, after an investigation carried on in Austria, Switzerland, Russia, and Germany, in which he said that one in every 85 female patients in the asylums for the insane was a teacher. The experience of alienists in Philadelphia has not been similar to that found in Illinois and in Europe. Whether the atmosphere East of the Alleghenies is less conducive to insanity among persons engaged in confined occupations or whether the school rooms of Chicago are less sanitary in their arrangements than those of Philadelphia, and the work of the school teachers more harassing and exacting, could not be learned. At the women's department of the Pennsylvania Hospital for the Insane there was a much larger proportion of saleswomen who became insane than of teachers. In the last year and ten months there have been admitted to the Pennsylvania Hospital for the Insane only seven women and one man whose occupation has been that of teaching. The man was 76 years old, his condition being chiefly if not wholly due to senility. At the Philadelphia Hospital the superintendent said that out of 299 women patients admitted to the insane department in the year 1900 only one was a school teacher, and among the 353 men there was no school teacher. Dr. Edward Brooks, superintendent of public education, said, in his experience the ratio of insanity among teachers was very small. "In ten years," he added, "I have known only two cases, in both of which the sufferers were women. I was connected with the State Normal School for 28 years and in that time knew of very few instances of insanity among teachers."—*Philadelphia Times*.

CANADA.

Fewer Deaths in September in Ontario. The total number of deaths in Ontario during September was 1959, against 2160 a year ago, consumption showing a slight decrease. Some time ago the provincial Board of Health, believing that municipalities were becoming lax in making statistical returns which are required by law, sent out official circulars cautioning against neglecting these returns. The result of this warning is seen in the fact that for the month of September no less than 99 per cent. of the population was reported. Scarlet fever claimed 13; diphtheria, 45; measles, 2; whooping cough, 17; typhoid fever, 41; and consumption, 165, seven less than in the corresponding month of 1900. In Toronto alone sixteen cases of typhoid fever were reported in October.

The Medical Course at McGill is to be extended. Following the action of the Science Faculty, which has lately increased the percentage standard requirements for pass, second and first-class honors, the Medical Department now contemplates making the course at McGill University five years instead of four, the sessions to remain periods of nine months in extent. This is not likely to be put into effect until Dr. Roddick's bill upon Dominion Registration has been passed by the Houses of Parliament. So soon as this becomes law, in order to comply with the recommendations of the British Medical Council, the standard will be raised at McGill. It is fully expected that Dominion Registration will become adopted in 1903 at the latest.

The Toronto Board of Health has again recommended to the Council the submission to the people, in January next, of a by-law for the purpose of granting \$50,000 for a sanitarium for poor consumptives, to be situated not further than 40 miles from the city and to comprise at least fifty acres of land. The city will then grant the usual forty cents per patient, as soon as the institution is ready for the reception of patients. Toronto will also place notices in public places requesting citizens not to spit upon the streets, pointing out the dangers of the habit.

A Medical Inspector for Northern Ontario has recently been appointed by the Ontario Board of Health. Dr. O. A. Hodgetts, who has for some time been connected with the Board as a special inspector, received the appointment. His duties will be to see that the regulations recently adopted by the Board with regard to sanitary matters in lumber camps are being strictly and efficiently carried out. This immense unorganized district has a frontier of 6000 miles on lake, river and railway, and has a population of 100,000, stretching from the Ottawa River to Rat Portage, near the boundary of Manitoba. Already the regulations are having marked effect, many of the lumber camps having appointed medical officers, with hospitals properly equipped.

The Yukon Territory has a well-organized medical body. In September, 1898, the College of Physicians and Surgeons was organized, with a Medical Council of five members, who conduct the affairs of the College. Any one desiring a license to practice in the Yukon Territory must pass the prescribed examinations, upon furnishing proof that he has put in the proper time in medical studies. The fee for registration is \$100, and there is an annual assessment at the option of the Council, of from \$20 to \$50. Members of the College of Physicians and Surgeons of Ontario, Quebec, Manitoba, the Canadian Northwest Territories, Great Britain, and Ireland, are registered without examination. The membership now reaches forty, although this number of physicians is not in actual practice in Yukon Territory now.

Research Laboratory Promised.—The free hospital now being erected near the Muskoka Cottage Hospital will soon be ready for patients. The main building is the gift of W. J. Gage, of Toronto, and the late H. A. Massey. It is located in a beautiful park of 56 acres half a mile from the town of Gravenhurst. Fifty beds for Toronto's poor are being provided; the Grand Trunk Railway will carry free of charge 100 patients each year to and from the institution. All in excess of that number will be carried at half rate. Physicians and nurses will also be carried free of charge. This hospital will be for those in the earlier stages of consumption; the National Sanatorium has purchased a fine site near Toronto at a cost of \$30,000 for ad-

vanced cases. It is understood that the late W. E. H. Massey has bequeathed \$30,000 for a research laboratory in connection with the Gravenhurst institution.

MISCELLANY.

The Morphine Habit in Porto Rico.—The Insular Board of Health of San Juan estimates that there are 1,000 victims of the morphine habit in Juana Diaz, a town with a population of 2,500.

Measles Fatal in Alaska.—Dunlap More, Assistant Surgeon United States Quarantine Service, stationed at Nome during the past season, confirms the report that the natives of Western Alaska are rapidly disappearing from the effects of disease. He states that at least one-third of the native population at Cape Nome, Prince of Wales, Nome, Port Clarence, St. Michaels, Kuskokwim, Unalaska, Pribyloff Islands, Nunivak Island, and St. Lawrence Island, and those along the Yukon River, have suffered from the effects of an epidemic, which at first was thought to be small-pox, but upon investigation proved to be measles.

Pan-American Congress.—The Mexican delegates to the congress oppose obligatory arbitration. *El Imparcial* says the Mexican delegates are united in a determination to advocate the principle of suppression of quarantine. England has shown the way, and her public health has not suffered by the removal of quarantines.

Oxygen as an Antidote.—That pure oxygen may be made a successful antidote to poison is the important result of experiments now in progress in Berlin, at the Institute of Physical Diagnosis, under the direction of Dr. Rogovin, a Russian medical scientist, and Dr. William Cowl, of New York. Unqualified cures from poison by morphine, strychnine and arsenic have been made in the cases of cats, rats, mice, and guinea pigs affected. The experiments have been guarded with the utmost secrecy, with the intention of making the discovery public for the first time at the German Medical Congress in 1902. The following, however, is a synopsis of the discovery; the treatment contemplates the substitution of pure oxygen for the means generally employed in giving medical relief in poisoning cases. The inhalation of oxygen provides four times as much nourishment as breathing air, as has been shown in the demonstrations, accurately recorded by means of an instrument resembling the sphygmograph heretofore used for pulse writing. Berlin's health authorities are interested in the experiments on account of the possibility of saving the lives of suicides. It is pointed out that ninety per cent. of suicides result from morphine dyspnea, against which medical antidotes are powerless.

Obituary.—Dr. J. Marcus Rice, at Worcester, Mass., November 11, aged 74 years—Dr. T. O. Linthicum, at Corbins, Va., November 12, aged 45 years—Dr. William S. Latta, at Lincoln, Neb., October 20—Dr. J. Sappington Pyle, at Delta, Pa., November 12, aged 81 years—Dr. David C. Reynolds, at Philadelphia, Pa., November 12, aged 71 years—Dr. Calvin Edward Hull, at Black Rock, Conn., November 13, aged 84 years—Dr. Jarvis S. Wight, at Brooklyn, N. Y., November 15, aged 67 years—Dr. Samuel Ashurst, in London, Eng., November 13, aged 61 years—Dr. C. L. Harmanson, at Onancock, Va., November 15, aged 43 years—Dr. Albert L. Gihon, at New York City, November 16, aged 70 years—Dr. Joseph N. Narcross, at Old Town, Me., November 9, aged 50 years—Dr. L. L. Todd, at Indianapolis, Ind., November 16, aged 66 years—Acting Assistant Surgeon Stuart Eldridge, at Yokohama, Japan.

GREAT BRITAIN, ETC.

The Health of the Troops in India.—The number of men arriving in India for service at an age peculiarly susceptible to typhoid fever has fallen from 16,911 to 3,363 as a result of the war in Africa. On this account also there are nearly 25,000 men still in India whose time is up and whose places have not yet been taken by younger men. Men who have spent six or seven years in India are much less likely to contract disease than those fresh from home, and are therefore of greater value from a military point of view.

Westminster Hospital, London.—The Westminster Hospital has recently opened an electrical laboratory and a room with X-Ray apparatus, at a cost of \$5000.

London School Board.—Dr. W. R. Smith, professor at King's College, who has been medical officer to the London

School Board for over 11 years, has recently resigned that position. His resignation was sent to the Board because it had been decided to reduce the salary paid the medical officer of the London School Board from \$4000 to \$2000.

Munificent Bequests.—The late Mr. Matthew Whiting, of Wandsworth, has left \$600,000 in equal shares to St. Thomas's Hospital, St. George's Hospital, Guy's Hospital, King's College Hospital, the Westminster Hospital, the Middlesex Hospital, the London Hospital, the Royal Free Hospital, St. Mary's Hospital, the Great Northern Hospital, the Brompton Hospital for Consumption and Diseases of the Chest, the New Hospital for Women, Euston Road. Sir Robert Sexton has left \$65,000 to the Dublin Hospital, and Mr. T. K. Hardie has bequeathed \$400,000 to various hospitals in England and Scotland.

Gartnavel Asylum, Edinburgh.—Dr. Yellowlees, superintendent of the Gartnavel Asylum, has resigned on account of eye strain. He will, however, continue his lectures and consulting practice.

Medical History.—The Royal College of Physicians of London has accepted a gift of \$10,000 from Mrs. Fitzpatrick to found a lectureship on the History of Medicine in memory of her late husband, a distinguished member of the college, born in Ireland in 1832. This brings England into line with the recent advances made on the Continent and in the United States.

A School for Cripples.—The London School Board has opened the first of a series of schools for cripples. The children are taken from their homes to school and afterward taken home by ambulance. The school curriculum includes a substantial midday meal.

Simple Remedy Cured Cancer.—Lady Margaret Marsham, aged 67 years, was ill with a throat affection pronounced cancer. Analysis and clinical research in the Medical Association's laboratory confirmed the diagnosis. Death was expected within a week, when a neighbor recalled an old remedy, a handful of fresh green violet leaves put in a pint of boiling water, allowed to stand for twelve hours; after straining off the liquid, a piece of lint dipped into the heated infusion was applied hot and covered with oil silk. The infusion was made fresh every other day. Its effect was described as miraculous. The large, hard external swelling disappeared in a week, the pain ceased, and the cancerous growth of the tonsils disappeared in a fortnight. The patient now seems to be in good health.

The Water Famine in Edinburgh has become so serious that householders have been recommended to dispense with baths in their houses and local authorities to discontinue public baths.

The Plague at Liverpool.—Although no new cases have been reported since October 25th, Assistant Surgeon J. F. Anderson, of the U. S. M. H. S., who has been detailed by the President to investigate the outbreak of plague in Liverpool, sailed from New York November 16. He will make such recommendations as may be necessary to protect ports of the United States which ships from Liverpool enter.

Obituary.—Dr. A. H. Bennett, consulting physician to the Hospital for Epilepsy and Paralysis, formerly physician to the Westminster Hospital, graduate of the Universities of Edinburgh, London and Paris, died in London November 1, aged 53 years.—Dr. H. S. Smith, consulting surgeon to St. Mary's Hospital, a graduate of St. Bartholomew's Hospital, died in London October 29, aged 89 years.—Dr. W. J. Marshall, a graduate of Edinburgh University, physician to the Edinburgh Hospital, died in Edinburgh, October 24, aged 57 years.—Dr. C. M. Robertson was killed in action at Whitbank, South Africa, October 25. He was 26 years old, and graduated at the University of Edinburgh.

CONTINENTAL EUROPE.

Mozart's Skull.—The reputed skull of Mozart, (the only known remains of the great composer), has been deposited in the Museum at Salzburg, Austria. Though his grave is unknown, the late Professor Hyrtl kept this skull in his home. That it is Mozart's skull was shown by the evidence of a grave digger, an engraver, and Professor Hyrtl.

Women in Medical Schools.—Germany has, until late years, generally discouraged the study of medicine by women, and there were certain restrictions, mainly in the

matter of examinations, that it was impossible for women to overcome. The barriers have been removed slightly, and now a small contingent of women studying medicine will be found at a number of the leading German universities. At Berlin there are twenty-five registered women medical students; at Leipzig 24; at Freiburg 18; Halle 12; Heidelberg 6; Bonn 5; Breslau 2. Dr. Ludwig Stieda, professor of anatomy, Wilhelm Lossen, professor of chemistry, and Carl Pape, professor of physics of the University of Königsberg, will not allow women to attend their lectures. At the Swiss universities, however, are found the largest number of registrations, by far the greatest number being Russians. For instance, at Berne, there are 188 female students of medicine, and 180 of the number are Russians. At Lausanne University there are 61, and at Zurich 85 women students.

Quacks.—Besides about 24,000 legitimate physicians, there are in the German Empire nearly 6000 individuals who are allowed to carry on the nefarious business of quacks.

A Rare Diagnosis.—The doctors of Vienna are greatly interested in the case of a young man, 23 years old, who died after a six months' painful illness which puzzled the physicians. Shortly before his death his ailment was diagnosed as the result of the hatching of eggs of a blue-bottle fly, which the patient had swallowed, causing perforation of the intestines. The sufferer was then too weak to undergo an operation. The autopsy confirmed the diagnosis. Part of the large intestine was riddled. Professor Nothnagel will shortly read before the Vienna society of physicians a paper on the case, which is almost unprecedented, though one or two similar cases are recorded in medical literature.

Feeble-Mindedness of Women.—The Congress of Progressive Women recently held in Berlin, which has already been well advertised, attracted considerable attention. It is a strange coincidence that while the women were passing resolutions in favor of coeducation and higher education for girls, a book dealing with women should be published by Prof. Möblus of Leipzig, one of the most eminent German physiologists. This book is entitled "The Physiological Feeble-Mindedness of Women." Women, according to the professor, occupy a position midway between men and children. Their intelligence is receptive rather than creative, imitative rather than original. The professor declares that women have not advanced the intellectual life of mankind a single step. Even in their own branches, such as cooking, tailoring and education, the discoverers of new methods are always men. He points out that the increasing intellectualism among women is dangerous, and tends to bring on sickness, barrenness, and blunting of the instinct.

The Fourteenth International Medical Congress.—The general committee of organization of the Fourteenth International Congress of Medicine, to be held in Madrid, April 23 to 30, 1903, decided at a meeting October 15, 1901, that the second section (otology, rhinology, and laryngology) be divided into two sections, IIa., otology, and IIb., rhinolaryngology. Each subsection is to have its own officers. It was announced that the sixteenth section (medical jurisprudence) be called the section upon medical jurisprudence and toxicology.

A Polyclinic in Paris.—A number of former dispensary chiefs have decided to found a polyclinic in Paris. They intend copying those of Vienna, Berlin, and the United States. No physician who has not already been chief of a dispensary will be admitted to the teaching staff of this institution.

Pasteur Institute, Constantinople.—Dr. Paul Remlinger has been appointed director of the Pasteur Institute in Constantinople, in the place of Dr. Nicolle, who returns to the Paris Pasteur Institute.

Norway, Ireland and Spain have more blind people in proportion to population than any other European countries. Spain has 216 per 100,000; Norway 208, and Ireland 111.

Dysentery.—The epidemic of dysentery which has affected so many people last year in the department of Finistère, France, has reappeared in Carhaix, Gléden-Po-

her, Kergloff and other cities. Pupils in boarding schools seem most affected and several deaths have occurred.

Suicides in France are decreasing, though perhaps not as fast as is the population. In 1894 there were 9,703 suicides, and in 1898, 9,438. Illness, poverty, drunkenness, family trouble, love and jealousy were the causes, in the order named.

Professors Agree.—The cancer investigations made by Professor Roswell Park, of the University of Buffalo, have given results in every way identical with those secured by Professor Maximilian Schüller, of the Berlin University, although the investigations were made independently of each other.

Antityphoid Serum.—It is announced that Dr. Chantemesse, of the Pasteur Institute of Paris, has discovered an anti-typhoid serum which has invariably reduced the mortality in desperate cases. The serum also cures albuminuria.

A New Cure for Leprosy.—A simple treatment for leprosy has been advised by a Paris physician, Dr. Toffrin. He has already effected a wonderful cure in a patient suffering from gangrene. To stop fresh decomposition he used permanganate of potassium in solution, twenty grammes to a quart of water, washed and cleansed the sores with this solution, applied compresses saturated with it for a whole day, and on the second day he was able to take off part of the decomposed flesh by the aid of bread crumbs soaked in the solution. By continuing the application of compresses he removed all the dead flesh in a few days, which, owing to the permanganate's decomposing action, came off readily. Then the sores began to heal quickly. He is confident that leprosy will yield to the same form of treatment with the permanganate solution made stronger. As soon as a case of leprosy becomes manifest through small shiny spots on the skin one must wash the affected parts with the solution and apply compresses. If scales begin to appear over the spots they are to be cleaned with bread crumbs soaked in the solution to take away the scales, and one must go to the quick if necessary.

Biological Research in Northern Waters.—A Copenhagen dispatch to the *Morning Leader* says that Dr. Nansen, the Arctic explorer, is negotiating concerning the proposed institution of a great biological research expedition in Northern waters; Norway, Sweden, Denmark, England, Holland, Russia and Germany are to take part in it.

The Plague in Turkey.—Two cases of bubonic plague are reported from Constantinople.

University Notes.—**Rostock:** Dr. Theodore Thierfelder, professor of medicine, has been retired, and Dr. Martius has been appointed director of the medical clinic in his place.—**Vienna:** Professor Josef Englisch, director of the First Surgical Division in the Rudolf Spital, has been retired.—**Bremen:** Dr. Tjaden has just been appointed director of the Bacteriological Institute.—**Freiburg:** Dr. Thomas, director of the medical clinic, celebrated the anniversary of his twenty-five years' professorship on October 31.—**Giessen:** Dr. Leutert, of Königsberg, has been appointed professor of otology and director of the clinic, replacing the late Professor Steinbrügge.—**Christiania:** Dr. H. A. Schiötz has been appointed professor of ophthalmology.—**Ghent:** Drs. Van Duyse, Gilson and Van der Schricht have been made professors.—**Liege:** Dr. P. Smyers has been appointed professor of medicine.

Obituary: In Stettin, on October 28th, Professor Karl Schuchardt, director of the General Hospital Dispensary, died after an operation. A pupil of Volkmann's, he had lived in Stettin since 1889.—Dr. Arthur König, professor of physiological optics and director of the Physiological Institute in the University of Berlin, died recently, aged 46 years.—At Prague, on October 28th, Dr. Alois Kaulich died, aged 62 years. He was formerly assistant in several departments of the Prague General Hospital. The death of Dr. Wilhelm Strasser is also reported.

1.—Semon's lecture on local treatment in diseases of the upper air passages is a protest against unnecessary operative measures. He points out that in the treatment of diphtheria local have been victoriously superseded by general measures. The symptoms and objective manifestations arising in pathological conditions of the upper air passages may be subdivided into (1) affections of a purely local character; (2) local manifestations of general or systemic diseases; (3) local manifestations in the nose and throat dependent upon local diseases in correlated areas; (4) affections of the upper air passages, supposed to exercise a direct or a reflex influence upon other organs and parts of the body; and (5) local symptoms and sensations of obscure origin. If a disease of the upper air passages be purely local, causing considerable local discomfort or serious disturbance of the general health and amenable to local treatment, such should be adopted. Foreign bodies ought never to be allowed to remain impacted and energetic local interference is always indicated in the early stages of malignant disease of the larynx. In all purely local affections of the upper air passages there are certain cases in which all reasonable men will agree that local treatment is required, and others in which it is not. [J. M. S.]

2.—Whipham reports the case of a man who had a rheumatic family history. He had no history pointing to syphilis. In 1884, the patient began to suffer from an incessant cough and indefinite thoracic pains, accompanied by loss of flesh. In April, 1886, he first noticed a swelling on the right side of the sternum, after having had anginal pains for two months previously. The tumor was expansile, but no bruit was heard over it, though one was present in the right subclavian and carotid arteries. The aortic second sound was accentuated. The voice was hoarse, the cough suggestive of pressure and there was inspiratory stridor. The patient declined distal ligature and was treated with potassium iodide and morphine. The fluid part of the diet was restricted to a pint in the 24 hours. The tumor began to decrease in size steadily under this treatment and seemed to consolidate. The patient was kept in bed for 8 months, at the end of which

time the pulsating area had greatly lessened. He was discharged in January, 1887. A year later he returned to work, and followed his employment with intervals of rest until the early part of 1892, when he took cold and began to notice shooting pains in the neck and left arm, and a rapid bulging of the aneurysm at the site of the episternal notch. His condition was regarded as imminently serious. The iodide treatment was resumed, the pressure symptoms gradually became less marked, and in three weeks the man was able to take solid food. In 1895 he had an attack of pleurisy and pneumonia, and was in the hospital for a period of six months. From this time the aneurysm became markedly worse. In February, 1897, an increase in the size of the tumor was noticed, but after five months rest he was discharged improved. Oozing was first observed in August, 1899. In February, 1901, the aneurysm had increased in size and anginal pains had been severe. The temperature soon became irregular and the patient had much pain in the neck with occasional hemoptysis. After a month the temperature subsided to normal; the aneurysm became more conical in shape, and the leakage of blood, which had ceased, recommenced. On April 9 the patient had a rigor, and 60 hours later a large conical mass of laminated fibrin, the whole of the superficial part of the aneurysm, became detached, leaving a considerable cavity in the chest in which no definite pulsation could be seen. There was only slight leakage, and the patient continued fairly comfortable with the exception of pain for about nine days. The aneurysm then suddenly burst externally, and the man died in about a quarter of an hour. At the necropsy the whole of the ascending and transverse portions of the arch of the aorta were found to be greatly dilated and very atheromatous. A sacculated aneurysm projected from the upper and anterior aspects of the arch. The trachea was eroded about $\frac{3}{4}$ of an inch above its bifurcation, and the lung showed signs of bronchitis. The heart was slightly dilated, but not obviously hypertrophied, the aortic valves alone being a little thickened. The remarkable points about the case are: (1) the length of time, 15 years, during which the patient was known to have had an aneurysm; (2) the frequent and at times rapid variation in the size of the aneurysm; (3) the marked benefit that accrued from prolonged periods of complete rest and treatment; (4) the recovery from an intercurrent attack of pleurisy and pneumonia; (5) the fact that the entire external portion of the aneurysm sloughed and came away, after which the patient lived for nearly nine days; (6) the termination by rupture externally. [J. M. S.]

3.—Whitehead and Syers report the case of a man, aged 35 years, who complained of *carache*. Three days later he suffered from attacks of shivering, and at the same time it was noticed that his urine was dark and thick. On microscopic examination it was found to contain a granular detritus, but no complete bloodcorpuscles. The temperature was 102°, and a distinct systolic murmur was audible over the aortic area. A week later, rigors set in and the temperature presented the most characteristic features of septicemia. During the attack the patient had parotid inflammation, pleural effusion and pleuropericardial frictions. Expectoration ceased somewhat suddenly and the temperature fell and remained normal. On examination a loud systolic murmur was heard in the aortic area and there was dulness and diminished entry of air over the base of the left lung. The treatment was with salines, quinine, strychnine, iron and sodium sulphocarbolate in 15-grain doses every four hours. The latter drug was continued until the patient became convalescent. A diagnosis of *ulcerative endocarditis* was made. [J. M. S.]

4.—McCaw reports a case of *infantile scurvy* in a baby aged 10 months. A week before he was first seen the child suffered from a mild gastric attack during which he vomited a considerable quantity of blood, and this was followed almost immediately by copious, loose motion, which was undoubtedly composed largely of altered blood. The child had been fed from birth upon condensed milk, and later, upon a proprietary food and oat flour; it had never been given any fresh milk or other food of an antiscorbutic kind whatever. Treatment consisted of one

teaspoonful of orange juice every two hours, whey and cream at frequent intervals, and in small quantities; with one teaspoonful of raw meat juice every 4 hours, and an icebag was applied to the epigastrium for half an hour. Eight days afterward arsenic and iron were given, a small quantity of scraped potato or other fresh vegetable was added to the diet and the child was taken to the seaside. He made a satisfactory recovery. [J. M. S.]

8.—Gustavus Hartridge calls attention to the disadvantages and limitations which accompany the employment of *nitrate of silver* in diseases of the eye. These are the pain and irritation, the caustic effect of silver, and the staining of the conjunctiva which may ensue after long continued application of the drug, finally the superficial action of the nitrate of silver on account of the facilities with which it is precipitated by albumin and chloride. In discussing the comparative value of the various preparations of silver in ophthalmic practice, the author alludes separately to the following compounds that have been supplied by manufacturing chemists: Actol, itrol, argonine, argentamine, nargol, largin and protargol. [M.R.D.]

11.—The authors state that the results of their observations oppose the current idea which is prevalent among ophthalmic surgeons that *tubercle of the choroid* is a rare condition and almost confined to cases of acute military tuberculosis, but that on the contrary in their experience it may be met with in any form of tuberculosis, although by far more common in the acute variety. In 42 unselected cases of acute military tuberculosis and tuberculous meningitis they found the choroid affected in one half of the cases. In 119 cases of chronic tuberculosis examined ophthalmoscopically, choroidal changes were found in eleven. In 18 instances there were choroidal lesions in patients with quiescent tuberculosis. There are several varieties of tuberculosis of the choroid as manifested ophthalmoscopically, and the knowledge of this fact is *absolutely essential* at the outset of the examination. Thus in acute military tuberculosis, generally but one eye is affected, and generally confined in that eye to the central region of the fundus, and is seen as an oval round grayish or fawn colored spot. The aggregation and proliferation of the pigment epithelium of the retina give rise to the formation of a darker narrow zone around the edge of this spot. In chronic cases, on the other hand, the lesion may be single, multiple, disseminated or diffuse. [M.R.D.]

12.—F. Richardson Cross believes that, whatever the nature or variety of an *after cataract*, it can be assumed to be due to faulty operative technique or to imperfect healing. In regard to the question as to whether any special precautions can be taken at the time of extracting the lens in order to avoid the subsequent obscuration of vision due to the after cataract, he offers the following suggestion: rapid healing is facilitated by a peripheral corneal section or a peripheral conjunctival flap, both of these lessening the likelihood of adhesions between the cornea and lens capsule. He advocates a free laceration in the performance of the capsulotomy for the purpose of leaving a large opening, but calls attention to the care that must be exercised not to dislocate the lens or damage the hyaloid membrane. When a distinct capsular membrane co-exists with a lenticular cataract, it should be removed with the latter. Furthermore it is of the greatest importance to thoroughly remove the remnants of cortex which remain after operation. He does not favor early secondary operations and rarely operates at an interval less than three months between the original cataract extraction and operation for secondary cataract. While the primary object of a secondary operation is to provide an aperture sufficient for good vision, at the same operation nevertheless the correction of anatomical defects such as synechiae and the tendencies to glaucoma are to be carefully looked into, avoiding as much as possible damage to the surrounding tissues. There are cases where the secondary membrane cannot be effectually removed or disturbed by means of the discission needle or even the knife. In such cases capsular or iridotomy scissors must be employed. Extraction of the capsule by means of forceps should be our last resource. [M. R. D.]

6. The Removal of Superfluous Hair by a Combination of X-Ray Exposure and Electrolysis. DAVID WALSH.
7. A Case of Septicemic Plague in a European. J. M. ATKINSON.

1.—Gowers delivered a lecture on metallic poisoning at the National Hospital for the Paralyzed and Epileptic, Queen Square, W. C., on October 22, 1901. In this address he points out the difficulty of recognizing some cases of lead poisoning; describes the chief symptoms of this condition and arsenical poisoning. He presented a case of lead poisoning which showed a great variety of symptoms and he emphasizes the importance of not overlooking the cause in consequence of the equivocal character of the effects. In chronic cases the symptoms largely depend on the manner in which the poison acts and on personal predisposition. He had observed the following symptoms: Peripheral neuritis; slow chronic atrophy of the muscles, wrist-drop, sclerosis of the cord, optic nerve atrophy, tremor, chronic convulsions not unlike epilepsy; hysteria with its various manifestations in predisposed subjects; neuralgia; headache and general nerve weakness. He remarks that all of these symptoms do not suggest the cause unless the occurrence of other associated cases of lead poisoning, or the occupation of the patient or the presence of the great sign, the lead line on the gum, is inquired into. Occasionally the lead line is absent in cases of lead poisoning, and not infrequently it exists upon the gums in a fragmented form so that only two or three isolated spots are to be seen. With regard to arsenical poisoning, he points out that the skin lesions, particularly the pigmentation induced by this drug, are of great importance in the diagnosis. [F. J. K.]

2.—Crookshank delivered an introductory address on "human and bovine tuberculosis, at the Royal Veterinary College, Camden Town, on October 1, 1901. The author makes a plea for higher education in Veterinary Science and clearly shows that there is a demand for well trained Veterinary Surgeons. He does not accept the theory that abdominal tuberculosis in children is due to infection from tuberculous milk and believes that the advocates of this opinion set aside the view that infection is possible from human sources, such as self-infection from a concurrent disease of the lungs or from infection by the mouth with bacilli from human sources. He does not believe that there is any great danger of infection from tuberculous meat and cannot recall a single recorded instance. He remarks that the Jews have a very thorough system of meat inspection, but they are by no means free from tuberculosis. The Hindoos who eat sparingly of meat and who live for the most part in small and badly ventilated buildings, are particularly liable to tuberculosis. He concludes that the destruction of every animal with tuberculous deposits would almost involve the ruin of the agricultural industry. If a carcass is well nourished, the meat is perfectly wholesome in spite of local deposits of tubercle in organs and glands which should of course be condemned. Eradication of tuberculosis in cattle should be looked upon as a special duty for the Veterinary Surgeon to undertake and one to which they must direct all their energies. [F. J. K.]

3.—This is an abstract of an address on ventilation delivered at the annual meeting of the Incorporated Society of Medical Officers of Health by A. Wynter Blyth. In this abstract there is discussed mainly the necessity of using mechanical ventilation especially by electric fans in the ventilation of sewers, dwelling houses, work-places, and mines. [F. J. K.]

4.—Selby believes that whey is a food possessing distinct advantages over milk in the treatment of enteric

fever cases. He remarks that milk curd is apt to give rise to pain, intestinal hemorrhages, perforation, and death, through their mechanical effects, and that milk acts as an excellent culture media for the bacillus typhosus. In this article there is included a table showing the details of 75 cases of enteric fever in which the patients were fed on whey. With this treatment the mortality has been decidedly decreased. The following formula for the preparation of whey is given: "To two quarts of milk stir in two table-spoonsful of rennet. Put into a pan, warm slowly until it curdles. This takes about 20 minutes. Break up the curd and stir the whole through fine muslin, the curd is thus separated from the whey." If required, cream may be added to the whey, and in summer whey can be sterilized. By the addition of tea, coffee, or other flavoring substance, it may be made more palatable. The following table, which is included in the article, represents the results of an analysis of whey and milk expressed in percentages:

	Whey.	Milk.
Total solids	7.4	12.43
Lactose	4.9	4.9
Fat	1.2	3.4
Albuminoids	0.8	3.3
Mineral matters	0.49	0.73

In conclusion, the author makes an urgent plea for the adoption of this treatment and that the results of such trials should be published. [F. J. K.]

6.—Walsh writes on the removal of superfluous hairs by combination of the X-rays and electrolysis. The author has found the following method useful: "Exposure to the focus is made in the ordinary way and a week or ten days later when the hair becomes loose, each hair is abstracted and the electrolysis needle is passed into the follicle." This method requires a large number of electrolytic punctures and a considerable amount of time is required to complete the operation. At times a second exposure of the focus-tube is needed in order to loosen the hair.

[F. J. K.]

7.—Atkinson reports a case of septicemic plague in a European boy, aged 11 years who was admitted to the Government Civil Hospital, Hong Kong, September 11, 1901, with the following symptoms: He complained of pain in the abdomen particularly in the iliac fossa, the tongue was coated and the temperature was 102.4°F. On the following day the pain still persisted and the patient was very drowsy. A papular rash developed on the 11th, which was confined to the face, neck, and chest. Delirium and tympanites set in. On the 12th there was vomiting of bile-stained fluid tinged with blood. On the 13th, the urine was albuminous and its specific gravity 1030. Death occurred on the 14th. Necropsy revealed enlarged glands which were full of plague bacilli. The author remarks that this case developed after the epidemic had practically ceased for some weeks. [F. J. K.]

MEDICAL NEWS.

November 16, 1901. (Vol. LXXIX, No. 20).

1. The Making of a Modern Medical School: A Sketch of Rush Medical College. JOHN EDWIN RHODES.
2. On the Nature of the Process of Fertilization. WILLIAM J. GIES.
3. Infantile Pleurisy with Effusion. W. T. ENGLISH.
4. Tendon and Muscle Transference and Arthrodesis in Infantile Paralysis. E. H. BRADFORD.
5. The Management of Acute Gonorrhea. LOUIS BROTER.

1.—J. E. Rhodes, in his Sketch of Rush Medical College describes the Quarterly System which has been in vogue since December, 1898, in that college, as follows: The year is divided into quarterly divisions, instruction being given throughout the entire year. This permits the student to enter any time during the year at the beginning of a quarter and graduate at the end of any quarter when all the requirements are fulfilled. The number of months attendance required is forty-five. Instruction in all depart-

ments continues throughout each quarter, or in special cases for a single term, that is, half of a quarter. The advantages are numerous: (1) the expensive equipment is in use the entire year; (2) a student may begin his studies at the beginning of any quarter; (3) special course students may avail themselves of the summer quarter, and this season appeals strongly to the practitioner; (4) students who are paying their way can study during the summer and earn money in the winter (5) more abundant clinical material; (6) it stimulates all members of the faculty to do their very best work; (7) it favors the conservation of courses; (7) it lends itself admirably to the systematizing and grading of courses. [T. M. T.]

2.—W. J. Gies, in his paper on the nature and process of fertilization gives a few of the important experimental results: (1) extracts of the spermatozoa of the sea-urchin, which have been made by the ordinary methods for the preparation of enzyme solutions, do not possess any power of causing proliferation on the ripe ovum; (2) no evidence could be furnished of the existence of a zymogen in spermatozoa; (3) extracts of fertilized eggs, in the earlier stages of development, were likewise entirely devoid of segmental activity; (4) enzyme seems to be excluded from the catalytic substances which Loeb and others have thought may influence the initial divisions of the ovum after the introduction of the spermatozoon, although it is possible that the conditions of these and previous experiments were unfavorable to the manifestation of activity on the part of fecundative ferment. It seems more probable, however, that Loeb's theory of the influence of spermatic ions in fertilization affords the true explanation of the phenomena in question. [T. M. T.]

3.—W. T. English states that the disease most commonly confounded with infantile pleurisy with effusion is pneumonia. In examining a case of this kind it will be found that a history of chilliness, if any, will range from slight chill to severe rigor. The fever is irregular and intermittent and the chart shows extensive excursions and even suggests septic processes. Pain cannot be definitely located. In inspection loss of mobility is the same as in pneumonia. Flattening of the intercostals or distension is observed in few cases, but flattening is rarely perceptible and fluid sufficient to cause bulging does not often accumulate in the infant thorax. Displaced heart beat is seldom seen, but when seen is important, especially in left-sided effusion. Vocal fremitus is generally absent. Nervous symptoms are quite marked and in purulent effusions have been those of meningitis. In percussion a subtympantic note can be elicited over the thorax of the child. Immediately over, as well as around the fluid in the pleura, a clear note may be secured. Flatness belongs to a massive effusion and the tone elicited is a compromise between the tympanic and the dull note. Aspiration is advised when fluid is suspected, and evacuation of serous fluid should leave no bad results. The pressure of pus requires immediate evacuation and this can only be done by drainage, although resection may be required. As to treatment, the use of strychnine, iron, arsenic, etc., with plenty of fresh air is advised. The most important is the after treatment and should include pulmonary gymnastics with light exercises, especially for the side that was effected. [T. M. T.]

4.—E. H. Bradford reports three cases illustrating three methods of treatment: (1) medicinal; (2) muscular and tendon transference; (3) stiffening of the joint. The author calls attention to the value of tendon and muscular transference and arthrodesis in many cases of poliomyelitis and says it is frequently the case that some muscles remain which are not paralyzed, and these are generally the sartorius, the adductor group and the hamstrings. The transference of the sartorius to the rectus can be done without difficulty. The obstacle met is usually the abnormal position of the sartorius, which is often nearer the hamstring at its lower attachment. A curved incision at the lower end of the femoral will expose the attachment of these muscles, which should be entirely freed, brought up and transplanted into the firm sheath of the extensor cruris. Where the sartorius is

found to be weaker, the outer hamstring or adductor can be detached and brought forward and inserted on the outer side into the fascia and tendon of the extensor cruris. If the adductor jump is completely paralyzed, it is a more serious condition. It is a question whether the transference of the glutei can supplement the weakened adductors, but this is possible as is also the shortening of the paralyzed adductors that they may act as a cord to check extreme abduction. In paralytic disabilities of the knee, arthrodesis is a method only to be resorted to in cases where no mechanical treatment is possible. In the paralysis of the muscles controlling the feet the combined employment of arthrodesis and tendon transference is of great value. [T. M. T.]

5.—L. Broter divides the treatment of gonorrhea into (1) abortive; (2) local; (3) constitutional. The abortive treatment finds no favor in the author's eyes. He believes it does more harm than good. In the local treatment he finds irrigation the best method. The standard solution of potassium permanganate, 1-4000 to a quart of water with a temperature of 100°F. is advised. This is placed in the percolator. It will be found after a while that the strength and the temperature of the solution can be increased. When using the irrigation method chordee has been absent, no complications have arisen and the duration has been shortened. In the constitutional treatment alkalies and diuretics are employed to keep urine unirritating. For the first two weeks a pill may be given of the following: methylene blue, grain one; boric acid, grains five, one pill three times a day. After two weeks oleum santali, balsam copaibae, etc., in capsules. [T.M.T.]

GEORGIA MERRIMAN.

1.—W. H. Thomson presents a paper on the pathology and treatment of migraine. As to the etiology of the condition, the predominance of purely nervous symptoms is cited in favor of migraine being due to a specific derangement of the nervous system. The undoubted fact that migraine is more distinctly hereditary than any other nervous disease, or, in fact, than almost any disease, is brought forward to show that it is caused by an original constitutional defect in the nerve nutrition. Not unfrequently in the course of years the patient's general health becomes deteriorated, and there is emaciation and anemia. The writer believes that this state will be present as long as the conception of the disease being a neurosis is held by the physician. He believes that the proper conception of the disease must take into consideration a great class difference and the sufferers from the condition, which is as unmistakable as it is significant, viz., the physical habits of life or those physical habits which most affect the portal circulation. He believes that the condition is due to chronic portal stasis; that many of the poisonous properties of the products of imperfect digestion are exclusively nerve poisons, and that one of the great functions of the liver is to neutralize gastro-intestinal nerve poisons, so that when its functions are experimentally interfered with, prompt poisoning with distinctively nervous symptoms follows. As to treatment. First, prophylaxis is of the most importance. All severe cases, without exception, are chronic dyspeptics, and of this one of the commonest symptoms is chronic constipation followed by an intestinal anti-

septic. He believes that prophylaxis is the main indication in the treatment of this complaint, but that for the attacks themselves the fluid extract of ergot given in drachm doses with a drachm of elix. cinchona in water, by the stomach or rectum, is the most certain agent to cut the attack short. The patient should lie perfectly still after taking it until all pain passes off. In some cases the dose may be repeated after two or three hours. In those who cannot take the ergot without vomiting, the writer relies on ten grains of lactophenin with two grains of caffeine citrate, repeated every two hours until relief occurs; or fifteen grains of antipyrin, always taken with a teaspoonful of aromatic spirits of ammonia. [T. L. C.]

2.—D. B. St. John Itoosa contributes a paper on the present position of ophthalmic science and art. He reviews the contributions of many ophthalmologists to their specialty including the introductions of the ophthalmoscope and the ophthalmometer. He believes that a great advance has been made in the treatment of myopia of high degrees by the invention of the method of lessening the refraction of the eye by the removal of the lens. He devotes considerable space to the subject of strabismus, in the treatment of which, he believes, advance has been slow. He states that the mistaken conclusions of Dieffenbach, who first proposed operative means for the relief of strabismus about fifty-five years ago, led to sanguine hopes which could not be realized, for the deformity was supposed to depend upon something morbid in the muscle. This, at the most, we now know to be a spastic condition, while the origin of strabismus, as Donders endeavored to show, is found in fixed condition of the eyeball. The writer discusses the operative measures employed in the treatment of senile cataract, the various operations of iridectomy, and the use of the magnet in the removal of foreign bodies from the eye. The treatment of acute glaucoma, and detachment of the retina are also briefly discussed. [T. L. C.]

3.—E. V. Stoddard treats of the official relation of the medical profession to private charitable institutions. The object of this article is to call the attention of the profession to the responsibility of medical officers in order to establish the well-adjusted systems of education and training for those institutions which have for their inmates the young and adolescent. He believes that the suggestion should come from the medical profession connected with such institutions as to the best methods of educating the defective and delinquent in them. [T. L. C.]

4.—A. C. Bardes presents an article upon nasal obstruction and ear disease. Nasal obstruction may exert its pernicious influence upon the ear in one or more of the following ways: By the extension of a catarrhal or other inflammatory affection along the tubes, or by the actual passage of disease germs. It may cause a swelling of the walls of the tubes or may obstruct their orifices. It may interfere with the action of the tubal muscles, or may impede the venous return from the middle ear, or by the passage into the ear of inflammatory or septic matter by means of the blood or lymph vessels. This paper goes over the well beaten ground of the symptoms and complication of adenoids and deviation of the septum. This writer believes that the use of nasal sprays, douches, and washes is to be deprecated, on account of the fact that they irritate and inflame the delicate nasal membrane. The restoration of the diseased ear, by the proper treatment, is brought about in one of the following ways. Removal of cause, cleanliness of the parts, astringents, and constitutional treatment. Those cases of ear disease that are benefited by tubal inflation are usually assisted by a nasal operation; in the others the infirmity is certainly retarded, and increasing deafness prevented. [T. L. C.]

5.—M. I. Knapp contributes a paper upon butyric and acetic acids in the contents of the stomach and tests for their detection. He states that the present method to prove the presence of these acids in the chyme is by the very cumbersome process of distillation. The test which he describes requires but one glass apparatus, a separatory funnel, and a small amount of time suffices to perform it. The reagents necessary are: A ten per cent. solution of ferric perchloride and ether. The test is made in the same way as described in his test for lactic acid (See *New York Medical Journal*, August 10, 1901), only the color of the ring at the line of junction, between the ether and the iron solution differs—the color of the ring in the lactic

acid test is sulphur yellow, the color of the ring in butyric acid is a reddish-orange color. The method of procedure is as follows: One c.c. of the filtered gastric contents is extracted with about 5 c.c. of ether in a glass separatory funnel. The ether with the filtered chyme is shaken up a few times, and then allowed to stand for a short while to allow the ether to separate from the underlying stratum. In the meanwhile, a solution of the iron is made in the following way: One drop of a ten per cent. solution of iron perchloride is dropped into two c.c. of distilled water in a narrow test tube. Now, the lower stratum in the separatory funnel is allowed to escape by opening the stop-cock and the remaining clear ether is floated on the clear iron solution. At the line of junction of the two clear fluids an orange-colored ring appears if it is butyric acid, and a rather rusty-colored ring if it is acetic acid. A few drops of alcohol will increase the intensity of the color of the ring. To differentiate between the two—butyric and acetic—acids, a little more alcohol is added, the finger placed on the test tube, and the test tube shaken a few times by inverting it. If it is butyric acid, the ether layer will be colored a beautiful orange; but if it is acetic acid, the ether layer remains clear. Acetone and aldehyde respond to the same method of testing, but the color of the ring formed is different. Acetone and aldehyde give a light ochre-yellow color, shading somewhat into a light green. The ring in aldehyde is very distinct, the line between it and the other being very sharp, looking almost black; acetone gives the same color, but is not so distinctly and sharply marked off. A sheet of white paper held back of the test tube, our back turned to the source of light, will make us better appreciate the colors.

[T. L. C.]

6.—John G. Sheldon reports a case of gangrene following the use of carbolic acid. The patient entered the hospital complaining that his foot was very painful and felt cold and dead. A few days previously, he noticed a sore on one of his right toes. A physician gave him a dilute solution of carbolic acid with instructions to use it on the affected member. While preparing to follow directions, he accidentally spilled some of the carbolic acid solution on his left foot. This frightened him, and he neglected to apply any of the medicine to his right foot. All went well for five days, and then the left foot began to feel numb. This numbness increased, and on the eighth day the foot had become numb and painful. The left toes and foot presented the appearance of dry gangrene, and no definite line of demarcation could be made out. Amputation was performed at the middle of the leg. The gangrene extended, being now of the moist type, and in two days reached the knee. Sixty hours after the first operation was performed, a second amputation was done at the junction of the middle with the upper third of the thigh. From this recovery followed. The general condition of the patient previous to his first operation was good. The heart and blood vessels were normal. Urinalysis was negative, no sugar and no albumin being found after repeated examinations.

[T. L. C.]

7.—Georgia Merriman contributes a brief paper upon food as an etiological factor in disease. He believes that the proper digestion and ingestion of food contributes the most important field of therapy now known. He emphasizes the importance of supplying a written dietary, being most exact as to the quantity of food which the patient should take. He believes that the study of digestion and the food value of articles of diet are most important, and that correct dietarys for the brain-worker, the manual laborer, and the average citizen in good health, have been carefully estimated by Government experts, and that physicians should be familiar with the general scope of these studies. [T. L. C.]

5. Pyopericarditis. HERBERT O. COLLINS.

6. The Daily Medical Inspection of Schools.

D. S. LAMB.

2. C. Beck gives the following in treating a case of sarcoma by Roentgen Rays. He began to irradiate the defect left after the last extirpation. The first exposure was ten, the following twenty and thirty, increasing to forty-five minutes. With the longest exposure the patient felt an itching sensation over the whole area, lasting for several hours. In the case reported irradiation was done seven times. Up to six weeks there was no trace of relapse, but a number of metastatic nodules on the calf, especially those near the area of irradiation have disappeared, while others have shrunk. [T. M. T.]

3.—C. Denison, in his article on devitalized air toxemia as a cause of tuberculosis gives the meaning of the above as follows: That tuberculosis mainly springs from, and must be the outgrowth of, a common predisposing or uniform cause, which will account for its finding a congenital "soil" in birds, cattle, horses and other animals as well as in man. The author also says that the first thing to do is to make a most thorough and searching investigation to determine the amount per head of air and ventilation needed in order that the predisposition to tuberculosis may be prevented. [T. M. T.]

5.—H. O. Collins gives three indications for opening the pericardial sac: (1) When the sac is distended with a large exudate which shows no tendency to absorb; (2) when there is an intense dyspnea; (3) when the exudate is known to be purulent and the liability of absorption is so small that it need hardly be considered, and prompt measures are necessary. There are four different methods of operation (a) aspiration; (b) simple puncture; (c) incision through an intercostal space; (d) incision with the resection of one or more ribs and thorough drainage. The last procedure is recommended on account of the fairly clear view of the field and thus avoiding injury to the cardiac walls, besides obtaining a more thorough drainage. [T. M. T.]

1. Medico-Legal Examination of Blood Stains.

EDWARD S. WOOD.

2. The Correction of Old Lateral Displacements of the Nasal Bones. J. L. GOODALE.

3. Cleft Palate. J. S. STONE.

1.—One of the most important parts of the medicolegal examination of blood stains is the preliminary examination, which consists of a very careful observation of the gross appearance of the stains. This includes the color of the stain, its exact form, and whether it is completely or only partially dry. After examining each stain carefully with the naked eye, it should then be examined with a magnifying glass to detect foreign matters mixed with the blood. Foreign substances that are liable to be of importance in medicolegal cases are pieces of hair coming from the victim, or a cloth fibre, which may throw light upon the nature of the body from which the blood came, or particles of tissue, such as adipose muscle fibre, or pieces of bone with the muscular attachment. In cases in which the body of the victim has been sufficiently mutilated by a club or hatchet to separate portions of these tissues. The great value of the gualacum test is as a preliminary one. It is easily performed, and gives a marked reaction quickly. If we obtain a negative result we may be sure that the stain tested does not contain any blood. If the result of the gualacum test is positive, the hemin test may be employed. There are many agencies that will decompose normal blood pigment to such an extent as to prevent this reaction. The sodium tungstate test is of great value in cases of washed blood stains, or in cases in which it is necessary to test a liquid for blood. The spectroscopic test requires a considerable volume of blood, and the only practical instrument for use in medicolegal examinations is the spectroscopic eyepiece, which can be set into the tube of a microscope. This instrument is sometimes called the microspectroscope. All of the tests and methods mentioned above enable us to state only whether or not

blood of some kind is present. They give us no information, however, as to the kind of blood. In order to determine the kind of blood, we must resort to a microscopic examination of the blood status, so that we may see the form and the size of the blood cells. To distinguish between human blood and the blood of other mammals the only method used until recently has been by measuring the diameter of the red blood cells by using a micrometer eyepiece. The agglutination test has been recently proposed. The principle upon which this test depends lies in the fact that, if a clear human blood serum is treated with a dilute solution of animal blood, no precipitate or cloudiness occurs, but the mixture remains perfectly clear. Any of the domestic animals may be humanized, but a rabbit is usually selected. The blood of this animal is humanized by injecting into the peritoneal cavity or blood vessels about 10 cc. of human blood or human blood serum, 5 or 6 times, at intervals. If a little of the clear blood serum of the humanized animal be treated with a solution of human blood, a precipitate will be formed. It is found that this test is just as applicable to a dried stain as it is to fresh blood. It is necessary to make a solution of the dried blood in sterilized normal salt solution. [J. M. S.]

2.—Goodale describes a method for the correction of the old lateral displacements of the nasal bone. [J. M. S.]

3.—Stone publishes a series of pictures of frozen sections of 2 cases of cleft palate in children. Both children died within the first few days of life. [J. M. S.]

5.—Lambert Ott discusses feigned and real injuries from a medicolegal standpoint. He divides injuries generally into those presenting visible signs and symptoms and those with invisible symptoms and considers the various means of differentiating between real and feigned pain. Mannkopf's sign, which consists in observing the pulse before, after and during pressure upon an area alleged to be painful, Ott does not consider of much value, depending more upon the changes which result from long continued pain in the part. He shows the effect of suggestion by either lawyer or doctor in the production of traumatic neuroses. It is suggested that patients be examined repeatedly or at least more than once, before the expert gives testimony regarding the condition present, and that careful notes should be kept of the condition from the time of the accident. Ott recommends that in the settlement of damage suits the liability of the defendant should be decided by a lay jury and that the question of the degree and nature of the injury and its probably permanent influence on the future life of the injured should be submitted to a body of physicians who shall also decide upon the amount to be paid the plaintiff. [J. H. G.]

6.—Danforth gives an account of the life of Samuel

Fuller, Pilgrim, Doctor and Deacon, who was amongst the 11st of the Mayflower passengers and who was the earliest practitioner of medicine in Massachusetts. This article gives a most interesting account of the life of Dr. Fuller. [F. J. K.]

7.—Happel writes on the enforcement of medical laws dependent on an organized profession. He states that there are men who know practically nothing about the laws in certain States which regulate the practice of medicine, and some of the best men of the profession are of the opinion that medical legislation should be opposed, believing that every man should be allowed to be a practitioner of medicine regardless of qualifications. Other medical men hold the view that the possession of a diploma from a medical college in so-called good standing, is proof that the holder is qualified for his work. The author remarks that they are some of the obstacles that interfere with the enforcement of medical laws. He further states that it is self-evident that medical laws can only be enforced through and by the concerted effort of the medical profession. The establishment of well organized county medical societies he regards as one of the best ways in which to accomplish this object. Not only should medical men attend to the duties of their profession, but they should also be model citizens and take an active part in the every day affairs of life and should be the leading citizens of their respective communities. The author also mentions that "the step taken by the American Medical Association in adopting the report of the Reorganization Committee and accepting the new Constitution and By-Laws by that committee will prove to be of incalculable advantage to the medical profession of this country, if the State societies reorganize in accordance with the suggestion of this report." Happel believes that in order to be a member of the State society in good standing, a physician should be a member of a well organized county society. Enforcement of medical laws will become easy when the profession is well organized. [F. J. K.]

8.—Harrison discusses the difficulties encountered in enforcing State medical laws. He writes that it is the duty of the prosecuting or district attorney to enforce State laws including medical laws. But while many of them endeavor conscientiously to enforce what they consider necessary laws, still when it comes to enforcing laws which in their judgment are unimportant and unpopular, they refuse or neglect to employ the necessary legal machinery at their disposal. Much good could be done toward remedying the difficulties met with at the present time in enforcing medical and other important acts by frequent and rigid inspection of the prosecuting or district attorney's department by the attorney general's department. The ignorance of the physicians and citizens generally relative to the duties of the prosecuting or district attorney are also responsible for the non-enforcement of some laws. The article is concluded with a résumé of the laws regulating the practice of medicine in the various States and Territories of the United States. [F. J. K.]

AMERICAN MEDICINE.

November 16, 1901.

1. Infection in a General Surgical Sense.

D. N. EISENDRATH.

2. The Bacteriology of Otitis Media, etc. (Concluded.)

JOHN FUNKE.

3. The Vexed Questions of Vaccination, etc.

CHARLES GOOD.

4. Granular Lips. J. C. HUIZINGA.

5. A Case of Lupus Vulgaris. P. R. EGAN.

6. When should the Oculist be Consulted?

FRED. B. LEWIS.

1.—D. N. Eisendrath discusses infection in a general surgical sense. He states that the most frequent forms of surgical infection in man are produced by the pyogenic organisms. He discusses the types of suppuration to which the groups give rise. The surgical anatomy, in so far that it influences the spread of a suppurative process, is described.

His chief object in the presentation of the paper is to emphasize the necessity of the treatment, and a more thorough treatment of infection as soon as it is recognized. He states that ample incisions and counterincisions to lay bare every portion of the infected area, and to relieve the collateral edema. 2. General anesthesia and a bloodless method of operating are advised whenever possible. 3. The disinfection of an infected wound with strong antiseptics is of little avail, and may do great harm. 4. We should place most dependence upon free drainage and moist dressings, with the use of mild antiseptics. No powder should be used until granulation is well established. 5. Absolute rest and elevation of the infected area is demanded. 6. After treatment by secondary suture and early active and passive motion; and 7, general treatment by strychnin, whiskey and attention to the excretory organs should be employed.

[T. L. C.]

2.—John Funke concludes his exhaustive paper on the bacteriology of otitis media. This summary records the laboratory study of 76 cases. There is no specific organism of otitis media, and the disease is not invariably monomicrobic. The author believes that in a definite otitis due to influenza, the bacillus of this disease becomes quickly associated with, or replaced by other organisms. The bacillus of diphtheria is more commonly present in otorrhea than is generally believed. It may be the initial infecting agent or secondary infection. The importance of its relation and frequent association with the pseudodiphtheriae bacillus is a factor not yet fully determined. The streptococcal infections are more grave and persist longer than the pure pneumococcal infections, and both are usually supplanted by staphylococci sooner or later. The chronic suppurative otitis media is always a sequence of the acute, and like the acute possesses no specific organism, and is practically always polymicrobic. The author concedes that anaerobic organisms play an important part in the causation of chronic suppurative otitis media, but have not established their almost constant presence as maintained by Rist. He explains the fetor met in certain cases reported in this communication by assuming the presence of bacillus pyogenes foetidus without anaerobic organisms. The existence of primary tuberculous otitis is generally conceded, but all observers are of one mind as to the almost utter impossibility of routine demonstration of the bacillus in the discharge. The writer advises the examination of tissue obtained by the curette in suspected cases for the demonstration of the tubercle bacillus. [T. L. C.]

3.—Charles Good presents a paper devoted to the vexed question of vaccination, and the best method of securing immunity from smallpox. The writer has taken the pains to reply to a paper dealing with the so-called failure of glycerinated lymph, and he believes that in view of the differences of opinion that prevailed among medical men, and because of the want of knowledge on certain points, it would be well if Congress would appoint a commission to take evidence and deliberate upon this subject. He believes that the following questions might suggest themselves: 1. Does one attack of smallpox give absolute immunity? If not, for what time is immunity accorded? 2. How soon after an attack of smallpox can vaccine vesicles be produced by careful vaccination with a good virus? 3. Should a person be considered not immune if, having had an efficient vaccination some few years before, a revaccination produces vaccinal possibilities? 4. The importance of carrying out control tests with one species of virus from four to six weeks after the original vaccine had apparently taken. 4. What kind of lymph is it most safe to rely upon, and what is the most approved technique? [T. L. C.]

5.—P. R. Egan reports a case of lupus vulgaris. A photograph of the case is presented, showing its ravages during 15 years. The cartilages of the nose had been completely destroyed. From the nose the disease had extended to the upper and lower lips as far out as the left angle of the mouth, and then over the face and down to the lower border

of the inferior maxilla. From the angle of the jaw it rose upward to the outer corner of the right eye and just the least trifle above the eyebrow at that point. From the nose one point extended to the left cheek but practically the disease was confined to the right side of the face. The treatment included the removal of the crusts by forceps and bathing. Sulphur and glycerin were rubbed up to the consistency of a cream and applied to the abraded parts. This was also painted over the exterior of the nostril and back part of the pharynx, after the turbinated bones, which were loose, had been removed. Tonics were given internally, and all preparations of opium were immediately discontinued. After a week there was no more pain nor evidence of extension of the disease, and in three months the health was restored. The writer states that the drug used by him in this case does nothing more than excite a mild degree of local inflammation, but he believes it is quite as effective as more irritant remedies. It neither increased scarring nor destruction of tissue, and must have been curative by means of the local inflammation it produced. [T. L. C.]

AMERICAN JOURNAL OF THE MEDICAL SCIENCES.

October, 1901.

1. On the Clinical Aspects of the Plague. L. BARKER.
2. The Pathology of the Bubonic Plague. S. FLEXNER.
3. The Bacteriology of the Bubonic Plague. F. NOVY.
4. A Case of Malarial Nephritis With Massing of Parasites in the Kidney. J. EWING.
5. Influenza as a Casual Factor in Acute Mastoiditis, and the Early Treatment. J. M'CAW.
6. A Method for the Differential Modification of the Proteids in Percentage Milk Mixtures. T. WESTCOTT.

1.—Barker gives some notes on the clinical aspect of the plague as seen during the recent epidemic in San Francisco. In six cases the disease was observed by the Commission. The epidemics progressed very slightly, and he ascribes this to the fact that there appears to have been no general infection of the rats. In fact dead rats and living rats caught in the sewers of the Chinese quarter showed no evidence of infection. The epidemic lasted about a year, and altogether 31 deaths were reported. It was difficult to determine the total number of cases, because so many of the patients were concealed by their friends. The type of disease was bubonic, and in the majority of cases the inguinal glands enlarged rather than the axillary or cervical glands. He reports two cases of this condition, one of which is remarkable on account of the excessive hemorrhagic diathesis that accompanied the infection. He also reports a case in which the primary buboes were found among the cervical glands; a case of plague septicaemia; and he mentions a case of plague pneumonia. Regarding the existence of pestis minor in San Francisco many local physicians stated that they had observed glandular swellings among the Chinese that resembled the glandular swellings of the plague, and that this mild form had existed for many years. The Commission apparently did not do any bacteriological work for the purpose of elucidating this subject. Diagnosis is perhaps the most important thing in meeting an epidemic of this disease, and it should be made certainly in the first case observed. If a case is seen alive, the best method is to extract some of the substance of an enlarged gland with a hypodermic syringe, and to make cultures and inoculations from it. In a dead case the morbid anatomy is usually quite characteristic, but cultures and inoculations from the tissues should also be made. Barker does not believe that the serum reaction is of any value, because it does not appear early enough to enable us to diagnose cases during the acute stage. Certain forms are more difficult to diagnose; the cutaneous form of plague can readily be confused with anthrax infection, and the septicemic form can only be recognized during life by cultures from the blood. The treatment consists in the administration of the Yersin-Roux serum if the disease has

developed and Haffkine's inoculation as a prophylactic. [J. S.]

2.—Flexner, under considerable difficulties, has made post-mortem examinations upon six cases of bubonic plague. The chief results were enlargement of the glands; considerable enlargement of the spleen; edema surrounding the glandular structures; and in one case marked enlargement of the tonsils. Films were made from the involved tissues, and the characteristic bacilli usually obtained. Inoculations in all cases were positive. Microscopically the glands of the second order showed partial involvement of the lymph sinuses, no necrosis; a certain amount of fibrin scattered throughout the glandular tissue; and evidence of leukocytosis in the blood vessels. The plague bacillus was usually found in the lymph spaces. The glands of the first order differ chiefly in the fact that there is often considerable necrosis, and that the histological changes are more pronounced. In the diseased tonsil the changes resembled those in the glands of the first order, but in addition there were numerous cells resembling Unna's plasma cells. The hemo-lymph glands were enlarged apparently due to distension of the blood vessels. There was considerable necrosis of the nuclei and the bacilli were found in considerable numbers. The spleen was enlarged; the tissue was proliferated, and there was a considerable number of cells resembling Unna's plasma cells. The blood vessels showed sometimes hyaline degeneration of the wall, and sometimes proliferation of the cells beneath the intima. Experimental inoculations produced the following results. The animals usually died in from two to eight days. Sometimes, especially in the more rapid cases, the changes resembled those of bacteremia and in other cases there was focal disease of the internal organs. The local lesions were necrosis, pus formation, and edema. The spleen and liver were enlarged, and when death had been delayed, the latter organ showed focal necrosis. The lungs sometimes contained small nodules. Hemorrhages were usually found in the serous membranes. Histologically, focal necroses were found scattered throughout all the tissues; the lymph glands showed changes somewhat resembling those in human beings, and in the spleen there was proliferation of the pulp and occasionally nodules. In the liver focal necroses also occurred, giving rise to various types of necrotic change. The lungs also contained nodules which were frequently filled with bacilli. The adrenal glands showed extensive hemorrhage. Two rats were examined, one found dead and the other dying in captivity, and both were negative. [J. S.]

3.—Novy describes the bacteriological features of the plague, and calls attention to certain important points in the culture of this organism. All the media must be slightly alkaline; large amounts of material must be used for making growths or inoculations; the most satisfactory staining features are best obtained if the specimen is heated very carefully. The virulence of the cultures changes very rapidly, and often inoculation experiments are negative. He reports a very interesting case of accidental laboratory infection that occurred in Michigan. A man had been employed for some time in preparing Haffkine's vaccine, and in some way introduced the organism into his mouth. The symptoms commenced with intense headache, fever and vomiting, and then severe headache. On account of the work with which he was occupied, it was decided to give him an injection of anti-pest serum. The same day he coughed up a small quantity of blood-stained sputum which contained plague bacilli. He was therefore isolated, and the anti-pest serum given intravenously on account of the obvious severity of the infection. In 24 hours after the diagnosis had been suspected he received 120 ccm. of serum, one half of which was given intravenously. A few hours after the last injection the temperature dropped to 100°, and on the third day had reached normal. He made a complete recovery although weakness of the heart persisted for more than two months after the onset of the disease. [J. S.]

4.—Ewing reports the following case. A girl of 17 had

been ill for some time; finally she had chills and fever, and was brought to the hospital, when it was noticed that the area of splenic dullness was enlarged; there was slight edema of the legs, and 2% of albumin in the urine. The temperature remained high; the diazo reaction was marked, and tentative diagnosis of typhoid fever was made, although it does not appear that the Widal reaction was tested. At the autopsy the spleen was enlarged; the kidneys were much enlarged, and the cortex was pale and the medulla dark. A diagnosis was therefore made of acute hemorrhagic nephritis. The kidneys were examined microscopically and huge numbers of pigmented malarial parasites found in the renal tubules, and in a superficial infarct in the cortex of the kidney numerous parasites were also found. The other organs unfortunately were thrown away. On account of the absence of congestion in the other organs Ewing believes that the parasites chiefly involve the kidney, and therefore that the case is one of true malarial nephritis. The degeneration in the cells of the tubules is rather peculiar. It is possible that in such a case the diagnosis might be made by the discovery in the urine of red cells containing parasites. The changes found in the kidneys in malignant cases of malaria are an acute degeneration of toxic origin; acute degeneration with focal necrosis; numerous hemorrhages, the exudation of blood serum and blood pigment; the massing of parasites in the renal capillaries; multiple hemorrhages and exudations of blood serum into the tubules. [J. S.]

5.—McCaw calls attention to the fact that in acute disease of the middle ear due to the influenza bacillus the characteristics are those of severe inflammation in tissues of low vitality. Incision usually fails to relieve the symptoms, and as a general rule the mastoid is very rarely involved. He believes influenza responsible for more cases of acute infection than scarlatina, measles, or diphtheria. The treatment must of course be varied with the case. He has attained his best results by rest in bed, catharsis, leeching, and hot douching of the canal every two hours. When suppuration is present, he incises the drum membrane early, using the hot douche every two hours, and if in the course of 36 to 48 hours the symptoms have not ameliorated, he operates. In doubtful cases an exploratory operation may be first employed. [J. S.]

6.—Westcott calls attention to the difficulty of modifying cows' milk so that it becomes suitable for young children, on account of the fact that it contains more caseinogen and less lactalbumen than human milk. Therefore all modifications of milk which consider only the total proteids are more or less inefficient. He therefore suggests the employment of whey as an additional element in the modification of milk, because it contains about 1% of proteids other than caseinogen. He suggests a formula to be used in the modification of milk, which is too complicated for a brief abstract, but which enables the physician to determine the exact amount of whey, cream, milk, water and normal sugar to be introduced into any mixture for the purpose of securing exactly the proportion that he may desire. A number of illustrative examples are added. It has been found that in young infants the proportion of proteids that they will digest is frequently insufficient to nourish them. Westcott therefore advises that in these cases the preparation be partially peptonized, as it is found that by this method they can assimilate larger quantities of proteids. The mixtures are best prepared in the laboratory, but can be very satisfactorily prepared at home with two quart jars of milk per day. One of these jars is used for the purpose of obtaining cream and subsequently whey, the former being obtained by allowing the jar to stand in ice or in ice and salt for several hours, and the latter, by adding to the skim milk essence of pepsin or rennet. The milk is then brought to 100° F. until coagulated and then placed in the refrigerators for some hours. The whey is then extracted by drainage, heated to 150° and mixed in the proportion that has been determined by the formula.

He warns practitioners that all the difficulties of infant feeding will not be overcome by the employment of modified milk. [J. S.]

1. Early Infantile Inguinal Hernia of the Vermiform Appendix. GEORGE A. PIERSON.
2. The Conservation or Preservation of the Ovaries and Functionating Uterine Tissue in the Operation of Hystero-Myomectomy. HENRY D. BEYEA.
3. A Review of Some Recent Literature on the Etiology of Carcinoma. ALOYSIUS O. J. KELLY.
4. Appendicitis in Children of Two Years and Under. J. P. CROZER GRIFFITH.
5. A Series of Twelve Articles on Medical Men Prominent in the Civil and Military Affairs of Revolutionary Times. FRANCIS R. PACKARD.

1.—George A. Piersol discusses early infantile inguinal hernia of the vermiform appendix. About one hundred and twenty-five herniae of the vermiform appendix have been recorded since Morgagni noted this condition. Piersol describes a case recently examined. A colored infant about three months old presented the following conditions: The cecum, of the typical form, occupied a position considerably lower than usual in the right iliac fossa. It narrowed to an apex continued into the appendix. The latter, somewhat stretched, descended to the groin and disappeared in a peritoneal sac leading into the scrotum. On opening the sac the appendix presented the peculiarities of position and course which are illustrated in the paper by drawing. About 40 mm. from its commencement the tube formed a conspicuous S-like flexure, following the slightly curved terminal portion. The entire length of the appendix was 84 mm., or about two and one-half times longer than at birth. The hernial sac, the dilated and thickened upper portion of the processus vaginalis, loosely enclosed the appendix and extended a little more than half way to the bottom of the scrotum. Its lower end lay in intimate relation with the sac of the tunica vaginalis investing the testicle, which, with the epididymis occupied an anomalous position, the lower pole being displaced upwards and mesially, so that the long axis of the testicle was horizontal, and the globus major lay laterally and below. The investment of the testicle by the tunica vaginalis was somewhat less complete than usual, or as it was on the opposite side, the displaced inferior pole of the organ being closely bound to the sac by an uncommonly conspicuous scrotal ligament—the remains of the gubernaculum. The conditions presented by this specimen suggest two points: (1) the probable cause of the attachment to the appendix to and its presence within the hernial sac, and (2) the cause of the secondary upward displacement of the appendix and testicle. The descent of the testicle is described by Piersol, as well as the cause of the condition presented in this case. The unusual size of the appendix and its circumscribed attachment to the wall of the sac, as well as the marked thickening of the latter, will warrant the conclusion that the adhesion of the appendix has been in this case the result of an early inflammatory process, and not of persistent fetal attachments. [T. L. C.]

2.—Henry D. Beyea contributes a paper on the conservation or preservation of the ovaries and functionating uterine tissue in the operation of hystero-myomectomy. The two operative methods which are now advised and practiced for the removal of myomata of the uterus through an abdominal incision are hystero-myomectomy and myomectomy. The selection of either the one or the other of these operations is dependent upon the extent of pathological destruction of the uterus by the tumor and the presence or absence of the tubes and ovaries. Myomectomy is applicable only to isolated pedunculated tumors, and some isolated sessile, interstitial or broad ligament growths so disposed, that they can be readily excised or shelled out of their bed without undue injury or loss of uterine tissue. The tubes and ovaries must be normal. All myomata not coming within this class are removed by hystero-myomectomy,—in which operation the uterine body to the internal os, or with a portion of the cervix, and both tubes and ovaries are excised. Beyea states that about a year ago it occurred to him that there must exist

a class of myomata of the uterus in which the actively conservative operation of myomectomy could not be performed, the destruction of tissue by the tumor was too great, and the actively radical operation of hysteromyomectomy, as it is now performed, removed functioning uterine tissue and normal tubes and ovaries. The first of that class to which he refers is that which destroys the upper three-fourths, two-thirds or less of the uterine body and the tubes and ovaries to either side are normal. The method of operation which suggested itself to him was to leave both tubes and ovaries intact, both ovaries or one ovary, depending upon the pathological condition of these tissues, and to amputate the uterus at the highest possible point, so that a portion of the uterine body lined with corporeal endometrium, even though it be small in amount, would be left in the stump. A case is reported in which this operation was practiced, and was eminently successful, the patient menstruating regularly every twenty-eight days since the operation was performed. Beyea's search of the literature fails to find the report of a similar conservative operation. Three cases were found operated upon by Zweifel, in which more or less menstruation occurred after myomectomy. These cases, says Beyea, are probably to be accounted for that accidentally a portion of functioning uterine tissue was left in the uterine stump. Beyea discusses the value to a woman of ovulation and menstruation in the absence of all possibility of conception, and the problem as to the frequency of which pathological changes may develop in such ovaries left in position. He also takes up the question, if secondary atrophic changes take place in the ovaries, when a portion of the functioning uterine tissue is left in the stump, resulting in the menopause, and making the conservative treatment of no avail, as well as the question as to whether such ovaries will produce molar menstruation, dysmenorrhea, necessitating a second operation. In conclusion Beyea states that he believes this operation can be associated with no greater danger to life than the usual hysteromyomectomy, and that there seems to be no cause for complicating sequelae, because its object is the preservation of normal tissue, organs and functions, and through these good health. These are important factors as well as the point that it should be limited to women under 40 years of age, and to the special class of myoma described. [T. L. C.]

3.—A. O. J. Kelly presents a review on some recent literature on the **etiology of carcinoma**. This paper deals at length with several questions of interest. First—the increasing prevalence of carcinoma, as well as the geologic, hydrographic, mineral, vegetable and animal factors, in so far as they may have a bearing upon the etiology. The local distribution of cancer and cancer houses are mentioned, and finally, a critical summary is given of the recent literature upon the etiology of carcinoma. A valuable bibliography accompanies the article. [T. L. C.]

4.—J. P. C. Griffith reports a case of **appendicitis occurring in an infant of three months**. The child suffered at first with diarrhea, with mucus in the stools. The day after this condition developed, fecal movements ceased, although some blood is said to have been passed on the same evening. Vomiting began at the same time. Nothing at all had passed from the bowels for three days previous to the admission to the hospital. The symptoms on admission were those that suggested an intestinal obstruction, and with this condition in view, large enemata were ordered, but only a small quantity of mucus, with reddish-stained fecal matter, was obtained. The day after this the child vomited a slight amount of greenish material, and died a short time afterwards. The temperature while in the hospital ranged from 102° to 105.5°, generally being over 103°. The autopsy performed by Dr. Alfred Hand, Jr., revealed the cause of death in this case to have been appendicitis, and the notes of the autopsy are given. Griffith states that he has seen two cases of children four and four and a half years, respectively, and recently a child of three years, suffering from the same condition. The relative frequency of appendicitis at different ages in children is shown by a résumé of the literature which accompanies the article. Of nine of the fifteen cases given, the appendix was found to be perforated; in four cases the appendix had descended into the scrotum; nine cases were operated upon with seven re-

coveries, and in two cases the disease had been diagnosed as Intussusception. [T. L. C.]

5.—Dr. Francis R. Packard, continuing his series of articles on medical men, prominent in the Civil and Military affairs of Revolutionary times, gives a sketch of **Dr. Edward Hand**, Surgeon and Major-General, and **Dr. William Irvine**, Surgeon and Brigadier-General. [T. L. C.]

VRATCH.

August 4, 1901. (Vol. XXII, No. 31.)

1. **Pentose in the Animal organism and the Origin of Pentosuria.** N. P. KRAFKOFF.

1.—Kraffkoff found that if a piece of rabbit's muscle be boiled with hydrochloric acid in the presence of a small amount of phloroglucin, a characteristic **pentose reaction at once appears**. This suggested to him the idea of looking for pentose in the muscles and organs of animals, with the view of establishing the distribution and fate of that carbohydrate in the animal economy. He isolated the pentose by the following method: Pieces of meat were minced in an ordinary meat grinder and freed from the soluble carbohydrates, such as glycogen, glucose, etc., by soaking in cold water and then boiling several times until the washings no longer gave the reactions of glycogen or glucose. It was then boiled in a porcelain dish on the naked flame with 1-2% hydrochloric acid for ½ hour. When cooled, the liquid was filtered and the **pentose separated in the form of osazone**. This was accomplished by first neutralizing the liquid and then acidifying with a little acetic acid; the resulting sediment was then filtered off and phenylhydrazin dissolved in acetic acid added to the filtrate. The liquid was heated in a water-bath for one hour. Upon cooling, a heavy yellow precipitate of osazone formed. This was purified by repeated crystallization, washed with water, alcohol and ether and dried in the dessicator. The elementary composition of this substance was found allied to that of pentose, and the author, therefore, considers the two practically identical. Pentose thus isolated or merely detected by qualitative tests was found in the **muscles, heart, liver, intestines, kidneys, brain, bones, crystalline lens and pancreas**. The muscles were found to contain proportionately more pentose than any other structure. It is thus evident that the organism is richly supplied with pentose, and the conclusion is justifiable that **pentosuria bears the same relation to metabolism as does glycosuria**. The opinion is expressed that, with our increasing knowledge of the newer animal carbohydrates, other forms of glycosuria will eventually be discovered. Taking into consideration the close chemical relationship between glycuronic acid and pentose, it is reasonable to suppose that **both are produced by the tissues, especially the muscles**. From the fact that the appearance of glycuronic acid may be due to various poisons, the author concludes that pentosuria may be of similar origin. The poisons may be of vegetable or microbial origin, or may be formed in the body itself (leukomaines). For this reason pentosuria is generally observed in morphine habitués or persons suffering from chronic poisoning, under which conditions glycuronic acid is also found. Considering pentosuria as a form of glycosuria, the author attributes certain cases of glycosuria to the influence of poisons or toxins. [A. R.]

August 11, 1901. (Vol. XXII, No. 32.)

1. **Inflammation of the Spine and Large Joints, Accompanied by Ankylosis (spondylose rhizomelique).** L. M. PUSSEP.
 2. **The Application of the Mathematical Theory of Probabilities to the Question of the Infectiousness of Eclampsia.** G. V. KOLOSOFF.
 3. **The Serotoxins and Their Application to Distinguish Human Blood from that of Other Animals.** V. I. NEDRIAGALLOFF.
 4. **Report of the Siberian Eye Commission Sent by the Committee Connected with the Siberian Railway.** P. V. PUTIATIKERSHBAUMER.
- 1.—Will be abstracted when concluded.
3.—Nedriagalloff gives a brief résumé of the work done by others and himself on **hemolysis**. He considers the

hemolysin identical with the cytotoxins of Metchnikoff and therefore proposes the term *serotoxin*, instead of "coagulin" of Uhlenhuth or the "antiserum" of Stern. He concludes with the following statements: (1) By the aid of serotoxins human blood can be distinguished from that of animals or birds; (2) the serotoxins make it possible to discover the slightest traces of the corresponding blood; (3) the albumin of the albuminous urine in man is identical with that of the blood; (4) the study is undoubtedly of scientific as well as practical importance. [A. R.]

4.—Puttlitz-Kerschbaumer reports the work done by the commission sent into the region of the Trans-Siberian Railway, with a view of rendering aid to those suffering from eye-diseases. Data and tables are given which are of interest only to Russians. The following statistics, however, are of general interest. Of the 21,762 cases treated 16.1% were due to diseases of the mucous membranes and the eyelids, 38.4% to trachoma and its complications, 15.2% to disease of the cornea, and the others were distributed among the various affections of the visual organs. As causes of incurable blindness trachoma and its complications figured in 15.6% of the cases (1137), glaucoma in 14.5%, gonorrhea of the new-born in 3.3%, gonorrhea of adults in 0.1%, injuries and unsuccessful operations in 4.3%, sympathetic affections in 1.8%, diseases of the vascular system in 2.8%, diseases of the retina in 3%, diseases of the lachrymal apparatus in 0.6%, abnormal development in 0.6%, smallpox in 18.5%, other acute general diseases in 3.1%, syphilis in 4.3%, other chronic general diseases in 3.6%, diseases of the brain, cord and optic nerve in 12.5%, unknown causes in 11.3%. [A. R.]

1. The Limitation of Röntgenoscopy in the Diagnosis and Treatment of Fractures. G. I. TURNER.
2. Inflammation of the Spine and Large Joints, Accompanied by Ankylosis (spondylose rhizomelique). L. M. PUSSEP.
3. The Treatment of Lupus with Blue Electric Light. A. V. MININ.
4. The Medical Report of the St. Petersburg City Maternity, for 1900. E. L. PUSHKINA.

1.—Turner describes two cases of fractures, showing the material aid to be derived from the Roentgen rays in judging of the condition and progress of a given case. However, experience is necessary to avoid erroneous conclusions. With regard to the final results of the treatment the evidences furnished by the skiagraph should be considered with care and circumspection. [A. R.]

2.—Pussep, from a perusal of the literature and a study of a case under his care, reaches the following conclusions: (1) There are two clinical forms of immobility of the spine: (1) the form described by Bechtereff or Kyphosehredo traumatica, and (2) the form of Struempell-Marie, accompanied by inflammation and ankylosis of the vertebra and large joints, spondylose rhizomelique or the spondylitis deformans of the older writers. (2) The case reported belongs to the second form with the rare peculiarity of a downward extension of the process. (3) The origin of spondylose rhizomelique is up to the present not established, but in all probability is of an infectious nature. (4) Spondylose rhizomelique fully resembles the form of disease which was described by the older writers under spondylitis deformans. [A. R.]

3.—Minin claims that better results in the treatment of lupus can be obtained with blue light from a 50 candle power lamp than by the use of the costly and cumbersome apparatus of Finsen. The following rules should be observed: (a) the lamp should be held in such a position that the rays of light fall at a right angle; (b) the distance should be about 16 inches; (c) the illumination should be performed daily for 10 to 15 minutes or every other day for 25 to 30 minutes; (d) if considerable itching occurs, the patient should be given a rest for two days; (e) in some cases warm compresses of 1% solution of boric acid diluted with an equal quantity of alcohol may be applied over night and borated vaselin during the day; (f) the skin should be washed with pure alcohol, but if the latter causes pain it should be diluted with boric acid solution (1%). It is well to remember that tubercular syph-

lides also yield to this treatment. The following very interesting case is reported: A man, 38 years old, developed some 3½ years back a redness of the end of the nose and a few pimples on the upper lip, which soon transformed into small tubercles. The condition was at first diagnosed as acne or syphilis, it was then treated as syphilis and finally diagnosed as lupus. Israel of Berlin employed Koch's tuberculin at first as a means of diagnosis, and when a positive reaction was obtained, as treatment. This, however, proved a failure. Unfavorable results were also obtained with hot air. Lassar employed resorcin in combination with the hot air treatment and succeeded in making the condition worse. Finsen employed electric light and sun light with some slight improvement following the 230 applications. When the patient came to the author, his upper lip presented the form of a large, smooth, solid, red mass, drawn up close to the ulcerated end of the nose, which was drawn towards the left. The lower lip was thickened and drawn down, thus exposing a set of almost black teeth implanted in ulcerated gums. The left cheek was infiltrated, the mouth and throat ulcerated, rendering the opening of the mouth and deglutition extremely difficult. Two weeks treatment with blue electric light in twelve sittings brought a remarkable change in the condition of the patient. After the second sitting deglutition became free and painless and the ulcers commenced to cicatrize. After the fourth sitting the lower lip became normal, and the upper after the eleventh. While the patient is not entirely well, yet the improvement was so marked and rapid as to justify the author in reporting this case. [A. R.]

4.—Will be abstracted when concluded.

5. Anguish as a Nervous Disease. P. HARTENBERG.
6. Note on the Determination of the Different Principal Sugars which May Exist in Diabetic Urine. R. LEPINE and BOULUD.

1. Brissaud and Londe report the case of a man, aged 47, who was suffering from an edematous swelling of the fingers of both hands. The swelling was accompanied by loss of power and was the sequel of an attack of pain with contracture which occurred about one week before the patient was first seen. The attack commenced as a sensation of needle punctures in all the fingers except one and this sensation became increasingly painful. The area concerned in the disease pulsed, the skin was reddened and the hand was held in a position of tetany. Later, the contractures became generalized and the patient began to sweat. After lasting for a certain time, the contractures diminished, but a second paroxysm began before the first one was completely terminated; this was followed by a third and this last attack was terminated by a profuse sweat. During the third attack, the patient was nearly suffocated from spasm of the larynx. Within about 3 weeks, the patient's hands became useless. He was gouty and neuropathic, but without renal disease and with but slight arteriosclerosis, although at one time there was a transitory albuminuria. The affection from which he suffered was characterized by a syndrome more or less periodic which presented the following features: paresthesia, pain and contractures, loss of power, vasomotor difficulties with vasodilation, vascular erethism and edema. The attacks resembling acroparesthesia, tetany and erythromelalgia, but were quite distinct from Raynaud's disease. The authors consider the disease a synthesis of the conditions named. The disease was considered to have a gouty origin on account of the white line seen between the ends of the

phalanges in a skiagraph of the hands and the appearance of Heberden's nodosities. In the treatment of the condition the alkalies, colchicum, applications of moist heat and washes of chloral and potassium bromide were employed. [J. M. S.]

2.—Will be abstracted when finished.

3.—Bard's paper on the intrapleural pressure in pneumothorax, which began in June is concluded in this number. From his study the author draws the following conclusions: (1) On account of the anatomical structure of the lung, the various kinds and the most extensive wounds of its parenchyma are only permeable to gas and liquids in the bronchopleural sense. Severe and extensive lesions of the organ or absolute obstacles to the retraction of the tissues such as are seen in partial pneumothorax, allow the passage of gas or fluid in the pleurotracheal sense only. (2) In generalized pneumothorax, when the fistula is not obliterated, the pressure of the gas is positive in both stages of respiration, when the breathing is quiet. This positive pressure results from the spontaneous tendency to equilibrium between the intrabronchial and intrapleural gas by the regular play of respiration without cough playing any part in its production. The so-called valvular pneumothorax is the normal form of generalized pneumothorax, open internally. Cough and muscular exertion act upon intrapleural pressure more energetically than upon intrabronchial pressure; so that they serve to compress the lung, to produce atelectasis and to compress the mediastinum, but they do not cause the air to enter the pleura through the wound in the lung. The degree of positive intrapleural pressure is a little raised and remains nearly constant in the same patient, presenting respiratory oscillations of some centimetres around a mean of 6 or 8 cm. of water. (3) The degree of this pressure is, if not equal to the pulmonary elasticity, at least in relation with it and determined by it. This elasticity, which in combination with the action of the thoracic walls, creates in the pleural cavity a negative pressure when the lung is intact, produces, on the other hand, in pneumothorax with a persistent pulmonary wound a positive pressure by the fact of its direct transmission across the fistula. (5) The positive intrapleural pressure in pneumothorax is a phenomenon of adaption and of pathological compensation, which serves to obliterate a fistula. This positive pressure ought not to be destroyed when it has been established and, in the stage of initial suffocation, means should be adopted to hasten its appearance. (5) The mensuration of the pressure of the intrapleural gas is an essential element in the diagnosis of the varieties of pneumothorax, principally of the appreciation of the existence, the persistence or the obliteration of a pulmonary fistula. The mean pressure does not furnish exact information for this diagnosis, on the contrary, it is necessary to study the extreme pressure: pressure is positive during both stages of respiration in generalized pneumothorax with persistent fistula; it is positive during expiration and negative during inspiration in partial pneumothorax with open fistula; it is negative during both stages of respiration in generalized pneumothorax when there is no fistula or after the obliteration of a fistula. [J. M. S.]

4.—Roger continues his observations concerning infectious diseases at the isolation hospital of the *Porte d'Auberbilliers*. In one case of diphtheria death was due to associated acute tuberculosis. There were 57 cases of mumps. In nearly half the adult male patients suffering from this disease there was metastasis to the testicle. There were 29 cases of gastroenteritis, which the author classifies with the infectious diseases. [J. M. S.]

5.—Will be abstracted when finished.

6.—In addition to glucose, maltose and the pentoses are found in diabetic urine. In estimating the total quantity of sugar in a diabetic urine errors will occur if only one method is employed. In order to overcome such a difficulty Lépine and Boudin advise the clinician to employ the polarimeter, Fehling's solution and the fermentation test to each specimen. [J. M. S.]

August, 1901. ((21 mo. Année, No. 10).)

1. Adiposis Dolorosa, Syndrome of Dercum.

CIL. FERE.

2. A Case of Peripheral Neuritis of Malarial Origin.

BUSQUET.

3. Study of Primary Carcinoma of the Bile Passages, Hepatic Duct, Cystic Duct, Common Bile Duct.

DEVIC and L. GALLAVARDIN.

4. Anguish as a Nervous Disease.

P. HARTENBERG.

1.—In painful adiposis the fat forms masses that are generally symmetrical and which are found on the trunk and on the limbs, leaving the head, the hands and the feet uninvolved. The fatty masses often present an unequal consistency. The disease occurs in 2 forms; the diffuse and the disseminated. Féré reports the histories of 4 patients, one of whom was a male. [J. M. S.]

2.—Busquet reports the case of a soldier, aged 24 years, who complained of loss of power in his arms and legs. The patient had been invalided to France from Madagascar on account of dysentery and a bilious attack. He had had malaria at the age of 15 years, which persisted for 8 months. During the passage from Madagascar to France the patient complained of pains in hands and feet with loss of power. This was followed by violent headache, vomiting, swelling of the arms and legs, increase of pain and more complete loss of power. On admission to the hospital the extensor muscles were atrophied, there were areas of hyperesthesia and complete anesthesia on both the upper and the lower extremities. There was no change in the perception of heat or of pain, and there were no trophic troubles, except abundant sweating on the palms of the hands and the palmar surfaces of the fingers. In the absence of all history pointing to saturnism, syphilis and alcoholism, and remembering that the symptoms appeared soon after the cure of a pernicious attack, the author makes the diagnosis of peripheral neuritis of malarial origin. Under treatment the patient made great improvement. [J. M. S.]

3.—Will be abstracted when finished.

4.—Hartenberg's paper began in the June number, was continued in July, and is concluded in the current number. Anguish as a nervous disease is characterized by 5 symptoms: General irritability, anxious expectation, crises of acute anguish, equivalents of the crises of anguish or rudimentary crises of anguish and phobias and obsessions. General irritability in a patient suffering from this disease is often manifested by auditory hyperesthesia, which is explained by the natural relations that exist between auditory impressions and the emotion of fright. Further, this auditory hyperesthesia is a frequent cause of insomnia. Anxious expectation is the essential symptom of this neurosis. Under the head of rudimentary crises of anguish are included. (1) cardiac crises, such as palpitation, arrhythmia and tachycardia; (2) respiratory crises, such as nervous dyspnea and asthmatic attacks; (3) disorders of the digestive apparatus, such as sudden excessive hunger, insatiable appetite, often associated with vertigo, paroxysmal thirst and periodic diarrhea; (4) attacks of vertigo, (5) paresthesias, (6) nocturnal terrors and agonizing dreams, (7) muscular tremors, (8) profuse sweats, (9) vascular and congestive phenomena, and (10) tenesmus and urgent call to urinate. The nervous system reacts in anguish as a nervous disease against an internal excitant, just as it reacts in fear against an external excitant. This internal excitant is often of a sexual nature, and the disease is frequent in those who present sexual irregularities. The disease, which is due to the exhaustion of the sympathetic system, is distinct from neurasthenia, which, in turn, is due to the exhaustion of the cerebrospinal system. The disease should be treated by hygiene, rest, isolation and local applications. [J. M. S.]

1. De la Camp has made some very careful experiments with quinic acid, particularly with quinic tropin, a synthetic combination of china acid and uratropin. The first of a series of experiments was made upon a young girl suffering from chlorosis. It was found that the administration of quinic tropin produced moderate increase in the amount of uric acid excreted (the greatest quantity being upon the day on which the drug was first administered), and a very great increase in the amount of hippuric acid. The second and third cases suffered from arthritic gout, and the effect upon the amount of uric acid was very irregular. In the first case the daily amount excreted diminished in spite of the administration or withdrawal of quinic tropin, and in the second it varied considerably. In the third case the amount of hippuric acid was greatly increased; in the second case technical difficulties interfered with its estimation. A brief examination of a case of myelogenic leukemia was also made, and it was found that in this the amount of hippuric acid excreted was enormously increased as a result of the administration of quinic tropin. The drug appears to be harmless even in doses as large as 20 to 30 grams per day. Probably the best dose is about 5 or 6 grams daily. It appears to be clinically the best remedy against gout. In conclusion de la Camp states that in his opinion quinic acid does not influence the excretion of uric acid in any particular way. It invariably causes an excessive production of hippuric acid, but as the relation of neither of these substances to gout is understood, it is perfectly justifiable to depend upon clinical experience. It deserves a further trial in cases of uric acid concretions. [J. S.]

2.—Hensay has performed a series of experiments upon young women consisting of the administration early in the morning, after prolonged fasting, of an agreeable mush, containing chiefly carbohydrates. Then, after a definite time, the stomach contents are withdrawn, assimilated with HCl, carefully filtered, and the whole tested for sugar according to the iodometric method of Lehmann. The results are expressed in a table which shows a very considerable amount of the starch had already been converted into soluble form, proving that the chemical function of the saliva is not unessential, but, on the contrary, of the greatest importance. An attempt to determine how much of this sugar was absorbed by the stomach wall was rather fruitless because the method recommended for this experiment was not entirely trustworthy. The method consists in the administration of definite quantities of fat and sugar, the withdrawal of the contents and the estimation of the relative proportions of these two. As fat is not absorbed, the proportion of sugar should be diminished, but as a matter of fact the contrary is the case. [J. S.]

3.—Schmitt employs a 1% solution of cocaine for the production of local anesthesia in abdominal operations. He rarely administers as much as one grain. Usually $\frac{1}{2}$ a grain suffices for the most extensive operation. Among the operations that he has performed by this method are: Gastroenterostomy, exploratory incision, incarcerated hernia, perityphilitic abscess, stones in the bladder, etc. In one case (carcinoma of the esophagus) the patient died shortly after the operation, chiefly as a result of previous exhaustion. In another case of umbilical hernia in which 40 ccm. of the intestine were found to be gangrenous and required resection, the patient died three days later. The objections to local anesthesia are the impossibility of securing complete relaxation of the abdominal muscles and the absence of

anesthesia of the peritoneum. This latter structure appears to perceive cuts very slightly, but is exquisitely tender to any form of tearing, such as breaking of adhesions, or the placing, and especially the removal, of gauze packings. The intestine and stomach are entirely insensitive. Intestinal section appears to be moderately painful; incision into the bladder on the other hand, does not hurt the patient at all. The advantages are of course the greatly reduced danger of shock, and especially of the respiratory complications produced by ether. As, however, in cases of gastroenterostomy by local anesthesia developed pulmonary inflammation after the operation, its advantages are more theoretical than real. One of these two patients died 9 days after the operation, of bilateral pneumonia. It appears then, that the technique of local anesthesia for abdominal operations is still in a very incomplete state. [J. S.]

4.—Torggler calls attention to the following method of treating inoperable carcinoma of the uterus. Thorough and repeated applications of strong solution of peroxide of hydrogen are applied to the surface until it has become perfectly clean and granulations appear. Then a palliative operation may be performed, consisting of curettage or perhaps application of the cautery. Finally the tumor mass is kept clean, dry and odorless by the application of tampons soaked in formalin. [J. S.]

5.—Grünwald reports some interesting cases. The first, a girl of 20, developed severe pain in the left pharyngeal region. Two defective teeth were extracted, and although no pus came from the alveolar process, there was a very fetid odor, and a sound could be inserted through the posterior alveolar process into a large cavity around the left tonsil. Incision was made and a large quantity of fetid pus evacuated. In another case, a man of 30 had an acute suppurative tonsillitis which was discharged, and then subsequently a chronic abscess of the tonsil. This was cured with the greatest difficulty. In the third case, a phlegmonous inflammation in the region of the larynx, which was incised, a considerable amount of pus was evacuated. The same night, however, the patient had acute heart failure and stenosis of the larynx requiring tracheotomy. He had always indulged excessively in alcohol. [J. S.]

5.—Gerson suggests that, as the ordinary surgeon's plaster is apt to lose its adhesiveness from frequent removals from the skin in dressing wounds, it is desirable to make an attachment to the skin permanently in the centre, after which the two ends are brought together over the dressing. By this method the end over the dressing can be freed, the dressing made, and then the ends replaced. In some cases it is necessary to use 2 bandages, one attached to either side of the wound. The advantages over the ordinary gauze and linen bandages are that it takes less time to change the dressings, they are more secure and more comfortable. [J. S.]

7.—The conclusions of the commission for the examination of the lighting methods in the various institutions of Munich, are as follows: The Welsbach light for indirect illumination is probably the most satisfactory where gas is already employed, on account of its cheapness. The electric arc light comes next for the purpose of indirect illumination. The expense of installation is not greater than that of the Welsbach, and the light closely resembles that of the sun. It requires, however, rooms with very high ceilings (more than 5 metres). The Welsbach may be used for direct illumination in small rooms, or rooms that are only used in part, or only occupied by a small number of scholars. The electric incandescent light may also be used for direct illumination, but is inferior to the Welsbach because it eradicates more heat, does not resemble daylight so well, and is more expensive. It does not, however, increase the temperature of the room, does not cause any deterioration of the atmosphere, and is very easily managed. [J. S.]

1.—Fürstner reports two cases of tortuosity of the vessels of the retina. The first, a woman of 37, showed extraordinary dilatation and tortuosity of all the vessels in the eye grounds. There were varicose veins in the legs, enlargement of the heart, with modification of its sounds and murmurs, and some symptoms of cerebral lesions. At the autopsy a general, diffuse arteritis was found involving the blood vessels of the eye. In the second case, a man of 56 was brought to the clinic apparently in the midst of an epileptic attack. The same condition was found in both eyes, as was found in the previous case. The patient gradually recovered. There were some symptoms of cerebral injury, but he did not complain of any impairment of vision. In neither case could the condition be ascribed merely to arterial sclerosis. After a brief and careful discussion of the literature, in which he calls attention to the diversity of opinion, particularly in regard to the fact whether this condition may be congenital or acquired, Fürstner reaches the conclusion that in his first case it is certain that the changes increase slowly. In cases in which the condition is unilateral there is more reason to assume a congenital origin, but the subject requires more careful observation.

[J. S.]

2.—Franz, after quoting a few opinions of distinguished gynecologists, some of whom appear to consider vaginal puncture as a most reprehensible procedure, and others to recommend it warmly, gives an analysis of 81 cases in which he personally employed it. These were as follows: Tubal gestation, 20; tubo-ovarian tumor, 16; exudative pelvic peritonitis, 16; abscess in Douglas's pouch, 5; pyosalpinx, 5; retro-uterine tumors of uncertain diagnosis, 4; parametritis, 3; hematoma of the lateral ligaments, 2; parovarian tumors, 2. Intraligamentary tumors of uncertain diagnosis, 1. The results of the puncture were that in 56 of the cases the diagnosis was confirmed. In 5 cases a doubtful diagnosis became certain. In 10 cases the original incorrect diagnosis was corrected. In 6 cases the results were doubtful, and in 4 the puncture was useless. The immediate results of the puncture were that in 5 cases there was slight temporary elevation of temperature, in one case with chill, and one case of intraligamentous cyst with clear contents was evidently infected and became purulent, the patient was, however, cured by incision. In one case the patient, with bilateral disease of the adnexa, developed peritonitis after the puncture and died. It is doubtful whether the infection occurred during the operation. In 35 of these incision was subsequently performed. Twenty were completely cured; 11 improved; 2 were unimproved, and 2 died. Of the deaths one was due to hemorrhage and one to pyemia. Some of the cases that were unimproved were subsequently relieved by laparotomy. The most favorable cases are those of uncomplicated abscess in Douglas's pouch. The least favorable are hematoceles, and incision is only justified when the sac has undergone suppuration. The technique he gives as follows: A needle, 15 to 20 cm. in length, should be employed and carefully sterilized, the vagina cleansed as thoroughly as possible, and then under the guidance of the two fingers, the needle thrust into the densest part of the tumor through the posterior wall of the vagina. Occasionally some form of suction syringe may be required to withdraw the fluid, but this is rarely necessary. When incision is required it may be made immediately after the puncture while the needle is *in situ*, a small incision being made in the mucous membrane of the vagina, and then a pair of forceps thrust in, opened, and withdrawn. The tumor is then evacuated, a drain inserted, which should be kept clear and maintained in position until healing is so far advanced that there is no danger of the formation of a new abscess. [J. S.]

3.—Schattenfroh has discovered that the blood of the animals into which the urine of men and goats has been injected subcutaneously, acquires the property of coagulat-

ing the red blood cells of the animals from whom the urine was derived. On the other hand, the blood of a rabbit into whom urine from a horse had been injected did not acquire any agglutinating power. If, however, the rabbit was treated with injections of the serum of goats, its blood developed a considerable quantity of complements and precipitine, although the hemolytic quality disappeared entirely. The interest in these studies is the possibility of their employment for medico-legal purposes. [J. S.]

4.—Ascoli has studied the isoagglutinative and isolytic qualities of the human blood serum from 17 healthy and 97 diseased persons. The method employed is as follows. The blood is obtained, placed in a test tube (well sterilized) and allowed to coagulate. The blood used for testing was taken from the lobe of the ear, placed in 85% sodium chloride, defibrinated, and the corpuscles then mixed (in the proportion of 1 to 40) with sodium chloride solution. An oese of serum and one of the suspension of blood corpuscles more or less diluted, were then mixed upon the cover ground glass, placed over a hollow ground glass slide, and then examined at varying intervals. In the 17 healthy cases it was found that the blood serum was capable of agglutinating the blood corpuscles from the same individuals, or from healthy individuals. Its quality was rather feeble, however, and usually disappeared when the dilution exceeded 1 to 20. In the cases suffering from various diseases the following results were obtained: Isoagglutinin and isolysin were either absent or not increased in 5 cases of chlorosis. In 2 of anchylostomiasis; in one of liver abscess, and in 2 of acute articular rheumatism. In 3 cases of exudative pleurisy; in various cases of bronchial catarrh, and acute chronic gastric catarrh. In 3 cases of lead poisoning. In 1 case of acute and 2 of chronic nephritis. They were increased in 2 cases of gastric carcinoma; in 1 of probable Addison's disease; in 1 of pneumococcus infection, and in cases of pneumonia, typhoid fever and tuberculosis, particularly in the latter condition the blood serum was capable of agglutinating the blood corpuscles of other individuals in a high state of dilution. In pneumonia the changes were variable. When urobilin was present in the urine the isolytic qualities were often active. In one case they were absent during the fever, but developed after the crisis. In another case the isolysin gradually decreased from week to week. Ascoli was also able to determine that the isolysin has 2 complements, one destroyed by heating to 56°, and the other not. In a few cases of malaria the ferments were found to be active. The fluid of transudates and exudates apparently has the same qualities as the blood serum. The source of these ferments is difficult to determine. They may be due either to the direct action of bacteria or the product of degeneration of tissue. Experiments made upon rabbits by injecting into them their own defibrinated blood mixed with an equal volume of distilled water showed that the ferments had become greatly increased in activity, proving that the resorption of their own blood by animals has distinct effects. [J. S.]

5.—Loeb having found that a mixture of pepsin and hydrochloric acid is not sufficient in cases of achylia gastrica, to produce such a degree of digestion in the stomach as to render the chyme readily acted upon by intestinal juices, has employed pankreon, a preparation from the pancreas, that continues to act in an acid medium for 5 hours. This is particularly applicable in cases in which the acidity of the gastric contents is greatly reduced. The dose is about 7.5 grains 3 times a day. With this preparation he has treated 13 cases, of which 4 were associated with diarrhea, 3 of these being chronic alcoholics. In 7 cases there was constipation, the others were normal in this respect. The results showed: In 9 cases marked improvement; in 2 moderate improvement; and in 2 no improvement. Of the cases with diarrhea 2 were markedly improved; 1 not improved (this patient also suffered from chronic enteritis), and 1 improved but withdrew from treatment. Objective changes in the cases that showed marked improvement were only observed twice; in both of these the character of the gastric juice was improved. In the others no chemical changes could be determined. Subjective improvement was nearly always pronounced.

[J. S.]

6.—Horn reports the case of a woman who, at the birth of her fourth child, which required the application of the forceps, apparently suffered from a slight contusion of the bladder, the urine being mixed with blood. On the third

day, however, the pulse became very weak, the urine was mixed with lochia, and there were evidences of severe general sepsis. The patient died on the 6th day. At the autopsy a communication was found between the bladder and the uterus, and infiltration of the peritoneal cavity with urine. In this case free incision and lavage of the peritoneum might have been of use, had the condition been recognized at once. It is probable that the prolonged position of the head in the cervical canal caused a pressure necrosis of the wall of the bladder and uterus. The opening was, however, probably partially closed by contraction of the uterine wall causing congestion of the urine to the infiltration of the surrounding tissues. [L. S.]

7.—Baeyer reports an interesting case. A man carrying mineral water into a drug store, was offered a drink of schnaps by the servant. This he accepted, but unfortunately the woman selected the wrong bottle, and he drank some battery fluid. Almost immediately he had severe pain with repeated vomiting, and died in 7 days with symptoms of cardiac paralysis. At the autopsy there was found a severe necrotic inflammation of the esophagus, mouth and stomach, and hemorrhage erosion of the duodenum. There was also an acute parenchymatous nephritis. As the fluid contained bichromate of potassium, sulphuric acid, and sulphide of mercury, the question arose as to which was the active toxic agent. Bichromate of potassium was of course converted into chromic acid in the solution. The symptoms resembled those of chromic acid or mercurial poisoning more closely than those of sulphuric acid, and it is probable that the man drank too small a quantity of the latter to be poisoned by it. In regard to the treatment of his condition, Baeyer suggests that instead of alkalis, eggs, etc., the patient be given sodium sulphide, which converts the poisonous chromic acid into chromic sulphide, a substance at least 100 times less poisonous. [J. S.]

8.—Neustätter believes that in many cases it is desirable to apply solutions to the conjunctiva directly instead of dropping them in. For this purpose he recommends a small piece of absorbent cotton twisted into a point, as much better in every respect than the ordinary hair brush. If required it can be twisted around a match-stick in order to make it more easily handled. [J. S.]

9.—Pregowski observed the following objective symptoms in himself during an attack of pericarditis with exudate. When, whilst in bed, he turned on the right side he had a sensation as if there were some heavy objects in the mediastinum that pressed downward toward the right side. This disappeared with the absorption of the exudate, and he supposes it was due to the weight of the latter.

[J. S.]

10.—Maul makes a very rigorous reply to Sternberg in regard to his strictures upon oleum cinereum as a substance for hypodermic injection in syphilis. In a number of injections he had no complaints from his patients except that the subsequent pain was exceptionally bad, and he found that this was due to the fact that he had not sterilized his preparation. If this is prepared according to Neisser's formula, and then sterilized, no pain is produced. [L. S.]

11.—Schulze considers that under favorable circumstances spirits of camphor is the best dressing for leg ulcers. However, it must be changed frequently by the physician himself, and the patient should remain in bed. These conditions are rarely fulfilled by the poorer classes.

[J. S.]

12.—Galli insists that in ancient Rome the hygienic conditions were very favorable. This was due to the extensive sanitary constructions that had been undertaken by the government, in the form of aqueducts, baths and sewers. During the government of the Popes in the Middle Ages the conditions were somewhat changed. Epidemics, disease, etc., were regarded not as the result of human carelessness, but of neglect of some of the divine precepts, and therefore an effort was made to combat them by erecting churches and by performing similar pious works. The Popes allowed all the sanitary structures to go to ruin, with the exception of a few aqueducts absolutely necessary to supply the city with water, and the condition of the inhabitants, that is, of the poorer classes, was miserable in the extreme, all attempts at cleanliness being practically abandoned. The Popes almost entirely neglected the Campagna, but the best proof of their pernicious influence upon the city was the rapid diminution in the mortality with the institution of the civil government. [J. S.]

1.—Buchner and Geret continue their interesting communication upon the nature of globulite. It will be remembered that in a previous abstract we stated that their conclusions were that this was a form of calcium sulphate, and they have since been occupied in an endeavor to determine in what manner this is formed. In a series of experiments they show that this globulite can be produced by making a contact test between a solution of ox serum, to which a small amount of sodium sulphate has been added, and a peptone solution containing baryta. From this they conclude that normal serum contains an amount of sulphuric acid or sulphate insufficient to produce the reaction. As the result of a series of experiments they reach the conclusion that the increased quantity of sulphate in the serum of animals treated with the injection of blood of other animals is due to the activity of the leukocytes which absorb an excrete sulphuric acid. This seems to be confirmed by the discovery of these crystals in the leukocytic thrombi that occur in tubes filled with peptone baryta solution and introduced beneath the skin. The leukocytes, according to the authors, have the capacity of selecting certain nitrogenous substances from the materials with which they are brought in contact, in the course of which activity sulphuric acid may or may not be excreted. It is probable that they may also be regarded as the producers of the immunization substances. [J. S.]

2.—Wilms reports an interesting case of a man who thrust a sharp chisel 4 or 5 inches into his abdominal cavity. There were evidences of collapse and severe hemorrhage into the peritoneal cavity. An operation was immediately performed, the liver was found perforated, and the wounds were sutured. In addition there was hemorrhage into the lower part of the abdomen, which was found to come from a wound in the lobe of the mesentery that had apparently involved about 13 blood vessels. These were caught in forceps, but it was impossible to pass ligatures around them; the forceps were therefore left in situ, and removed three days later. There was no further hemorrhage and the patient ultimately made an excellent recovery. Wilms has performed a series of experiments in order to determine whether ligation of the superior mesenteric vein will produce gangrene of the intestines. He concludes that in rabbits it is invariably fatal; in dogs, not unless the vein is ligated below the pancreas; in human beings it is probable that the results are the same as in dogs. It is a much more serious matter to strip the peritoneum from the intestine. [J. S.]

3.—Grünfeld reports an interesting case occurring in a woman of 30, who developed symptoms of gastro-intestinal disorder, and later symptoms of cerebral disturbances. She finally died and at the autopsy a huge colloid carcinoma of the rectum was found infiltrating the peritoneum and giving metastasis to the stomach. Also some extradural tumors in the anterior portion of the central cranial fossa, apparently involving the hypophysis, and consisting

of proliferated endothelium. The case is therefore one of simultaneous existence in one subject of two very different forms of malignant tumor. [J. S.]

4.—Bock reports a very interesting case of lymphangio-sarcoma occurring on the left external malleolus. The tumor was pigmented, and when removed recurred rapidly, and there was evidence of involvement of the glands of the groin. After the third removal the growth still recurred, and the condition of the patient appeared hopeless. Bock therefore attempted to control the growth of the tumor by exposure to the Roentgen ray, according to the method for the cure of lupus. The patient was subjected to a severe exposure commencing at 10 and gradually increasing to 45 minutes. The local recurrence rapidly improved, and also the metastasis in the calf. He believes that in these cases the maximum exposure bearable by the patient should be employed. [J. S.]

5.—Krug reports the case of a woman 67 years old, who had gall stone colic. At the operation a number of stones were removed from the gall bladder; then three by careful manipulation of the cystic duct; two from the common duct, and finally a stone from the papilla. The latter occasioned great difficulty. The patient, however, made a good recovery and was apparently permanently cured. The last stone was only discovered by careful sounding of the common duct. Of course, in many cases this method of removing stones from the biliary substance cannot be employed, but in suitable cases it enables the operator to avoid what is probably the most serious operation in surgery; that is, incision of the common duct. [J. S.]

6.—Hacnel describes his method of treating wounds. He considers it impossible to render hands absolutely germ-free, and also that as a result the hands are the chief agents of infection. Permeable sterilized gloves are valuable only when the operator does not moisten the hands. Impermeable gloves are, of course, much more efficient. He regards silk as the best material for ligatures. The best material for bandages is gauze. The most important feature of all dressings is to keep the wound thoroughly dry. For this purpose he believes gauze saturated with some powder, either antiseptic or sterile, is better than gauze not so treated. Free exit for the secretion must, of course, be provided. In cases where disinfection is required iodoform is probably the most efficient substance. The occurrence of erysipelas is one of the best indications of inefficiency of technique. [J. S.]

7.—Flade believes that in the majority of cases of peptic ulcer of the stomach there is increase in the proportion of acid, and that this hyperacidity is of differential diagnostic significance for the exclusion of carcinoma and degeneration of the mucosa. His paper is still incomplete. [J. S.]

8.—Vidal believes that certain precautions should be observed in the treatment of aphasia. Usually in these cases the patients have defect of certain vowels or consonants. This can be detected at once. The patient should then be carefully educated, and, during this education in vocalization, should be directed to observe attentively the movements of the teacher's lips. It must be remembered that these patients do not support severe intellectual effort for any length of time, and should therefore be spared as much as possible. Cases with the best prognosis are those of pure motor aphasia. He reports a case occurring in a man of 62, who had moderate aphasia, for example he was unable to say the number "18." He spoke French more fluently than German, but in the course of a few weeks of careful treatment he was able to express himself in conversation with moderate ability, and in the course of a few weeks more it was almost impossible to detect that the lesion had occurred. [J. S.]

9.—Fischer reports two cases in which a mild solution of carbolic acid applied to wounds of the fingers produced dry gangrene of both. He therefore warns against the use of such dressings. [J. S.]

2.—Krecke recommends very highly vioform, a substitute for iodoform. According to his idea it is equal to the latter, or better than it, in all the conditions for which it can be used. Vioform chemically is iodochloroxycholine. It is neutral in reaction, yellow in color, and entirely odorless. It has the advantage of keeping the wound dry. Physiologically it is remarkably chemotactic, for, when injected beneath the skin of animals, it produces an aseptic abscess. It seems to hasten the healing of non-tuberculous wounds more rapidly than does iodoform, and in tuberculous conditions is apparently equal to the latter. It does not appear to be of benefit in wounds that are completely closed by sutures. In one case of tuberculosis of the spinal column into which a suspension of vioform was injected, suppuration occurred and the patient suffered greatly. However, in this case ultimate recovery took place. [J. S.]

3.—Schattenforth and Grassberger made an additional note upon their articles regarding the bacillus of symptomatic anthrax. They believe this microorganism to belong to the group of butyric acid-forming microorganisms, but desire to retract their previous statements that it is invariably non motile, and that it is always a clostridium. The microorganism which they describe occurs in nature under two forms, one non motile and containing spores, and the other motile, non spore-bearing, and supplied with cilia. These two forms differ culturally in their chemical qualities. Injected into animals the clostridium form produces a hemorrhagic edema, with more or less accumulation of gas, while the motile form produces the typical picture of malignant edema. The characteristic toxin of the organism is produced only by the clostridium form. The transition from one form to another can be produced by various cultural methods. [J. S.]

4. Gebele criticises the employment of atropine in the mechanical forms of intestinal obstruction, regarding it as a distinct error of treatment. He admits that it may be of value in simple severe coprostasis. In obturation of the intestine, especially that caused by tumor, it may possibly be of use, but not infrequently delays the operation and renders the chances of the patient less good. He reports the case of a woman, 72 years of age, who developed diffuse pains in the abdomen, and absolute constipation with vomiting of biliary substances. After various measures had been employed unsuccessfully, the patient was given three injections of .001 (1-66 grains) of atropine sulphate. The

immediate results were very satisfactory: The vomiting ceased, the abdomen became less tense, and although no movement occurred, the patient was regarded as saved. Three days later, however, all the symptoms recurred; and an operation was performed at which peritonitis was discovered, evidently due to a gangrenous loop of the small intestine. This had been produced by a fecal stone about the size of a walnut. Death occurred a few hours after the operation. The conditions were apparently one that should have been relieved by atropine, and as it was not, Gebele believes that, where it is necessary to allay the symptoms, morphia should be preferred, and in no case should operative interference be delayed. [J. S.]

5.—Pritchard reports the case of a man 62 years of age, a chronic alcoholic and entirely edentulous. He developed pains in the abdomen, some retention of feces, and in the course of a few days **obstinate constipation** with ballooning of the colon. There was some fecal vomiting, and therefore 1/50 of a grain of atropine sulphate was injected hypodermically, and four hours later 1/100 of a grain. At the same time he was given several ounces of olive oil. The next morning the patient had a copious evacuation of the bowels and was completely cured. The condition appeared to have been produced by hard fecal accumulations. [J. S.]

6.—Aronhelm reports the case of a man 51 years of age who developed severe pains in the abdomen, and exquisite tenderness on the left side at the level of the umbilicus. He had frequent vomiting of bile and obstinate constipation which could not be relieved by enemata. Finally .003 gr. (1/22 grain) of atropine sulphate was injected subcutaneously, producing moderate physiological effects. This however, produced also entire relief of the pain, and in the course of a few hours there was a copious evacuation of the bowels and the patient recovered completely. [J. S.]

7.—Pincus describes the case of a man, 35 years of age, who had worked in a distillery where he was exposed to lead. After moderate symptoms of lead poisoning he suddenly developed **total blindness** which lasted 4 days and then gradually slight returned. As the sight returned, however, there was marked disturbance of association and some hallucinations of sight. It is still uncertain what is the situation of the lesion that produces this form of transient amaurosis. The prognosis is usually good, particularly if the pupillary reflex is present as it was in this case. Treatment consists in that ordinarily employed in cases of lead intoxication. [J. S.]

8.—Batsch reports the case of a man who had swallowed several artificial teeth. It was impossible to discover their position by means of the Röntgen rays, but they could be accurately located by means of the **esophageal sound**, which touched them at a distance of 36 cm. from the teeth. An attempt to remove them by means of forceps failed, and therefore the sound was reintroduced and the teeth forced into the stomach, an operation that caused considerable pain. The patient was then instructed to eat large quantities of coarse vegetables, with the idea of enclosing the teeth and preventing them from injuring the intestine in their further passage downward. After several days they were actually found in a copious evacuation. Batsch considers that it is perfectly justifiable to attempt to remove foreign bodies with the use of the forceps, but that the attempt should not be persisted in for any length of time. In the present instance one of the hooks by which the teeth were attached was missing, and is possibly imbedded in the mucous membrane of the esophagus. He has performed the operation of esophagotomy on the cadaver and found it very easily accomplished. [J. S.]

9.—Niewerth reports the case of a man, 33 years of age, who had become infected with syphilis at the age of 24. Subsequently he had become the father of 2 healthy children. He developed a severe attack of **sciatica**, and upon careful investigation a small syphilitic lesion was found on the left leg. A hypodermic injection of an emulsion of salicylate of mercury and paraffine was made into

the gluteal muscles, producing almost immediate relief of the pain and enabling the patient to sleep. [J. S.]

10.—Futterer calls attention to the fact that in 1888 he reported the results of bacteriological studies upon 3 cases of typhoid fever, in 2 of which pure cultures of the **typhoid bacillus** were obtained from the bile. He also stated at this time that the infection of the bile was due to microorganisms carried from the blood to the liver, and that relapse might readily occur as the result of reinfection of the intestinal tract from the pure cultures of the biles. As this article appeared 6 years before Chlari's, he claims priority for the discovery of the condition. [J. S.]

11.—Flade, in continuation of his article, attempts to answer two questions. First, whether the employment of the **gastric sound** is justifiable if there is suspicion of **ulcer of the stomach**, and particularly whether the increased certainty of diagnosis compensates for any possible danger. It is a matter of fact that the employment of the sound does not lead to any severe hemorrhages as frequently as would be supposed, although a number of cases are reported in the literature. However, there is a second danger, perforation may be caused. Perhaps the least dangerous form is that of chronic ulcer situated upon the posterior wall, but when the seat and nature of the ulcerative processes are known, it is hardly necessary to employ the sound for the purpose of further diagnosis. He therefore believes that the introduction of the stomach tube is not justifiable in cases of gastric ulcer, and he believes that the same holds true of artificial inflation of the stomach, either with air or carbonic acid. The second question is whether the stomach tube can be useful in the treatment of gastric ulcer. It is possible to imagine that it could be useful either for the purpose of removing decomposed food, or the products of catarrhal inflammation of the mucous membranes, or for the purpose of applying various drugs to the gastric mucous membrane. For the first purpose there seems to be no doubt that the copious ingestion of warm water, producing thereby vomiting, is much safer and easier. Regarding the second, Flade does not believe that catarrhal conditions are frequently associated with gastric ulcers. He therefore does not believe in the use of the sound for either of the purposes mentioned, in fact he considers that it should never be used where there is any suspicion of gastric ulcer. [J. S.]

12.—Lautenschläger accuses Hecht of having overlooked his article on the use of **hot dry air in the treatment of middle ear disease**. He also warns readers from believing that Hecht's article represents the present status of this form of treatment. [J. S.]

13.—Schultz has collected various notes from the literature regarding the employment of **belladonna in cases of intestinal obstruction**. He calls attention particularly to the work of Rademacher which apparently was due to the suggestions of Fuzet and Dubouget, both of whom use it particularly in incarcerated hernias. It has also been used by various other physicians at different times, such as Harrius, Becker, Schwabe, Mitscherlich, Larne and others, and apparently it was known to homeopaths. [J. S.]

9. The Sanitary Condition of the Large Cities of Europe in Ancient and Modern Times.

O. SCHWARTZ.

1.—Schlatter reports two interesting cases of **diaphragmatic stab wounds** occurring at the same time in two young men who were attacked by a party of Italians. The first was stabbed in the right side, immediately sank to the ground, was carried to a house and a few stitches made in the skin. When admitted to the hospital the following day he was found to be extremely anemic, the pulse small, and the respiration rapid. The knife had separated the 9th rib, penetrated the diaphragm, injured the liver at two places and entered the substance of the right kidney for a distance of more than 8 cm. In order to obtain clear working space, Schlatter resected the 9th rib for a considerable distance, and enlarged the diaphragmatic wound. He was thus able to unite the edges of the wounds in the liver and kidney. The opening in the diaphragm was then closed by silk sutures, the parietal pleura likewise sutured, and the skin wound completely closed. Previous to closing the wound a considerable amount of clotted blood was removed from the peritoneal and pleural cavities. The case pursued an uninterrupted convalescence, the dyspnea diminished steadily, and finally the patient recovered so completely that he was able to take long mountain tours. The second case was less seriously injured, the knife penetrating between the 7th and 8th ribs and involving the subjacent diaphragm. The liver, fortunately, was not injured. The 8th rib was resected, the diaphragmatic injury repaired, and the wound closed as before without drainage. The patient rapidly recovered. Schlatter discusses the indications in the first case for thorough exploration. He was particularly impressed by the extreme anemic appearance of the patient, although there was no very great accumulation of blood in the pleural cavity. He believes, in the treatment of these cases, that it is exceedingly important to enlarge the external wound in order to enable the operator to make a thorough examination of all the organs that may have been involved.

[J. S.]

2.—Joehmann and Schumm report the case of a woman, 37 years of age, who suddenly developed severe pains in the spinal column. When admitted to the hospital tenderness was found over the lumbar vertebrae, and signs of severe nephritis. In the course of 6 months an extreme deformity of the skeleton had occurred, kyphosis of the dorsal and lumbar vertebrae, prominence of the sternum, spontaneous fractures of the necks of the femurs, and in addition hemorrhages into both eyes. A diagnosis of **osteomalacia** was made and confirmed by the autopsy and the microscopical examination of the bones. During the last weeks of her life the patient secreted a turbid acid urine, which, after filtration, gave a clear brownish-yellow liquid containing 3% of albuminous bodies. These were subjected to a great variety of tests, during which it was found that, after carefully removing all true albumen, a substance was removed that gave the biuret reaction. This led to the suspicion of the presence of **Bence-Jones bodies**, and a large quantity of urine was accordingly tested very carefully for their presence. They were found, and the authors therefore regard their case as the 8th in which a true albumosuria was present and as the first case in which it has been recognized in genuine osteomalacia. The other cases were 4 of softening of the bone produced by multiple myelogenous sarcomatosis, and 3 of osteomalacia which were not confirmed by autopsy. [J. S.]

3.—Ascoli discusses the formation of lysine, especially in reference to the tissues from which it is derived. Starting with the assumption that the very small quantity of anti-lysine existing in the blood of rabbits can be greatly increased by the gradual introduction of the blood serum of dogs, he asked himself whether the same results might not be obtained by the injection of leukocytes derived from dogs' blood. If so, then it would be reasonable to assume that the antilytic bodies are derived from the leukocytes. In order to determine this point he produced an exudate in the pleural and peritoneal cavities of dogs by injecting zelluronat, from which the leukocytes are precipitated by centrifugation, and repeatedly washing in 0.85% of chloride solution. Microscopically these were found to consist almost exclusively of polymorphonuclear leukocytes.

Injection of this produced a marked increase in the antilytic activity of the rabbits' blood. Moreover, the injection of lymph expressed from the tissues of dogs killed by hemorrhage produced similar results. As it is known that lysine is composed of two substances: the intermediate or sensibilizing substance and the complement (alexin), the question arose which of these two substances was acted upon by the antilytic material derived from the leukocytes? Experiments made by adding the leukocytes to warmed as well as natural blood seemed to indicate that the substances derived from the leukocytes counteracted the substances derived from the complementary body, that is, were anticomplementary. It was, however, impossible to determine with certainty that substances counteracting the effect of the sensibilizing or intermediate bodies were present. [J. S.]

4.—Lohse reports the case of a man, 28 years of age, who suffered from cough, expectoration, loss of energy, and diminution of weight. A diagnosis was made of tuberculosis of the right lower lobe. In the year 1893 he was carefully examined and no anomaly of the heart discovered. In 1900 the right side of the chest was markedly retracted, and moved very slightly during respiration. There was no area of cardiac dullness on the left side, and on the right side a distinct area of dullness ran somewhat parallel to the 4th rib. The heart sounds were heard only on the right side. Examination with the Röntgen rays was somewhat unsatisfactory. A diagnosis was therefore made of fibroid retraction of the right lung with **dislocation of the heart**. This dislocation apparently involved 2 things. First, the rotation of the heart around its fixed apex toward the right, and secondly, the movement of the central tendon of the diaphragm in the same direction, causing total dislocation of the heart. Congenital dextrocardia was easily excluded, partly by the physical signs, partly by the very thorough physical examination made in 1893. There was no distinct disturbance of circulation. There was, however, a slight inequality in the radial pulse, the left being the smaller. [J. S.]

5.—Zezschwitz reports a case of a man, 34 years of age, who at the age of 12 had received a severe injury in the precordium. From this he had apparently completely recovered. Six months before observation he had had an inflammation of the pericardium. When examined his expression was anxious; there was orthopnea; distinct cyanosis; the area of cardiac dullness was greatly increased, and there was also a huge exudate in the left pleura. Fever was not present. The exudate in the left pleural cavity was aspirated twice, producing very marked improvement in the subjective symptoms and increase in the loudness of the heart sounds. The fluid was cloudy, yellowish-red, and contained numerous leukocytes. During the course of the case the patient developed an extraordinary dilatation of the veins of the left arm, shoulder, and neck. He was transferred to the hospital, where a thrombosis of the external jugular vein was determined. A diagnosis was made of mediastinal tumor, exudative pleurisy and pericarditis, and **thrombosis of the left innominate and its constituent veins**. The patient died, and at the autopsy a huge pericardial exudate was discovered. The pleural cavity contained 5 litres of turbid liquid; the pericardial cavity contained a large quantity of blood. The heart was small and the left innominate and the other veins were completely occluded by thrombosis. A diagnosis was therefore made of acute hemorrhagic fibrinous pericarditis, compression thrombosis of the innominate vein, and left hydrothorax. The latter appeared to be due to the thrombosis. He also reports the autopsy notes of a second case in which a left-sided pleural effusion was present, associated with hemorrhagic pericarditis and aneurysmal sac of the arch of the aorta. In this case, although there was no thrombosis of the left innominate vein, a certain amount of endophlebitis was discovered. In the final discussion of the cases, Zezschwitz is inclined to believe that isolated left-sided hydrothorax must be exceedingly rare, and prefers to hold to the accuracy of the clinical diagnosis of a pleural exudate. [J. S.]

6.—Avelis reports a case of **hemoptysis** occurring in a man who for years had suffered from chronic passive congestion of the blood vessels. The source of the blood in the first attack could not be determined. In the second, some varicose veins were found in the mucous membrane of the larynx, from which the flow had evidently been de-

rived. A diagnosis was therefore made of tracheal hemorrhage. [J. S.]

7.—Stern replies to Dr. Maul that he was not the first to suggest the composition of *Oleum Cinererum*, but that it had already been used by a number of distinguished physicians, who are convinced of its extreme value on account of the fine suspension in which the mercury is held. [J.S.]

8.—Wassmuth, in reply to Emmerich's article, contends that his method of inhalation is efficient. That by testing a number of crystals deposited upon a given area, it has shown to be at least twice as effective as Clar's apparatus, and that he considers it a great defect of Hülling's apparatus that it requires a complete saturation of the room with moisture. [J. S.]

9.—Schwartz, in reply to Galli, urges that the present sanitary condition of Italy leaves much to be desired, and that the Popes destroyed neither the sanitary nor the architectural monuments of the ancients. He discusses the advantages of goats' milk for children, but regrets that the price is at present too high. [J. S.]

1.—Jordan discusses the specific relation of the streptococcus to erysipelas. He summarizes the literature for and against a specific form of the streptococcus for this disease, and shows that it certainly does not exist, but that the streptococcus pyogenes is capable of producing either suppuration or erysipelas according to the site of inoculation, and according to the degree of its virulence. He then discusses the question as to whether the staphylococcus pyogenes aureus is the only cause of osteomyelitis, and he proves that it is not. Some years ago he reported two cases in which erysipelas was apparently caused by the staphylococcus aureus, and he reviews the literature of this subject and shows that a sufficient number of other cases has been reported by this time to prove his contention that erysipelas is not a specific disease etiologically. In fact a typical erysipelas can be produced in the rabbit's ear by inoculation with staphylococcus pneumococci, or colon bacilli. However, it is produced, as a rule, in human beings by the streptococcus, and it is uncertain whether anything else excepting the staphylococcus in a few rare instances, is capable of producing it. The disease bears a close analogy to osteomyelitis because both can be produced by several organisms; both may be serous inflammations leading to suppuration, or suppuration leading to serous involvement; both show very varied degrees of intensity, and in both pyemia and sepsis may be produced by the specific cause of the disease. [J. S.]

2.—Heinleth has collected records of 153 cases of malignant disease of the tonsils—92 various forms of carcinoma, and 61 various forms of sarcoma. The disease is usually characterized by the very slight initial change, rapid spreading to the surrounding parts, and therefore the diminished possibility of cure. Among the diseases with which they may be confused are parasitic ulcers produced by *oidium albicans* or the *leptothrix*, which are usually more superficial and often multiple; tuberculous infection; secondary forms of syphilis which are usually very superficial; chronic inflammatory hyperplasia, and various forms of suppuration of the tonsils, gumma, actinomycosis, etc. The differential diagnosis between carcinoma and sarcoma is difficult, but may sometimes be

made by means of the following table which was first devised by Honsel:

Quality.	Carcinoma.	Sarcoma.
External appearance.	Tuberculous.	Tuberculous tumor.
Tendency to spread.	Considerable.	Slight.
Dissemination in the body.	Absent.	Moderate.
General subjective symptoms.	Pain on swallowing.	Difficulty in swallowing and dyspnea.

3.—Balacescu reports the experiments which he made under the direction of Professor Jonnesco, upon the spleens of dogs. In 58 cases total ligation of the tissue coming from the hilum of the spleen was practiced. Twelve of these 58 dogs remained alive, the rest died at varying periods up to 8 days. The autopsies showed that the spleen passed through a variety of stages. First swelling, then rapid necrosis of its elements, and occasionally the formation of gas gangrene. Invariably a sero-hemorrhagic fluid was found in the peritoneal cavity which was occasionally mixed with the products of the necrosis of the spleen that had escaped through its walls. The necrosis appeared to increase with the duration of the animal's life after the operation. Bacteriological investigations of the spleen showed the presence, in a few cases, of the colon bacillus and the streptococcus. These increased rapidly in number with the duration of the life of the animal, and it is therefore certain that they invaded the spleen after the ligation had been applied. Death is not due merely to the peritonitis, but probably also to the absorption of the poisonous products of the necrosis formed in the spleen. In the animals that survived, the spleen had apparently undergone a complete atrophy, being reduced to a small, hard, white nut. In 4 dogs the blood vessels alone were ligated, and the rest of the tissues left intact. Hard white masses were found in the splenic tissue at various periods after the operation, but the spleen did not undergo much reduction in size, although a perisplenitis apparently occurred. In a third operation an artificial adhesion was produced between the spleen and the abdominal wall, and then the blood vessels ligated. A moderate amount of cirrhosis occurred in the spleen, but it did not undergo extensive atrophy. He concludes, therefore, that ligation of the root of the spleen causes gangrene of the organ, that ligation of the arteries and veins of the spleen does not interfere with the organ, because the collateral circulation is capable of nourishing it; ligation only of the arteries produces a moderate atrophy which may be increased by subsequent ligation of the efferent vessels. When an adhesion is formed between the spleen and the abdominal wall the vessels that pass through it are capable of nourishing the spleen to some extent, although atrophy occurs. Finally micro-organisms from the intestines only enter the spleen after ligation of its vessels. [J. S.]

4.—Vieth discusses the physiological action upon the bowel of a large number of synthetic chemical substances, particularly the various modifications of anthrachinon. These were all tried on cats, and their activity, or lack of it, carefully determined. After a great variety of experiments it was found that anthrapurpurindiacetate, which is commercially known as purgatin, is an efficient laxative. It occurs as a yellow powder formed of minute crystals, with a melting point of 175°. It is not soluble in water; with great difficulty in alcohol; but dissolves easily in boiling glacial acetic acid and in xylol. A solution of sodium hydrate becomes red as soon as some of this material is added to it. The active dose for human beings is .5 grms. (7.5 grs.) It produces a slight reddish discoloration of the urine, does not cause abdominal pain or tenesmus, and the effect is prompt, the evacuation occurring about 12 hours after taking the medicine. As the powder is entirely tasteless and produces no disagreeable effects, it is particularly valuable in neurasthenic cases. There appears to be considerable difference in individual susceptibility to the drug, many cases requiring doses of as much as 2 grms. before the effect is produced. [J. S.]

5.—Hofmann has devised a small apparatus which consists essentially of a pleximeter, one end of which is attached to a long handle, and on this long handle a small hammer is fastened, so that it can be lifted and allowed to fall upon the pleximeter with the movement of one finger. The object is to permit this instrument to

be used in connection with the Blanchi phonendoscope, for the purpose of outlining organs, etc., by means of auscultatory percussion. As the sound transmitted by the ordinary hammer and pleximeter is very disagreeable, Hofmann covers his instrument with a layer of soft rubber. A small scale is attached to the handle, by means of which the height to which the hammer is raised before being allowed to fall can readily be determined, enabling the observer to measure rather roughly the force employed. By means of this instrument it is quite possible to outline the various lobes of the lungs. [J. S.]

6.—Holscher reports two cases of middle ear disease, in both of which thrombosis of the sigmoid sinus was discovered at operation, although it had not been suspected, nor had it given rise to any symptoms. In the first case, a boy of 16, there was evidently empyema of the mastoid process which necessitated the operation, and in the second case the same condition complicated by a subperiosteal abscess was present. Both recovered without bad symptoms, and the cases show that the sequelae of acute inflammation of the middle ear may be benign, as well as those following chronic inflammation. [J. S.]

7.—Kreisch reports the case of a woman, a 4 para, who for a month previous to the birth of her child had suffered from severe pains in the abdomen. The child presented by the feet and was extracted as far as the knees. The attending physician then found himself unable to complete the birth, and Kreisch was called in consultation. Careful examination showed that the abdomen of the child was enormously distended, and a puncture withdrew nearly a litre of fluid. Extraction was then accomplished to the navel, when obstruction was again detected and found to be due to an enormous distention of the thorax. A considerable quantity of clear fluid was again withdrawn through the trocar, and the dead child delivered. The placenta was very large and showed fibroid and cystic change. The mother recovered. An autopsy was not permitted, but the changes in the child, which included edema of the skin, indicated the existence of nephritis. [J. S.]

8.—Wagner reports a case of a man 45 years of age who had pains in the region of the liver. Subsequently he had a swelling in the right lumbar region, which after partially disappearing, reappeared, was opened and a considerable quantity of brown fetid liquid was evacuated. From time to time fresh quantities of yellowish-brown liquid were discharged. The spinal column was not tender; the urine was normal; there were no symptoms of disease of the right hip joint; and an elastic sound could be passed through the opening as far as the right kidney. There was no free hydrochloric acid in the stomach. The patient refused operation, and at the subsequent autopsy a small round opening was found in the descending portion of the duodenum which had perforated into the retroperitoneal space, and connected with the abscess. [J. S.]

HELMUTH.

1.—Passow describes a method of relieving strictures of the nasal tear duct without producing an unsightly external scar. He performs this from the nose; first removing the anterior extremity of the inferior turbinate bone, then waiting some time until the reaction is complete, then removing a portion of the crest of the turbinate, and of the lacrimal bone, until the canal is entirely exposed. This is determined by the fact that the sound which has been placed in it becomes readily moveable. The canal is

then split as far as is necessary, the sound forced through into the nose, and the operation completed. He reports three cases, in which the symptoms of obstruction of the duct had been present for varying periods of from 4 to 15 years, that were entirely relieved by this operation. The only precautions to be observed are that the area be thoroughly illuminated and that the blood be continually mopped away by an assistant. The symptoms are not always immediately relieved, because the aspiratory function of the duct may be temporarily destroyed. [J. S.]

2.—Busse reports 3 cases of diabetes mellitus, which he believes furnish, to a certain extent, a contribution to our knowledge of the action of the acid poisoning that occurs in connection with this disease, and is presumably the cause of the diabetic coma. These cases occurred in a woman of 36, a man of 52, and a man of 54. All of them died as a result of diabetic coma, and in all there was found diffuse parenchymatous degeneration of the liver, kidney and heart. These changes he regards as toxic and probably due to the formation of beta oxybutyric acid. He suggests that the comatose symptoms are probably due to the action of this acid upon medulla oblongata, and regrets that this structure was not carefully examined in his own case. [J. S.]

3.—Paul and Sarway give a careful historical analysis of the methods of cleansing the hands before an operation, taking up in particular the series of operations suggested by Fürbringer, which consist of first cleansing the nails; second, brushing the hands and nails for one minute with soap and water; third, immersing the hands and nails for one minute in alcohol, and then without drying them—fourth, immersing them in an antiseptic liquid. Subsequent experiments have shown that this method, although efficient, does not give the absolute security that is necessary in surgical operations. This method was subsequently employed by Reiche, who ascribed to the alcohol the most efficient antiseptic action. The paper is still incomplete. [J. S.]

4.—Wyss reports an interesting case of a physician who, in falling, thrust a piece of iron into the ball of his thumb. He felt a curious burning pain, and realized that the fingers had become anesthetic. Subsequent investigation showed that the median nerve had been separated. The wound was carefully dressed, and in the course of time sensation returned to the anesthetic parts. As a result of careful studies made during the entire course of the case, Wyss reaches the following conclusions: The section of a nerve with a sharp instrument does not produce severe pain. Neuralgic pains appear in from 2 to 5 days. During healing the pains are always most severe at the point reached by the growing axis cylinders. The sensation resembles that of tickling. From time to time lancinating pains occur. In the areas of skin that have recovered sensibility, touch is painful, although not intensely so. Warm objects produce more pain than cold objects. There is reason to believe that the proximal axis cylinders pass to areas of the skin that they did not previously innervate, either by uniting with the distal axis cylinders, or by growing; they may even extend into the areas that were not previously anesthetic. In the present case they occurred in the area supplied by the radial nerve, but not in that supplied by the ulnar. There is always difficulty in distinguishing between true trophic disturbances and injuries caused by the lack of sensation. The divided axis cylinders usually grow at the rate of 2 mil. per day. They do not grow sterily, but intermittently, and each increase in length is associated with the sensation of pain.

[J. S.]

5.—Luxenberger has had the opportunity of observing 2 cases of hemiatrophy of the face. The first, a girl of 19, had suffered occasionally from severe headaches on both sides of the head, and sometimes from pains in the throat. At the age of 17 the difference in the 2 sides of the face was sufficiently marked to attract attention. There was atrophy of the soft parts and of the bones, and, as a result, considerable deformity. The second patient, also a girl of 19, had suffered severely with tooth-ache. At the age of 17 the symptoms of facial asymmetry became pronounced. The tissues were apparently normal, with the exception of wasting. In this case the extraction of some carious teeth and galvanization of the atrophic areas had no effect, and, other forms of treatment appearing useless, Luxenberger decided to employ Gersuny's method of paraf-

fine injections beneath the skin, in the hopes of removing the more serious features of deformity. His method was to insert the hypodermic needle, then suction was made in order to be certain that it had not entered a blood vessel, and few drops of a solution of nlrvanin were injected in order to produce anesthesia. The melted paraffine was injected in quantities of .25 to .5 of a ccm., and a sufficient number of injections made to produce the requisite appearance of fullness. As soon as the paraffine was injected, and while it was hardening in the tissue, it must be moulded into shape. In these cases no signs of local reaction or injury appeared. There is some reason to believe that in the course of time the paraffine may undergo a certain amount of shrinking and hardening. The other dangers are very slight, with the exception, perhaps, of embolism as a result of careless injection. [J. S.]

6.—Dehler reports a case of traumatic tetanus occurring in a woman of 48. Twelve days after the wound there were symptoms of pain on chewing and swallowing, and two days later she applied to the hospital. The wound was opened and a splinter extracted, together with a small quantity of pus. Tizzoni's antitoxin was administered on 3 successive days, the dose being 2.5 grms. of the substance dissolved in 25 ccm. of water. Chloral was also given. On the 18th day of the disease, 4 days after the institution of treatment, the muscles began to relax slightly and the patient then proceeded to a very satisfactory recovery. [J. S.]

7.—Meusel reports some interesting cases. The first case, a man of 42, was first seen with a condition that was diagnosed as incarcerated hernia. There were symptoms of complete intestinal obstruction, and fecal vomiting. At the operation coils of intestine were found, which were readily replaced, and finally a small coil compressed by a carcinoma of the mesentery. It was necessary to resect a portion of the small intestine, 19 cm. in length. The patient recovered completely, with the exception of a slight tendency to the recurrence of the hernia upon coughing. The second case, a boy of 4 years, had had an inguinal hernia for 3 years. A radical operation was attempted, the mass of intestines in the hernia exposed, when it was found that they were firmly matted together, and covered with grayish-white tubercles. These were also found upon the other intestinal surfaces. A diagnosis of general tuberculosis of the peritoneum was made, a fecal fistula was formed, and the patient left with an unfavorable prognosis. Later the fecal fistula proving irksome, an operation was performed for its occlusion, when it was discovered that the peritonitis had been completely cured. The mass of intestines was resected, involving 14 cm. of the small intestine, and 3 of the cecum. The patient made an uninterrupted recovery. [J. S.]

8.—Heinleth reports the case of a man 59 years of age, who discovered some enlargement of the cervical lymph glands. Shortly after this he noticed a tumor in the mouth, and when examined a mass was discovered extending from the right wall of the pharynx. A diagnosis was made of sarcoma, with metastasis to the lymph glands. It was determined to perform an extra-buccal operation for the removal of the tumor, and this was accordingly done two years after the first symptoms. The details of the operation cannot well be given in an abstract. It required considerable plastic work before the openings were covered. Within three weeks recurrence had appeared around the edges of the wound. These were removed by means of the galvano-cautery ligatures. The wound finally healed satisfactorily, and the patient has hitherto (2 years later) showed no signs of recurrence. Heinleth appends a very careful description of the histological appearance of the tumor. [J. S.]

1.—Schjerning believes that military surgery has recently been advanced by war, the increased technique of fire-arms, and the progressive development of surgical knowledge. Much damage was done lately by the artillery, both by bombs and shrapnel. Shrapnel shots produce all kinds of wounds, several bullets from one shrapnel entering the same individual in different directions, often carrying bits of clothing with them. Their effect is serious and infection easily follows. Bombs injure by their broken shells, which are driven with great explosive force. Snock always follows bomb wounds, which are atypical in all cases. Schjerning believes that the shrapnel will be the only artillery shot of the future. Statistics of infantry shot have multiplied recently. While the new rifles permit accurate shooting from a great distance, and one bullet may injure as many as three men, yet they are better than the kind formerly employed. The relative number of the injured has also increased. The canal is generally clean and recovery is more frequent, as are injuries to the skull. Good surgical results follow abdominal injuries. Schjerning says it is not the rifles that are more humane, but the field surgery. It seems that injuries to the blood vessels are more severe when the combatants are near one another. Deaths have decreased in the recent campaigns, from the efficiency of the field surgeon, and not from the fire-arms used. This is in a great measure due to von Bergmann's teaching. Schjerning believes that the Germans can look forward to war, without fear and with trust in their surgeons. [M. O.]

2.—Out of 63 patients, Kukula found the urine of nine only sterile, seven of whom had stone in the bladder, and two, enlarged prostate. In 54 cases, staphylococci, colon bacilli, proteus, etc., were found alone or together. Colon bacilli were present in 39 of the cases. Next in frequency as a cause of cystitis, Kukula places the staphylococcus aureus. But the worst cases of cystitis are due to mixed infection. Kukula succeeded, in a few cases, in causing cystitis in dogs by injecting these micro-organisms. Kukula reports 23 cases of suprapubic cystotomy performed after bacteriological examination of the urine. In nine of these, with stone in the bladder and sterile urine, the bladder wall was sutured completely in two rows, one above the other. In six cases of vesical calculus, complicated with cystitis, caused by but a single infecting micro-organism, the bladder was also completely sutured. It had to be opened in every case, on account of suppuration. In the remaining eight cases, cystitis and vesical calculi occurred with mixed infection. Various operations were performed in these cases. Out of 48 operations of suprapubic cystotomy for stone in the bladder in the Mayall clinic, seven died of complications which had existed before operation. Secondary infection of the bladder sutures occurs from the external wound, not from sterile urine. Therefore Kukula advises closing the external wound, in children especially. When the sutures in the bladder wall had to be opened, the resulting destruction of tissue depended upon the virulence of the bacteria and the resistance of the tissues. Therefore, Kukula believes that, when but one bacterial species exists in the urine, suture of the bladder wall is not yet to be considered advisable, even with cystopexis. He thinks that in such cases the double operation by the method of Vidal de Cassis, followed by cystopexis by the Rasumowsky method is the safest plan of treatment. This is especially true when mixed infection exists, as was successfully shown in three of his cases. From a number of experiments upon dogs, Kukula's opinion that severe, membranous cystitis was due to mixed infection, was confirmed. The technique of the operations is described. Kukula pleads for the regular bacteriological examination of the urine in all cases of stone in the bladder, cystitis, etc. [M. O.]

3.—Sprengel reports four cases of appendicitis in which

operation was performed in the first 48 hours of the illness. From these results Sprengel decided, in the future to operate early. For three of his cases were very severe, and recovered after early operation. A review of the literature upon acute appendicitis follows. Nowhere in Germany have the results of early operation approached the success obtained in America. Sprengel makes his incision along the outer border of the rectus muscle. He believes that when the surgeon realizes the exact anatomical condition in each case of acute appendicitis, the result will be an increase in the number of early operations.

[M. O.]

4.—Tilmann reports two cases of traumatism of the head. From 10 to 15 minutes after accidents headache appeared, followed by unconsciousness later. Brain injury or concussion were excluded. Tilmann diagnosed intradural hemorrhage in each case. The striking thing in both cases was that the coma became marked when the patients sat up, while it decreased when they assumed a horizontal position. Tilmann experimented upon the brains of a series of large dogs, injecting fluids of different specific gravity. But no definite conclusions could be drawn. It is plain, however, in man, that while small hemorrhages cause symptoms by direct pressure upon the brain, the severity of the symptoms shows not the size, but the position of the hemorrhage. When the hemorrhage occurs at the base of the brain, there are no symptoms. In hematoma of the middle meningeal artery, depression, or impression of the skull, the pressure symptoms are local. Though unable to find any cases like those which he reports, Tilmann believes that it is possible for a change in the position of the head to change the pressure of an intradural hemorrhage, so that a free sensorium in the horizontal position can become unconsciousness when the patient sits up. [M. O.]

5.—Kroenlein reported a case of tubercle of the left hemisphere, extirpated six years ago, with a second operation to ascertain the brain condition two years afterward. Connective tissue had filled up the cavity formerly occupied by the tubercle. The patient is living and well. He also reported a case in which sarcoma of the motor region of the brain was diagnosed and operated, yet not found. Death occurred a year and a half later, and the autopsy showed the sarcoma just where Kroenlein had searched for it. He explains his failure to find the tumor by supposing it to have been very small and subcortical in position.

[M. O.]

6.—Ekehorn reviews the history of Meckel's diverticulum. Herniae of Meckel's diverticulum have never been diagnosed before operation. He has collected 22 cases, the histories of which follow in detail. In 15, the herniae were incarcerated, one of them observed by Ekehorn himself. Fifteen occurred in men, 13 were inguinal, and the majority occurred on the right side. All 7 cases of femoral hernia were incarcerated, while only 8 of the inguinal hernia were incarcerated. Of the 15 incarcerated herniae, 10 were pure diverticular herniae; four were cured by operation, four healed with fistulae, and two died with peritonitis. Of the 7 herniae which were not incarcerated, four were cured by operation, the other three only being found at autopsy. Ekehorn concludes that, with incarceration of a pure hernia, both symptoms and prognosis are favorable. All such cases are now operated upon. [M. O.]

7.—Oelsner has made a number of injections of Gerota fluid into the lymphatics of the skin, mammary gland, pectoralis major, and subcutaneous fat. After detailing his results, he states that the external oblique muscle, on the side of the nipple toward the umbilicus, forms a submammary ligament, preventing any connection between the mammary gland and the lymphatics in that direction, that the lymph glands, beside functioning as filter and creator of lymphocytes, act also as a pump to keep the lymph stream moving; and that other lymph glands exist, which have never been described, on the dorsal surface of the scapula near its inferior angle, and in the fifth intercostal space in the midaxillary and midclavicular lines. Oelsner concludes that the mammary gland sends two, rarely three, large lymphatic vessels to the anterior thoracic glands upon and under the edge of the pectoralis major in the second or third interspace, and through these to the subpectoral and subclavian, but not to the supraclavicular

glands at birth; that those lymphatics which perforate the pectoralis major and intercostal muscles carry off lymph normally, just as do the axillary vessels, that lymphatics originating in the pectoralis major were not, with certainty, found; and that no lymphatic vessels were discovered in the subcutaneous fat. From this it is plain that, no matter how radical the operation, some cancer tissue is bound to remain. Yet the results will differ according to the susceptibility of the individual. The most radical operation will include extirpation of the subclavicular glands, which are the last to be affected.

[M. O.]

8.—Billinger discusses the origin of traumatic herniae. By traumatic hernia he means a hernia which follows at once or within a few days after some forcible accident; further, there must have been no latent hernia or empty hernial sac previously. He reviews the subject, experimentally and clinically, and reports a case of traumatic hernia through the perforated abdominal muscles, which was cured by operation. After quoting a few cases from the literature, Billinger reports two more cases of his own, with traumatic hernia in the linea alba. He concludes that, though seldom, traumatic hernia does occur. It is found by autopsy at once after the accident. While it is generally not seen where ordinary hernia develops, traumatic hernia may be inguinal, femoral, or umbilical. It is caused by direct force at the point where the hernia appears. [M. O.]

9.—von Bruns reports the results of Honsell's experiments upon dogs and men. He found that concentrated carbolic acid was much less apt to produce poisonous symptoms than diluted carbolic acid; and that most bacteria were killed by it inside of a minute. Not only is it indicated in hydrocele, but he has employed it in 80 cases of septic processes, wounds, abscesses, mastitis, suppurating joints, etc. One application of pure carbolic acid exerts a favorable influence upon a septic process. The effect of pure carbolic acid is not weakened by the secretions from the wound. [M. O.]

10.—Braun has experimented with mixtures of ether and chloroform of different strengths. At low temperatures the ether only evaporated, while at high temperatures both the ether and the chloroform evaporated equally. Physiologically the effect of the ether-chloroform mixture, well diluted with air, is the same as that of chloroform with air. Out of 400 administrations of the mixtures, nothing serious occurred. Experience taught Braun that ether narcosis was often made easier by adding little or more chloroform. This led him to construct an apparatus which is fully described in detail, with diagrammatical illustrations. By means of this apparatus the amount of both the ether and the chloroform used can be regulated. His apparatus is not too complicated to be generally useful. [M. O.]

11.—Bler reviews the work upon spinal anesthesia done since his paper was published. One thousand two hundred operations have been performed by this method of anesthesia. He has made a series of experiments with tropacocain, nirvanin, holocain, eucain, etc., in concentrated and diluted doses. From this he noted that when diluted with much water the effects were visible higher up the spinal cord; that very small doses cause sufficient analgesia to permit all sensations except that of pain; that the sequelae are not due to the size of the dose injected, but to the level in the cord to which the fluid rises; and that dangerous accidents have not been observed. Patients must remain in bed on their backs for some days after spinal injections. Lumbar puncture should be performed upon the convex, not the concave, side of the vertebrae, while the patient lies on his side. The technique should be perfect. Finally Bler admits the priority of Corning's work in this direction. [M. O.]

12.—Tschudy reports a case of tracheal stenosis from the pressure of an enlarged thyroid gland. This patient had existed for twenty years, in a woman of 30. It was mainly on the right side, almost as large as a human head. In circumference it measured 53 cm. During operation for removal of the tumor, the patient stopped breathing. A catheter was at once introduced, down to the bifurcation of the trachea. With artificial respiration, breathing began through the tube in about 10 minutes. The operation

lasted two hours, and the patient recovered. Tschudy reports this result to show that tracheal intubation is to be preferred to tracheotomy when such accidents occur.

13.—Kroenlein, who reviews the subject of total resection of the upper jaw for tumors, calls attention to the different mortality statistics of the various operators. The main cause for the unusual mortality he believes to be the narcosis, as more than half of the cases develop affections of the respiratory tract. The result appears to be the same, whether ether or chloroform is used. Some surgeons operate with the head elevated, others with the head depressed. But Kroenlein advises stopping the anesthetic while performing total resection of the upper jaw. He reports 35 cases of total resection of the upper jaw performed by him in the past twenty years without anesthesia. He uses ether up to the first skin incision, giving a little morphin before operation. The patient sits up straight, his head bent forward. Of the 35 cases, but one died, with septic meningitis, on the sixth day. His patients ranged from 18 to 73 years of age. [M. O.]

14.—After a thorough review of the operative treatments of uterine cancer, Jordan concludes that for carcinoma uteri, limited to the uterus, vaginal hysterectomy is the treatment; and that abdominal hysterectomy, on account of its dangers, should only be performed where vaginal hysterectomy is absolutely impossible. Jordan prefers the operation by Schuchardt's paravaginal method. He considers this especially favorable in early diagnosed cases of cancer of the uterus. The literature of the subject is fully cited. [M. O.]

15.—Schuchardt describes in detail the technique of paravaginal hysterectomy, first performed by him for uterine cancer in 1893. Illustrations accompany the article, explaining the operation. In six years he has operated upon 90 cases, 11 of whom died. 83 of these were uncomplicated, 8 of whom died, a mortality of 9.6% only. The wound heals in from one to two weeks, leaving a tiny scar. Of 42 cases operated upon over two years ago, 15 are absolutely cured (35.7%); of 25 cases operated upon over five years ago, 10 are absolutely cured (40%). Compared with other operations, Schuchardt's results seem marvelous. He did not, however, operate upon any far advanced cases, or upon those with many metastases, cachexia, etc. He believes that better results are to be expected by his operation of paravaginal hysterectomy than were formerly obtained. [M. O.]

16.—Duehrssen reports the results of 875 operations of vaginal cellotomy. His mortality in the first 500 cases was 3%; in the next 200, 2% only. The possibility of any disturbance during child-birth later is prevented by suturing

his incision to the peritoneum covering the bladder. 37 children have been borne by women, who have been operated upon by Duehrssen, without any trouble. In 700 of the cases, retroflexion or retroversion occurred, generally with various diseases of the adnexa, or chronic pelvic peritonitis; in 300 cases one or both tubes were removed, (28 being cases of tubal pregnancy); in 70 cases ovarian tumors were extirpated. Salpingostomy was done in 200 cases. 57 myomectomies were performed, with 6 deaths. During 1900 he performed 133 conservative vaginal to only 26 conservative ventral cellotomies, and 51 ventral total hysterectomies. Only 21 times out of the 875 cases was he forced to do abdominal cellotomy or vaginal hysterectomy, after anterior colpopelviotomy. Besides, Duehrssen concludes from his experience, that anterior colpopelviotomy is to be preferred to posterior colpopelviotomy. [M. O.]

17.—Lotheissen, after reviewing the work done in suturing tendons and nerves, describes a gelatin tube which he has had prepared for use in such cases. This is hardened in a 2% formalin solution, and sterilized by dry heat. The tubes are kept in 96% alcohol. Experiments upon animals show that the tubes are absorbed in from one to two months, depending upon the length of time they are left in the formalin. They are useful in the direct suture of torn nerves and tendons. He has used them in seven cases thus far, with excellent results. High temperature will increase the rapidity of their absorption. For suturing tendons Lotheissen advocates a tube which has been hardened in formalin 48 hours; for suturing nerves, one which has been hardened 72 hours; and for nerve defects, one which has been in the formalin solution for six to seven days.

[M. O.]

18.—Ehrhardt made a series of experiments upon cats and dogs, to determine whether the flow of bile into the peritoneum produced poisoning. Jaundice followed in every case. When a bile duct fistula was left, symptoms occurred which resembled icterus gravis, with death in from two to six days. Jaundice was widespread, and the peritoneal fluid was sterile. No peritonitis occurred. The bile was absorbed by the peritoneum. Even the thoracic duct was filled with bile. In a few cases infection or cholemia produced death. Some reported cases in human beings confirm Ehrhardt's experiments. He concludes that the absorption of a large quantity of bile from the peritoneum produces poisoning and death. The treatment of these cases, with rupture of the bile ducts or serious congestions of the liver, should be by laparotomy, to prevent, by removal, the absorption of the bile by the peritoneum.

[M. O.]

19.—Stempel first reviews the subject of hemoglobinuria in full, giving the etiology, classification, treatment, etc. He then relates his own experience. A healthy man of 36, he had constructed in his operating room a gas stove, which heated the room by keeping water, circulating in the pipes, hot. This, when lighted, created an unpleasant odor. It was kept burning almost constantly. Stempel grew pale, and ill, and he noted that his nurse became ill after all long operations. Those who came to see him operate, left with severe headaches. One day, after an operation, he had a chill which lasted several hours. Albuminuria first appeared, then hemoglobinuria, with marked oliguria. His temperature remained high for four days. In the three weeks the albumen and hemoglobin had disappeared from the urine. Five weeks after the beginning of the attack he left for Italy to recuperate. Two weeks after his return, after another operation, he had a second attack of hemoglobinuria. Not until two months later was he again back at work. The only known cause of these attacks was the intoxication produced by the illuminating gas. Mice exposed to the apparatus died very quickly. Since the chemical products of illuminating gas are not as yet well studied, the specific cause of the intoxication and hemoglobinuria remains unknown. But Stempel insists that gas should not be burned in any operating room.

[M. O.]

20.—Henle states that pneumonia commonly follows the operation of laparotomy. Out of 1787 operations, pneumonia occurred in 143 patients, 65 died. The great majority of these pneumonias are lobular in character. As a rule pneumonia develops in the three days after operation. The morbidity increased with the age of the patient, as did the mortality. The greatest number of laparotomies was performed upon patients between 40 and 50 years of age. Pneumonia occurred most often with jejunectomy, incar-

cerated umbilical hernia, and resection of the stomach. It occurs a little less frequently when infiltration anesthesia is used than with general anesthesia. Allowing the body to become cold during the operation formerly predisposed to pneumonia, as did cold irritation of the abdominal cavity. The disturbance to respiration from opening the abdomen predisposes of pneumonia, in men especially. Hematogenous infection may cause pneumonia, and aspiration pneumonia may easily develop. Septic pneumonia is especially fatal. From his observations, it is most important to prevent the patient catching cold after operation. Ventilation should be good, and care should be taken to prevent all of the above mentioned deleterious influences from acting. Then pneumonia will become less frequent after laparotomy. [M. O.]

21.—Stitch abscesses develop at once after operation, or months later. In the former the thread was infected from the wound, in the latter it became infected in the wound. These have been known to develop five years after operation. From sections made by him, Haegler demonstrated myriads of bacteria in the thread itself. But generally some slight traumatism causes the stitch abscess, even though the thread was filled with microbes for years. While experiments showed that bacteria increased in silk thread, both that sterilized by steam and by corrosive sublimate, it was seen that they did not multiply in cat-gut. Silk-worm-gut is the material found most free from bacteria. Yet all suture material may be infected, and thus stitch abscesses will remain a common occurrence in surgery. Haegler adds a few technical details for the preparation of such material. [M. O.]

22.—Cancer is the only tumor found in the pancreas primarily. It is generally situated at the head of the pancreas. The operations already performed are quoted by Franke; then he advises total extirpation of the pancreas early, before any other organs are also affected. He has operated upon four cases of pancreatic cancer, and reports the case-histories in detail. Total extirpation was followed by recovery without permanent glycosuria. Death followed later in every case, but was not the immediate result of removal of the pancreas. In the first case the cause of death was hemorrhage; in the second, infection; in the third, gastric metastases; and in the fourth heart failure. Though all died, no permanent glycosuria or steatorrhea was observed after extirpation of the pancreas. Glycosuria did occur in one case, lasting only two weeks. The symptoms of pancreatic cancer are pain in the epigastrium, gastro-intestinal symptoms, emaciation, weakness, and then the tumor, jaundice, enlarged liver, spleen, edema, etc., follow. Exploratory laparotomy is advised to secure an early diagnosis. [M. O.]

23.—Kelling reports a case of acute dilatation of the stomach in a girl of 16, who wore a plaster jacket for scoliosis. Acute dilatation of the stomach occurred suddenly with the symptoms of collapse, three days before Kelling saw her. Her heart kept her up, though she lost 19 pounds. The gastric muscles were so badly paralyzed that even after two weeks of lavage, remains of food were found in the fluid returning. Immediate lavage, repeated at intervals, normal salt enemata, and a well regulated diet cured the condition. Her stomach from the scoliosis, was probably vertical in position. When overfilled, it compressed the duodenum as it could expand in no other direction. Then dilatation followed. Three similar cases have been reported. Kelling experimented upon 16 cadavers, from which he concludes that a fold in the intestine is not always found, but when found, it is generally situated in the duodenum. Infectious diseases, traumatism of the central nervous system, gastroparesis, pyloric stenosis, gall stone operation, bandages, etc., predispose to acute dilatation. When the duodenum or jejunum is closed by compression, and the stomach cannot be relieved by vomiting, from stenosis of the cardiac orifice, dilatation must occur. If after lavage for 12 hours, no bile is seen in the fluid returning, laparotomy should be performed. Should there be compression of the mesenteric arteries with the small intestine in the pelvis, the pelvis should be tamponed. [M. O.]

24.—Borchard considers gastrostomy with Schleich's local anesthesia absolutely without danger. He has performed 11 gastrostomies in the past four years, and has always secured a fistula which closed wholly. In most cases the power of swallowing returned almost at once, even in patients with impermeable stricture of the esophagus.

Only two of his 11 cases died, though some of the other strictures were carcinomatous. The one danger to be feared is acute dilatation of the stomach. A number of his cases are reported in detail. [M. O.]

25.—Ahrens reports a unique case of fetal inclusion in a girl of 17. She had always had a prominent abdomen. A cystic tumor was found in the left hypochondrium, reaching almost to the pelvis. Albumin and pus were seen in the urine. Laparotomy revealed a cyst containing four liters of hemorrhagic fluid, in the mesentery of the ascending colon. This was wholly removed, and she recovered rapidly. Examination of the cyst showed it to be both gastric and intestinal in parts, with peptic ulcers and hemorrhages. This probably began to grow in the fifth month of fetal life, and was then included in the mesocolon, retroperitoneally. Its origin was from the left upper abdominal colon of the fetus. [M. O.]

26.—Franke reports a case of right pes equinovarus and left flat-foot, in a girl of 4. On the right side he performed forcible reduction, with lengthening of the tendo Achillis by Bayer's method. When he attempted to shorten the tendons of the tibialis posticus and tibialis anticus, he found them adherent to their coverings. Franke detached the insertions of the tibialis anticus and sutured them into the tibialis posticus tendon. This was left in plaster over two weeks without success. Then he made another incision and sutured the tibialis anticus tendon to the first phalanx of the middle toe. The child can now walk well with or without shoes. Flat-foot is rare compared with club-foot. The cause of this flat-foot was the abnormal insertion of the tibialis anticus tendon, due to an anomaly of development. Shortening of the tendons is impossible when inflammation has existed with the formation of adhesions. The operation was only done as a last resort, not to effect a cure, but to improve the deformity. [M. O.]

27.—Kroenlein describes three pairs of bullets, probably due to one bullet hitting the other where it had already lodged, the two becoming welded together. Photographs of the three paired projectiles are given. [M. O.]

28.—Kocher generally excises that half of the goiter in which pressure seems the greater. Enucleation is only done when the goiter recurs. Of these 1000 cases excised, 929 were benign, with four deaths only. In 24 cases exophthalmic goiter existed, operated upon with two deaths; in 20 cases, strumitis, with two deaths; and in 27 cases, malignant struma, with six deaths. Hemorrhage and infection are no longer to be feared. Antiseptics were not used, simply normal salt solution. When the goiter is large, thyroid prophylactic treatment should be given before operation. Cocain anesthesia alone is used. In some cases the goiter lies mainly in the thorax. This variety of goiter causes dyspnea, emphysema, bronchitis, tracheal stenosis, heart symptoms, etc., depending upon whether the goiter is wholly or partially in the thorax. Kocher divides these symptoms into the cardiac, pulmonary, and mediastinal groups. The intrathoracic goiter may simulate exophthalmic goiter. This deeply seated goiter may be movable or immovable. There is dulness over the manubrium sterni, and the condition is revealed by Röntgen photographs. Here there is danger of hemorrhage during operation. Kocher operated on 22 such cases in his last 1000 goiter excisions and not one of them died. Experimentally, phosphorus seems to decrease the iodine in the thyroid gland. Kocher uses it in most cases, after excision of one half, in chronic iodism, hyperplastic, vascular and exophthalmic goiter. [M. O.]

29.—Treated editorially Philadelphia Medical Journal, August 31, 1901, page 326.

30.—Von Hacker states that operation is often too long delayed in case of periesophageal and mediastinal abscesses. He reports in full two cases operated upon by him. In one, a woman of 62, death followed in spite of neck incisions with drainage of the mediastinum. Emphysema of the skin of the neck occurred. In the other, a woman of 37, the same treatment, undertaken earlier, resulted in recovery, with a small fistula in the neck remaining. In this case perforation of the esophagus occurred. The endoscope was used to determine whether the esophageal perforation was to the right or left, in order to decide upon which side to operate. Röntgen photographs also helped in deciding upon right-sided operation. von Hacker believes that only when no improvement follows drainage through a neck incision, a counter-incision

should be made in the back. Other cases in the literature are quoted. Finally von Hacker describes in detail the technique both of collar and dorsal medlastinotomy. The Röntgen photographs follow. [M. O.]

M. BLUMBERG.

31.—After reviewing the various modifications of the technique of *uranoplasty*, von Eiselsberg describes his plan of operation, the von Langenbeck-Billroth method, using Billroth's anesthetic mixture in the Junker apparatus. The head, held securely by an assistant, hangs down, the neck being hyperextended. He uses Dieffenbach's needle-holder, with silver wire sutures. Iodoform gauze is left in the wound. Five extraordinary operations are then described in full, with numerous photographs. In a child of 4 he performed *uranoplasty* by employing a pedicled flap of skin from the forearm to close a bilateral cleft palate. In two cases of anterior *uranocolobosis*, he closed both clefts by using the mucous covering of the intermaxillary process. In three cases of unilateral cleft palate, he employed flaps from the vomer. In a case of anterior *uranocolobosis* in a girl of 19, he implanted a little finger, which at the same time raised a deep sunken nose. He appends the description of a case of *rhinoplasty* in a girl of 17, in whom a flap from the upper arm, with a bit of a boiled tibia, replaced a nose almost wholly wanting. Röntgen photographs show the bits of the tibia in good position in the nose. The results in all cases were excellent. [M. O.]

32.—Cancer of the breast has been more successfully studied during the past 25 years than cancer in any other part of the body. The prognosis is now much less unfavorable than it formerly was. Guleke has collected the histories of 982 patients with cancer of the breast, upon 835 of whom von Bergmann performed 943 operations. Cancer of the breast is most common between 40 and 60 years of age, the average among his cases being 49 years. Out of 552 women affected, 550 have borne children, 29% of them having at some time had mastitis. In 16% of the cases cancer had already occurred in the family. In half of the patients one breast, in the other half the other breast was affected. Both breasts were diseased in only 6 cases. Cancer is mainly found in the upper outer quadrant of the breast, the majority of the tumors being *scirrhous*. Guleke found the skin adherent on an average of about the twelfth month; the axillary glands infiltrated about the eleventh month; the pectoral muscle adherent about the thirteenth month; and ulceration of the skin about the sixteenth month. About seven months after the axillary infiltration the supraclavicular glands enlarged. Metastases were found most commonly in the liver, the other breast, lungs, pleura, stomach, etc. The prognosis depends upon the condition of the tumor and the method of treatment. The breast with all infiltrated glands was removed in 833 patients, 26 of whom died. While a woman with untreated cancer of the breast may live about twenty months after the tumor appears, accord-

ing to the von Bergmann statistics, she should live thirty months or more with the modern operation. In 236 cases there was recurrence. Out of 282 cases which have been carefully followed since operation, 110 have had no recurrence, a permanent recovery of 28.75%. Guleke advises removing the sternal portion of the pectoral muscle in some cases only, not as a routine practice in every case. [M. O.]

33.—Kuester gives a concise and thorough review of the progress made in renal surgery in the nineteenth century. Pain, swelling, and the changes in the urine may show the character of the kidney affection. Cystoscopy and catheterization of the ureters were employed to aid in forming the diagnosis. And lately, cryoscopy, the phloridzin method, and the examination of the kidney freely laid open by operation, have come into use, assuring a certain diagnosis. Naturally, following the introduction of these methods, the treatment has also changed. Nephropexy is done for floating kidney; suppuration of the kidney, primary or secondary, must be evacuated early; while tuberculous kidneys should be partially extirpated. Röntgen photographs confirm the diagnosis of renal calculus. For most nephrectomies, Kuester prefers the lumbar incision. [M. O.]

34.—Kuemmell believes that cryoscopy of the blood and urine, after simultaneous catheterization of both ureters, with the examination of the urine, makes certain the diagnosis of the condition of each kidney. Normal human urine freezes at close to 0.56° C. below distilled water. When under 0.58° C., both kidneys fail to functionate properly, and renal insufficiency exists. No operation should be performed until the freezing-point of the blood reaches 0.56° C. Kuemmell describes the technique of cryoscopy in detail. Besides cryoscopy, cystoscopy is employed and the uric acid is estimated. The phloridzin test is also used. When a large tumor exists in the kidney or any other abdominal organ, the freezing-point of the blood may be lowered, though the kidney remain sufficient. When the freezing-point of the urine from one kidney is under 0.9, that kidney is probably insufficient. Kuemmell gives a number of tables showing the results of cryoscopy in different diseases, renal conditions for which nephrectomy was done, chronic nephritis, tumors, calculus, etc. He lays great stress upon cryoscopy in the diagnosis of renal affections. [M. O.]

35.—Katzenstein reports two cases of concealed spina bifida recently observed by him. One was in a girl of three, with lordosis, right-sided flat-foot, paralysis, and atrophy of the right leg. In the other case, a boy of 17, there were ulcers of the left foot and buttocks, incontinence of urine and feces, left dorsal scoliosis, long hair over the spina bifida, and the left leg much shorter than the right. In this case, the third case of concealed spina bifida successfully operated upon, the tissue connecting the skin and the spinal column was removed. Katzenstein describes the condition as a slit in one or more vertebrae, the skin over it being normal, not prominent. It follows either deficient separation of the medullary canal from the ectoderm, or a meningocele. Its characteristics are a connection between the skin and the spinal column, an opening in the vertebral canal, and a muscle tumor about the vertebral canal. The spinal column may be normal or it may show changes due to the opening itself, to traction, or to pressure. These may cause secondary disturbances *in utero*, in childhood, or at puberty. When uncomplicated, the prognosis of concealed spina bifida is excellent. After trophic disturbances appear, there is danger of sepsis. When secondary changes have occurred *in utero*, nothing can be done; when in childhood, the posterior uniting membrane should be divided. When at puberty, the tissue between the spinal column and the skin must be extirpated. [M. O.]

36.—Langer reports the successful extirpation of a large hemangioma of the liver in a woman of 37, who had noticed a growing tumor during two years, on the right side, above the umbilicus. The tumor (21 by 21 by 11 cm.) was removed with much hemorrhage. Since the operation she has born another child, which she is now nursing. She seems quite well. The angioma contained 1½ liters of blood, and weighed, empty, 2½ kg. It arose from the under surface of the left lobe of the liver. The literature of the subject is fully reviewed. An attempt to determine the diagnosis by inflating the intestines was useless, the inflated intestines surrounding the tumor in such fashion

that its connection with the liver was not suspected. The diagnosis was first floating kidney, then, from the fluctuation, mesenteric cyst. Its communication with the liver being only noted upon operation. Diagrams show the histology of the tumor, a true cavernous hemangioma.

[M. O.]

37.—After operation upon local tuberculosis of the bones, joints, cold abscesses, etc., care must be taken to prevent secondary infection. Iodoform, which was supposed to exert a specific action upon tuberculous tissue, has been shown, by the experiments of Fraenkel, to do nothing of the sort. It causes chemotaxis, vascularization, and proliferation, separating off the tuberculous process, that it may later be absorbed. Other sterile powders will have the same effect as iodoform, without causing the inflammation which accompanies the iodoform injections. This was especially the case with animal charcoal, which Fraenkel employed in his experiments. He used this later, in glycerin emulsion, with great success upon human beings. There is no possibility of injury from animal charcoal.

[M. O.]

38.—After reviewing anesthetics, their advantages and disadvantages, Wohlgemuth describes in full the apparatus which he has constructed for the administration of chloroform with oxygen. Photographs show its details. He reports its use in 182 cases, a table giving the important points in each case. Patients never fight against it, nor do they complain of suffocating. There was not one case of cyanosis, disturbed respiration or pulse. Only five cases showed excitement and only 20% vomited, they having had no preparation for operation. The exact number of drops of chloroform used is noted by this apparatus, as is the percentage of the oxygen in the mixture. The chloroform is inhaled as a vapor. The literature of the subject is cited. [M. O.]

39.—Röger reviews the seven cases of injuries to the skull from gunshot wounds which Kroenlein reported at the German Surgical Congress held two years ago. In two of these cases recovery rapidly followed, the intracranial pressure diminishing upon deep inspiration. Röger agrees with Kroenlein in his conclusions, believing that the effect of hydraulic pressure showed in all these cases of gunshot injuries of the skull. [M. O.]

40.—Occasionally after inflammation or injury of the knee-joint, the patella may become adherent to the femur. There is no ankylosis of the rest of the knee-joint. The attachment may be fibrous or bony, but it is difficult, even when aided by Röntgen photographs, to tell which change has taken place. Cramer has operated upon 7 of his 10 cases of ankylosed patella, with successful recovery in six of them. In one case, the history of which follows in detail, one patella showed bony, the other fibrous connection. Both were easily and well movable after operation. On the fibrous side, as in five other cases, simple resection of the patella was done, followed by rest for one or two weeks. Then the ankylosis was forcibly broken, and mechanical movements, massage, baths, etc., were kept up for months. In only one case was it necessary to interpose part of the vastus internus muscle between the femur and the patella, to prevent ankylosis reforming. The other case-histories are given, and many opinions cited. [M. O.]

41.—Out of 150 cases of circumscribed perityphlitis, operated upon between attacks by Rotter, there has been but one death. In diffuse perityphlitis, Rotter waits until the third day; then, if fever, pain, etc., persist, he operates. Of 100 cases of diffuse perityphlitis, abscesses occurred in Douglas's pouch in 70 cases. Rotter opened 61 of these abscesses through the rectum in the male, or the vagina in the female, 10 of these patients dying. Of the other nine, evacuated through the abdominal wall, six deaths resulted. Rotter believes that irrigation of the abdominal cavity during the operation for perityphlitis generally spreads the infection throughout the peritoneum. It is hardly ever advisable. He concludes that the mortality is much less following evacuation of the abscess in Douglas's pouch through the vagina or rectum than through the anterior abdominal wall. [M. O.]

42.—After a complete review of the resections of the cervical sympathetic for epilepsy, Braun reports nine such operations performed by him. In all but one case, the operation was performed upon both sides of the neck. The upper ganglion, the middle ganglion, and the nerve as high as the inferior thyroid artery were removed. The

technique of the operation is described in full, with photographs of the nerves and ganglions extirpated. One man died of pneumonia two days after his second operation; another died during an epileptic attack, after the operation wound had healed. Three patients have had many light epileptic attacks since operation. Three of the remaining four patients, all of whom were also insane, seem to have had less frequent attacks, and to be less clouded mentally than they were before operation. Though the operation is not dangerous, there are not yet enough observations reported to show favorable results from it.

[M. O.]

43.—Payr describes a case in which he sutured a large vein, after extirpating a carcinoma of the left groin, in a man of 67, 4.5 cm. of the femoral vein were resected, the ends being joined by the use of a circular magnesium plate. The next few days showed that the circulation of that leg was perfectly maintained. On the third day after operation the patient died of broncho-pneumonia. The autopsy showed the absence of any blood about the site of the operation, and the presence of circulating venous blood in the vein above and below the point of operation. Only a slight trace of thrombosis could be found upon the intima of the vein. Upon one side the intima of the joined ends had already grown together. Histologically, the intima was thickened, the media contained many round cells, and the adventitia showed an increase in all kinds of cells. The absorption of the magnesium plate probably follows from the necessity of the tissues to draw water from all sources, absorbable magnesium oxide resulting. The technique of the operation, photographs of instruments and of the conditions found at the autopsy, are all described in detail.

[M. O.]

44.—Ehrhardt performed a series of experiments upon dogs, operating aseptically, and then treating the wounds with boiling water. This was sponged out in a minute, and the wounds healed rapidly. Caustics, on the contrary, caused the formation of a thicker membrane, which prevented further penetration of the liquid. In operations in which it is feared that a tumor may become implanted from the tissue remaining after extirpation, the use of boiling water, in contact with the wound for one-half to one moment, seems to destroy all bits of the tumor tissue left. Ehrhardt uses about 25 c.c. in each case. Recurrence is thus prevented. [M. O.]

45.—Blumberg describes his experiments upon animals to show the value of mercuric sulphate-ethylendiamin as a disinfectant for the skin. He concludes that it is not inferior to corrosive sublimate in power; that it never irritates the skin, even in strong solution; that it can therefore be used in more concentrated form than corrosive sublimate; that its effect goes much deeper than corrosive sublimate; and that it will soon be prepared in tablet form, the tablets dissolving at once, not causing the waste of time necessitated by waiting for corrosive sublimate tablets to dissolve. [M. O.]

1.—Ebstein has for years observed that one can feel the rectum when it is filled with feces in the fold between the buttocks on the left side. The patient is best examined when lying on the left side. It was also observed that stroking this sausage-like tumor produced by the full rectum caused the expulsion of feces, and the tumor then disappeared. Ebstein has, therefore, used, and now recommends for the treatment of constipation postero-anterior massage of this

region. This can at first be carried out by the physician, and afterward left to the patient. Electricity may well be applied along this groove also. The results are said to be very good, and one can thus avoid any intra-rectal irritating applications, such as glycerine suppositories. Ebstein also states that this is a satisfactory method of overcoming rectal impaction of feces, and it is much more esthetic than the usual method. [D. L. E.]

2.—Voleker contributes a very sarcastic article on Schuler's cancer parasites, concerning which the latter author has written a book of considerable size. Voleker could not find the parasites at all until he used a bergamot oil which had been for a long time in a bottle with the cork stopped. He then found large numbers, and upon examining the oil found that it contained quantities of Schuller's so-called parasites. Since Schuller always cleared in oil, it is almost certain that his parasites were really cork cells, for it is known that aromatic oils dissolve cork to a certain extent, and Voleker readily demonstrated this action himself. [D. L. E.]

3.—The soap is best produced by using a vegetable-fat soap; 60 to 90 gm. of this is cut fine and dissolved on a water bath in 300 ccm, 96% or 97% alcohol, using a condensation cooler. 700 ccm, alcohol should then be added, bringing the amount to 1000 ccm., and 300 gm. of finely pulverized pumice stone (previously sterilized) is added gradually, the mixture being thoroughly shaken constantly and allowed to cool, only slowly. This soap should then be kept in air-tight receptacles. Bacteriological investigations of the effect of its use showed that it gives satisfactory results, and it does not irritate the hands as much as the use of the brush and active chemical disinfectants, and Pforinger recommends it for use in armies, in country practice and under other circumstances when elaborate aseptic procedures are impossible. [D. L. E.]

4.—Uhlenhuth reports a series of instances in which he made a diagnosis of the presence or absence of human blood in specimens sent him by request by the city medical officers, the latter knowing in each instance whether the specimen was human or not. His diagnosis seems to have been correct. Also in a series of cases he was able to diagnose horse's blood, pig's blood and other forms of animal blood. He finds that the blood of closely related species reacts with the same serum in some instances; for example, pig's blood antiserum reacts with boar's serum (weakly) and horse blood antiserum with ass blood (very weakly); but these exceptions are not sufficient to interfere with the forensic value of the test. A more important matter is the fact that active sera cannot always be produced, and the serum should invariably be carefully tested before it is used. This point makes it desirable that the production of any such serum when it is to be used for medico-legal purposes at any rate, should be restricted to a well managed, properly authorized institute in order that errors may be avoided, and the usefulness of the test not impaired. [D. L. E.]

6.—The result of the chemical study of milk before and after Pasteurization in Hippius' apparatus was to show that the specific gravity, reaction and amount of fat, casein and sugar showed practically no change. If the Pasteurization is carried on for hours (eight to twelve) the same changes as those seen after sterilizing appear; i. e., the specific gravity becomes reduced, as does the amount of organically combined phosphorus and of fat, sugar and casein. Under these circumstances the acidity increases also, while after sterilizing it decreases. The action of the milk curdling ferment was at first delayed by Pasteurizing after six hours, increasing in rapidity beyond the normal, the increase corresponding to the increase in acidity. The coagulum after Pasteurizing formed in a jelly-like mass; after sterilizing it was in the form of loose clumps. Pasteurized milk did not color lead-paper; sterilized milk colored lead-paper brown. The effect on the number of bacteria in normal milk, on milk infected with various bacterial cultures, and on milk to which cow-dung was added was then studied. Normal milk showed as high as 89,000 bacteria to the ccm. before Pasteurizing, while the same specimen showed 2280 after fifteen minutes Pasteurizing at 65°C. and none after two hours. In the raw milk to which cow dung was added innumerable bacteria were found; after two hours Pasteurization only 288 to 576. Tubercle bacilli withstood Pasteurization for five minutes, but were killed after fifteen minutes. Streptococci were killed after thirty minutes; diphtheria bacilli after fifteen

minutes. Hence two hours Pasteurization may be considered wholly satisfactory, and the result is still better if subsequent fractional Pasteurization is carried out in the thermophore. This does not alter the taste or the value of the milk in any way. [D. L. E.]

7.—Hoppe records the case of a man of 35, who had an acute attack of indigestion after eating mushrooms, and made violent efforts to rid his stomach of the offending material by vomiting. He had a free secretion of tears, and afterwards an unpleasant feeling of tension in the eye-balls, which seemed to be pressing against the lids. Nasal breathing was difficult, mucus from the nose was blood-tinged, and when the man inspected his countenance in the mirror he was horrified to find that his face was swollen and of bluish color. Hoppe found innumerable small hemorrhages scattered over the whole of the upper half of the face and over the forehead, the eye-lids were much swollen and presented everywhere subcutaneous hemorrhages. The palpebral conjunctivae were covered with hemorrhages, the ocular conjunctivae were free. There was no disturbance of sight. The case ended in practically complete recovery within a few days. Nine similar cases of hemorrhage from the skin of the face and conjunctivae are reported from the literature. Hoppe goes into an extensive theoretical discussion of the cause, deciding that it is due to sudden increase of the blood pressure in the thorax, and consequently above the thorax, by any occurrence, such as vomiting, abdominal injury and the like, which increases abdominal tension greatly or has a very decided reflex action on the other vessels. The reason that the hemorrhages then occur in certain regions, and not in others (it is, for instance, extremely rare within the cranium if there is no arterio-sclerosis) is that the hemorrhage, in Hoppe's belief, actually results from the wave-like impulse given by renewed efforts at vomiting, for instance, to the blood contained in the vessels, the pressure in the thorax, the above being already very high. This wave is broken by the cranial bones, and hence is not carried into the cranial vessels. [D. L. E.]

3. On a Typhoid-like Disease Produced by a Previously Undescribed Bacillus (*Bacillus Bromensis Febris Gastricae*). Kurth.
4. Contribution Concerning Post-typhoidal Bone Suppuration. ERNST UNGER.

..1.—To be continued.

..2.—Rumpf directs attention to his previous description of cardiac disturbances which are due to excessive mobility of the heart, and, as he believes, as further convincing evidence that these disturbances are actually due to the cause he mentions, he reports an interesting case. A man of 30, who weighed 239 pounds, had, during treatment for obesity, rapidly reduced his weight to 153 pounds. He afterward complained of dyspnea and oppression when he lay on either side. The abdominal wall was greatly relaxed, and dropped to one side if he assumed a lateral posture, and it was noted that while under ordinary circumstances the cardiac signs were about normal, if he lay first on the left side and then on the right, the apex beat moved to the midaxillary line and then went over to the left border of the sternum, and the cardiac dulness showed a corresponding change of position. He was fattened again, and when he had reached about 200 pounds in weight he reported that his cardiac symptoms had disappeared, and an examination showed that the heart no longer moved with excessive frequency. He had at this time, however, a mild diabetes. Rumpf considers that the cardiac symptoms which often appear with dyspeptic disturbances are the result, in many instances, at least, of mechanical displacement of the heart by the distended stomach, though they are at times undoubtedly reflex. He also refers to cardiac disturbances after eating special forms of foods and to those (usually irregular action, etc.) which follow upon nervous excitement, such as the necessity for making a public speech, etc. The absence of distinctly abnormal physical signs, excepting the excessive

mobility, justifies one in a tentative statement that the symptoms are due to the excessive mobility, and not to organic disease, though one must always have in mind the possibility of beginning intestinal nephritis or early general arterio-sclerosis. [D. L. E.]

3.—In 1900 there was an epidemic of typhoid fever in Bremen, and in the course of this epidemic a number of cases became notable because the typhoid Widal reaction was constantly negative, though they presented the other usual characteristics of typhoid fever of mild form. These cases were, in part at any rate, apparently due to a bacillus not previously described. In five cases a very close, almost certain, etiological relationship between the bacillus and the disease was established, in one of these cases by both the serum reaction and the isolation of the bacillus, in three cases of a strong serum reaction, and in the fifth case by the isolation of the bacillus from the urine three weeks after the fever had disappeared. In the last case the serum reaction was negative, at the time when the bacillus was isolated, but the bacillus was present in large numbers (240,000 to the ccm.) in the urine, and its relation to the disease seemed very probable. The bacillus resembled the typhoid bacillus and Gaertner's bacillus enteritidis, but showed distinctive differences from both of these. It was actively pathogenic in pure culture. The cases ran a mild course, and all ended in recovery. Hence the anatomical changes are unknown. [D. L. E.]

4.—The case was that of a young merchant, who had typhoid fever in August-October, 1900. In February, 1901, he noticed a swelling below the right olecranon, and another swelling was found near the head of the right radius. An incision into the larger swelling showed suppuration, with bone caries, and the typhoid bacillus was identified in the pus. The interesting points in the case were the situation of the suppuration, which was an unusual one; the fact that, as is often the case, there were two points of involvement, though the smaller underwent spontaneous resolution, and the fact that at the time of the suppurative process the man showed no Widal reaction. (A similar observation was made by Conrad, abstracted from *Deutsche medizinische Wochenschrift* last year). [D. L. E.]

5. The Limits of the Ability to Elevate the Arm and the Physiological and Clinical Importance of the Same. STEINHAUSEN.

1.—Römer in this portion of his paper merely reviews some of the earlier and more modern theories concerning the nature of immunity and the manner in which it is produced. (To be concluded.) [D. L. E.]

2.—Rosemann reports some work done by Haeser. The subject was kept on about the same diet throughout three periods of ten days each; in the first period normal conditions were present, in the second 1 to 2 litres of water were drunk each day, in order to determine the influence of diuresis alone, and in the third period 75 ccm. of 96% alcohol were given daily in 1500 ccm. water. This quantity of alcohol was sufficient (with this subject, who was entirely unaccustomed to the use of alcohol) to produce a more or less constant condition of mild intoxication during the first few days, and throughout the entire period the physiological effects of the alcohol were distinctly felt. In the normal period the subject excreted 0.8288 gm. of uric acid, in the water period 0.5879 gm. and in the alcohol period 0.7611 gm. Hence the alcohol did not cause any increase beyond the normal amount. After reviewing the work of others on the same question, Rosemann states that we can say definitely that alcohol may have no influence upon the uric acid excretion, or it may cause the excretion to increase or decrease slightly—in other words, no characteristic effect can be observed. It might be thought that alcohol exerted an evanescent influence which would not be evident in the twenty-four hours' urine. The values for uric acid, which are found at different times of the day, are very variable unless the subject abstains from

food; in the latter case the excretion is high and somewhat variable in the morning and low, but nearly regular in the afternoon. Another subject was investigated while abstaining from food, alcohol being given at 1 P. M. and 5 P. M. (each time 50 cc.), and 150 ccm. water being taken every two hours to prevent retention of metabolic end products. No influence was observed from the first dose. After the second dose signs of acute alcoholism and a condition approaching collapse appeared, and the urine excreted during the two hours following this dose contained absolutely no uric acid! (i. e., there was no silver precipitate excepting that readily soluble in ammonia). The reaction which this very remarkable observation (which is apparently unique) bore to the ingestion of the alcohol could, of course, not be stated positively. Rosemann concludes that, while alcohol certainly appears harmful to subjects of gout, the study of its influence upon the excretion of uric acid does not explain its unfavorable influence in gout, and this is not to be wondered at, as we do not know that uric acid has anything to do with the causation of gout, and, on the other hand, we may feel assured that there are, at any rate, other factors than uric acid which do bear a close relation to the production of gout. [D. L. E.]

3.—The case reported was an unusually striking instance of a condition which is of itself not very uncommon, i. e., symptoms of appendicitis in the early stage of typhoid fever. The patient, a man of 32, who had previously been well, except for an attack of acute nephritis, in 1894, was taken very suddenly ill with chill, vomiting, constipation, violent pain in the region of the appendix and fever, roseolae, enlargement of the spleen, the Diazo and Widal reactions were all absent, the appearance of the patient was not at all suggestive of typhoid fever, the stools were not characteristic (they were found hard and of brown color), and the symptoms were typical of appendicitis. Examination had also disclosed severe tenderness in the right iliac fossa and localized resistance at McBurney's point. The illness began on May 4; the man was sent to the hospital on May 8, and on the evening of the 8th, since he seemed gravely ill, and gangrene of the appendix was feared, he was operated upon. Old adhesions between the appendix and cecum were found and divided, but there was no sign of recent inflammation of this organ. There was, however, an ulcer about ½ cm. in diameter in the cecum, which had advanced to the serosa, and was near the stage of perforation. This was turned into the lumen of the bowel by stitches and the wound closed. The character of the ulcer, the associated swelling of the mesenteric glands, the subsequent development of splenic enlargement, positive Widal reaction and characteristic Piorkowsky culture, and the course of the disease after the operation made it seem thoroughly well established that the case was one of typhoid fever. The man was never gravely ill after the operation, and stated almost at once after the operation that his pain was greatly relieved. Similar cases from the literature are given in abstract. [D. L. E.]

4.—To be concluded.

5.—Steinhausen has investigated the elevation of the arm, and states that there are a number of serious errors in the usual teaching. He finds that the scapula rotates in all through an angle of about 60°, becoming fixed when the arm has been elevated about 150°. Throughout the whole process of elevation of the arm the angle between the scapula and the arm constantly changes. The abductors act throughout an angle of 120°. The rotators of the scapula have, therefore, a much less important share in the elevation of the arm than is commonly taught, a fact which explains the observation that the arm can often be elevated to a surprising degree in cases of isolated deltoid and serratus paralysis. It is commonly taught that the greatest degree of simple elevation of the arm is to a right angle, and that elevation, without bending the trunk, can be carried to only 120°. Steinhausen finds, on the contrary, that elevation, without movement of the trunk, can in 71% of cases be carried to from 170° to 180°, and 6% of the persons investigated could carry it beyond 180°. He did not find it below 155° in any one. Passive movements could not be carried much beyond the degree of the active, the reason being that the normal muscular rigidity interfered. It is usually taught that paralysis of the brachial plexus, resulting from gymnastic exercises, etc., is due to compression of the plexus between the clavicle and the first rib of the lateral processes of the fifth and sixth cer-

vical vertebrae. Steinhausen thinks that this is impossible, as the clavicle is so acutely bent that there is, in all positions assumed, a space between it and the bones beneath. He attributes such paralysis to an overstretching and consequent laceration of the nerve fibres of the plexus itself and of the finer nerve fibres in the muscles, the cause being that the elevation of the arm is caused by passive force, beyond the physiological limits. [D. L. E.]

1.—Winternitz has investigated the action of turpentine oil upon inflammation by injecting aleuronat into the pleural cavity of rabbits and thereby producing an exudate which consists chiefly of fluid and mononuclear leukocytes, comparing untreated animals with those that have been given oil of turpentine. He found that the exudate was smaller in amount after using turpentine than when the animals were treated, the difference in amount of exudate not depending upon a mere difference in the amount of fluid, but upon a difference in all the elements of the exudate. He believes that this demonstrates that turpentine reduces the intensity of the inflammatory process and that its influence upon many conditions attended with inflammation is due to this direct action upon the inflammatory process itself rather than upon any bacterial infection present or upon the diuresis; he could not find that turpentine had any notable diuretic effect or that the urine of persons who had been taking turpentine controlled the growth of bacteria. He believes that the influence is probably a direct result of the positive chemotactic influence of turpentine—i. e., the leukocytes in an exudate or those that would otherwise collect in the exudate are very strongly attracted by the turpentine circulating in the blood and hence the amount of leukocytic exudate is reduced. Winternitz feels justified in recommending the internal use of ethereal oils (as represented by turpentine) in the treatment of inflammatory processes. In one way this treatment presents an advantage over local blood letting—it does not abstract nutritive material from the organism while blood letting does. [D. L. E.]

2.—Walko finds that picric acid is excreted as such, as picraminic acid and as a red pigment, through the urine; further a portion of the picric acid whether given subcutaneously or intravenously, is excreted through the intestine. The partial reduction of the picric acid to an amido-body must be looked upon as a "vital" process, as outside the body this takes place only at very high temperature, while in the body it occurs with ordinary temperature. The production of the pigment is probably the result of the action of bacteria. The reduction which took place was, however, so small in amount that it does not explain the physiological action of picric acid (as a representative of a class of nitro-substituted phenols). The nitro-substituted phenols have not so active a tendency to form aromatic sulphates

as have phenols themselves. Winternitz found picraminic acid more poisonous than picric acid. He adds some further investigations of the effect of nitro-compounds of the nux vomica alkaloids and makes the interesting report that like the alkyl-derivatives, the nitro-compounds of strychnia, brucin, etc., show the curare-like effect of these alkaloids to such a degree that the convulsive effect is entirely overcome and the action is in general of the curare type. [D. L. E.]

3.—Esslemont notes the now prevailing belief that the nerves of the heart include fibres which decrease the rapidity of the heart's action; others which increase its rapidity; fibres increasing and others diminishing the pulse volume. The results of experiments concerning the last two varieties of fibres have, however, been extremely irregular. Sometimes increase in pulse volume follows stimulation of certain fibres, sometimes decrease resulted from irritation for exactly the same fibres. Esslemont's experiments upon frogs and rabbits led him to the decision that the influence upon the pulse exerted by stimulating the fibres which increase or decrease the force of the heart's action is determined by the tonic condition of the heart at the time, i. e., whether it is over or under a certain optimum. If over this optimum, stimulation of fibres increasing the force of contraction would further shorten and make still more imperfect an already excessive diastole and would reduce the size of the pulse, while under the same circumstances stimulation of the fibres which decrease the force of contraction would to some extent increase the pulse volume. If the heart tone is below the optimum, stimulation of the fibres increasing contractile force will increase the pulse volume. In any case extreme stimulation of either set of fibres will decrease the pulse volume. [D. L. E.]

4.—Heffter describes his special methods for the quantitative estimation of arsenic and cacodylic acid in the urine. He finds that a small portion of the cacodylic acid ingested is found in the urine arsenous or arsenious acid, and he believes that the action of cacodylic acid is set free in the organism. He found that numerous organs, most markedly the liver, the stomach and the intestines contain substances which have exceedingly active reducing properties and which readily reduced cacodylic acid to cacodyl oxide. [D. L. E.]

5.—Karo states that the characteristics of the urine after the use of sandal oil, which distinguish it from urine after using balsam of copaiba, are as follows: copaiba urine gives color reaction after adding mineral acids and rotates the plane of polarized light. Sandal oil urine gives neither of these reactions. Sandal oil contains gummy acids in large amounts and they are precipitated by concentrated HCl. The intensity of the precipitate is proportionate with the amount of sandal oil ingested. The same reaction occurs after using copaiba, but is much less intense. Sandal oil in the urine contrary to copaiba urine has a marked reducing action due to the pressure of glycuronic acid compounds—probably the glycuronic acid compound of the sesquiterpenalcohol of sandal oil. Copaiba urine has no reducing power, and is said to exhibit the reactions peculiar to it for several days after taking copaiba, while sandal oil urine shows its peculiar reactions from only twelve to fifteen hours after taking sandal oil. Hence the latter drug is much more rapidly excreted than copaiba. [D. L. E.]

6.—Jolles and Friedjung find that the milk of normal women contains a small but constant amount of iron, really much more than has previously been generally stated and they believe that contrary to the statements of some of the authors (Bunge and others) this iron must be considered to be of importance to the suckling, and we can not justly maintain that the suckling derives all the iron it needs for tissue, blood building and repair from deposits in its own tissues until it begins to receive other forms of food than milk. Some authors describe a gradual reduction of the amount of iron in mothers' milk during the period of

nursing. Jollès and Friedjung could not confirm such observations. Bad physical surroundings, chronic disease, or relatively advanced age of the nurse seem to reduce the iron of the milk notably and nurses who were apparently healthy but whose children showed marked nutritive disturbance, usually exhibited a decided reduction in the amount of iron in the milk. The authors believe that besides other sources of failure artificial nourishment of infants may have the added error that the child is given too little iron. They discuss the method of estimating the iron of the milk and describe their own method in detail. [D. L. E.]

8.—Jaquet and Stäbelin makes the interesting statement that two apparently contrary changes are seen in the total end-products of metabolism when the subject examined goes from a moderate altitude to a high elevation—the nitrogen excretion and apparently that of the nitrogenous tissue is reduced, while the CO_2 expired and the O_2 inspired increase in amount, and the respiratory quotient rises in value. The change in the CO_2 and oxygen persists for some time after returning to the previous lower level. The very decided differences in the excretion of water during the different periods of study, made the records of body weight valueless, so that no conclusions could be safely drawn as to the effect on the total amount of tissue. The increase in the respiratory quotient could not be referred to the most economical oxidation of the nitrogenous tissues; it was too marked to be subject to such an explanation and was evidently the result of mere active oxidative process. Since the nitrogenous tissues were not involved in this more energetic oxidation, the carbohydrates were necessarily oxidized more rapidly and in greater amount and hence the quotient rose. Considering the high caloric value of the food taken, the authors believe that they may safely state that the lower altitude fat was stored, while in the mountainous region less was stored up and perhaps none was laid by or there was a loss. On the contrary, nitrogenous substances were stored up in the organism at the higher altitude. The contrary influence upon the nitrogenous tissue and the fats is an interesting observation which they do not attempt to explain. It is evident that the effect of mountainous regions upon metabolism is a complex one, especially when considered in connection with the influence of high altitudes upon the blood count. The subject of the experiment was one of the authors. The preliminary and final periods of study were made in Basle, the study of the influence of high altitude was carried out on the Chasseral at an elevation of over 6000 feet. [D. L. E.]

9.—Archangelsky has investigated the leaves of the *Rhododendron Chrysanthemum* and besides the glucoside ercolin, which was previously known, has found that they contain two formerly unknown substances which he calls rhododendrin and rhododendrol. The first is a glucoside which is probably found in other varieties of *Rhododendron*. Rhododendrol belongs to the camphor group and its physiological action is in frogs like that of camphor. Dogs and rabbits showed no effects from doses of 1.5 grains and larger quantities could not be tested from lack of material. Rhododendrol appeared in the urine—apparently in combination with glycuronic acid, in part at least. Rhododendrin showed no physiological effects. The formulae and the elementary analyses of these two substances are given. Andromedotoxin has been found in a number of varieties of *Andromeda* in some azaleas, in the *Rhododendron ponticum*, and in the plant mentioned by Xenophon in his *Anabasis* as "the poisonous honey of Trapezunt." Archangelsky obtained his specimen from *Rhododendron ponticum* and in studying its physiological effects found in agreement with previous authors that it causes vomiting, prostration, fibrillary muscular twitching, convulsive movements and finally complete paralysis. He also adds that in doses of 0.0015 grains (to frogs) it has pronounced effect upon the heart; it causes death by an action similar to that of digitalis, though differing in the fact that the

ventricle instead of stopping in full systole, is found in half systole. The auricles beat for some time after the ventricles have stopped. A similar action upon the heart was seen in mammals also. [D. L. E.]

1.—Van Yzeren reports that he has been able in a series of cases to do what many investigators have vainly sought to accomplish, i. e., he has produced typically situated chronic gastric ulcer in animals, the gross and microscopic appearance of these ulcers being practically identical with those observed in gastric ulcer in human subjects. His method was to cut the vagus below the diaphragm. Only one animal of the 20 operated upon died; the others were killed at various periods after the operation. The one that died suffered from some intercurrent disease not connected with the operation. With the exception of three cases, in two of which the animal was killed within 8 days after the operation, and in the third there was an acute perforating ulcer, there was but one ulcer; in the 3 cases mentioned there were multiple ulcers. 10 of the animals operated upon showed ulcers; six were killed after as long as 40 days after operating and one after 169 days, one even after 289 days! Yet ulcers were present that presented the characteristics of the human ulcer-necrosis first with subsequent inflammation and hyperplasia of the tissue in the neighborhood, and certainly the oldest of these ulcers must be called chronic in point of the time of their duration, and all those that had been present for any considerable length of time were evidently chronic both from gross and microscopic appearances. Van Yzeren believes that spasm of the pylorus and pyloric portion of the stomach is immediately responsible for the production of these ulcers; the effect of vagotomy is to produce spasm of the pars pylorica, and palpation of the abdomen of these animals also gave evidence of spasm in that the pyloric portion of the stomach could be felt as a well defined mass while in animals without ulcer it could not. He believes that spasm of the pars pylorica is probably the cause of ulcer in human beings also, and that it may sometimes be definitely diagnosed by feeling the contracted pyloric portion or by observing the occurrence of intermittent retention of gastric contents. Because of the danger attending all the operations which are now used in treating gastric ulcer and because the results from the best are not very satisfactory, Van Yzeren has devised a new operation which consists in dividing the muscular layer of the entire pyloric portion, pylorus and a small part of the beginning of the duodenum down to the submucosa, leaving the muscularis mucosa intact. 12 rabbits were operated upon in this way after vagotomy. 4 of the animals died of an epidemic which appeared at that time among the rabbits. Of the other 8 one died of peritonitis. Of the remaining 7 one only had gastric ulcer afterward. This seems to Van Yzeren good evidence that the operation has prophylactic worth and he believes that it will have curative value. At any rate it would seem less dangerous than any other operation that has been recommended for this purpose, and seems likely to relieve pyloric spasm. [D. L. E.]

2.—Among the interesting facts in Luthje's communication was the observation that the reaction for diacetic

acid was absent before the man was admitted to the hospital ward. After admission to the ward, coincidentally with a marked reduction in his food, particularly in the protein, the urine exhibited a very marked iron-chloride reaction, which again became greatly lessened in intensity as the meat diet was doubled. Marked diacetic acid reaction was also seen after a severe attack of diarrhea which was accompanied by marked prostration. A curious accident led to an interesting therapeutic observation. The man had become mildly comatose after steadily growing worse, and a 3% sodium bicarbonate solution was ordered. By mistake soda was used instead and he was given 500 c.c. of this strongly alkaline solution by the mouth and the same amount intravenously. His oral mucous membrane was red and swollen next day but the man was free from coma and signs of danger. He died three weeks later in deep coma, however, in spite of the intravenous administration of 500 c.c. of 3% bicarbonate solution. Extended observations of the metabolism of the patient are given. Contrary to the reports of numerous authors, Luthje could not observe any diminution of the sugar excretion or any increase in the nitrogen output during the period of coma. (See also Magnus Levy on the same point, abstracted from *Archiv f. Exper. Pathol. u. Pharmacol.*, April 26 (?), 1901.) The use of the large quantity of alkali during the first attack of coma resulted in a diminution of the NH₄ excretion by about 6 grams. The ammonia excretion in the last few days of life was enormously high, reaching over 11 grams on one day. Casein (nutrose) was used in the diet to see the effect on the sugar excretion—contrary to the statements of authors who base their remarks on test-tube experiments, casein did seem to furnish sugar and to increase the glycosuria distinctly. In discussing Rumpf's remarks (abstracted last year, or year before, from *Deutsch. Med. Woch.* or *Berl. Klin. Woch.*) concerning the possibility of the production of sugar from fat, Luthje sensibly states that we know too little as yet about the maximum amount of sugar that can be produced from protein to make it justifiable to reason concerning the production of sugar from fat on the basis of the nitrogen sugar ratio. Luthje thought it possible that the intestinal glands functionate to some extent in place of the pancreas, and therefore removed the pancreas of a dog with the entire duodenum to see whether the nitrogen-sugar ratio did not rise. 1 to 2.8 (Minkowski's figures) was the highest relative sugar quantity found, but the dog died from gastric hemorrhage 3 days after the operation, and other animals operated upon similarly died almost immediately, so that while the result was negative as far as it went, it does not definitely answer the question in the negative. Food was well absorbed by the patient, and the striking nitrogen retention which occurred with a high caloric ratio was strongly suggestive of the conditions in convalescence from acute disease. Luthje believes that in this instance one could not believe even from a pure chemical standpoint that the acid intoxication which ultimately caused death was due to destruction of body albumins. The man was taking enormous quantities of albumin, and must have had no period of "albumin-hunger" in the whole 24 hours, and he was not losing albumin. The whole cause of the suddenly developing acid intoxication made the impression that a new factor had come into the case and that the acid intoxication was a metabolic disturbance, *sine generis*, not a mere excess in body protein destruction. [D. L. E.]

3.—Mamlock discusses a series of case reports of other authors, and their views and causes to the conclusion that the previous teaching concerning the nature and localization of the patellar reflex is correct, but that we must accept the existence of fibers probably coming from the cerebellum, which maintain the tone. The various unusual conditions of the reflex are the result of alterations of these fibers. There are many instances which seem to indicate absolutely, finally, that the brain has a regulatory influence from the reflex, not solely an inhibitory influence. It is notable that Clarke's columns suffer first in tabes, and that there is a close relation between the fibers of this column and the cerebellum according to recent investigations. In this way one may build a theory which will explain all of the varieties of patellar reflex seen in tabes dorsalis. If the fibers of Clarke's column are much involved, as is usual, the reflex is lost, if the involvement is slight, the reflex may be regained. In transverse myelitis the condition of the reflexes would likewise depend upon the degree of disturbance of the fibers controlling

the tone. That the reflexes are at times preserved in total transverse lesions may be due to the early irritation which precedes complete loss of function, or perhaps it is in some cases the result of trophic changes in the columns of Clarke. Mamlock thinks that the alterations described by some authors in the ganglion cells of the anterior horns in tabes dorsalis may be the result of alterations in fibers controlling the tone—just as similar changes occur with disease of the pyramidal tracts.

[D. L. E.]

4.—Mosse and Tantz investigated the physiological action of berberin because this drug has been recommended and used for the treatment of malaria, though its actual physiological effects are not well known. As to its effect upon bacteria—it restricts their growth, the products of albuminous decomposition are relatively decreased. It has similarly unfavorable effects upon the growth of higher plants, and interferes with their assimilation. In animals it causes emaciation, muscular weakness, reduces all reflexes and causes local lesions in the nerves. It produces acute hemorrhagic nephritis after a short time, and it causes a leukocytosis to develop. No effect upon the spleen could be observed. In frogs the tendency to reduce the reflexes was so strong that the drug controlled the poisonous effects of strychnine, neither after giving berberin nor after injecting Witte's peptone could any change in the activity of the blood in breaking up H₂O₂ be observed in spite of leukocytosis. [D. L. E.]

5.—Umber was led to his investigations by the fact that nothing is known of the course through which the pre-formed carbohydrate complex passes in the digestion of nucleo, proteids or other protein substances. Nucleo-proteid was studied (that of the pancreas) as it seemed hopeless with present methods to investigate albumins. The most directly interesting result of his research is the discovery that pure nucleoproteid is readily digested by a pepsin-HCl mixture. Contrary to the usual statement that pepsin acts but slightly while trypsin acts very energetically, Umber found that pepsin-HCl mixture digested a pure nucleoproteid to the extent that after 5 weeks' action only 0.96 grams of undigested remainder was left from the original 10 grams of nucleoproteid. Trypsin acted much more rapidly, however (the statement that pepsin-HCl mixtures do not digest nucleoproteid has been so generally and entirely accepted that one of A. Schmidt's tests of good pancreatic digestion was the absence of numerous undigested nuclei from the feces). Umber finds that digestion of nucleoproteids takes the following course:

Nucleoproteid.

Nucleoproteid.

Nucleic acid
free albumoses
(primary and
secondary) and
the products of
their further di-
gestion

There is apparently no half-way stage for the nucleic acid-containing substance in which it is still united with partly digested albumin—the splitting off occurs at once and is complete. Hence so-called "nuclein" (in the commoner sense, i. e., a combination of nucleic acid with partly digested albumin) does not exist, and the term nuclein should be confined to those substances in which the nucleic is combined with histon or protanim and not with albumin;—such substances are almost exclusively certain fish spermatozoa. There is no essential difference in the nucleic acid of the various organs of the body. The albumin-complex, after being split off from the nucleic acid complex follows the usual course of digestion of albumins. The albumin of the pancreas nucleoproteid seems therefore to be like the other body albumins in its chemical nature. The main result of the investigation was the discovery that the carbohydrates (pentose)-purin-base complex is split off from the albumin complex at once, and the two follow entirely separate courses in their further decomposition, a fact which Umber hopes to prove to be of decided importance in metabolism.

[D. L. E.]

6.—The measurements for the normal heart which Karfunkel gives as a result of his studies with the X-rays are as follows: Greatest lateral diameter, 11 to 12 cm., in very large men as much as 13 cm. Length, 9 to 12 cm., smaller lateral diameter, 8 to 10 cm. Greatest diagonal distance of the border of the right auricle from the ster-

num, $2\frac{1}{2}$ to at most $1\frac{1}{2}$ cm. The measurements which he obtained with normal and pathological hearts corresponds well with those obtained at post mortem, and he believes that one may determine the true borders of the heart with absolute exactness by means of the X-rays, and the same statement applies to the examination of the great vessel-trunks. [D. L. E.]

7. Moraczewski concludes after a study of the excretion of nitrogen urea, phosphorus, chlorides calcium and magnesium of the urine, as well as after a partial study of other elements of the urine and feces, that there is in acromegaly a tendency to retention of the tissue-building substances, particularly of the calcium and phosphorus, the nitrogen and calcium retention are comparatively readily overcome, and a balance obtained by medication or other treatment, but the retention of calcium and phosphorus is difficult to influence. Thyroid and hypophysis tablets decrease the retention to some extent, but not markedly. A more striking influence was observed after using oxygen inhalations, and the most marked effect was obtained from silver nitrate. [D. L. E.]

1.—Struppler reports the following interesting case. A man of 26, at the age of 20, fell from the roof of a house to the ground, a distance of about 40 yards, fracturing two ribs on the left side and the left fore-arm. Immediately after the injury he had persistent vomiting of everything that entered the stomach. Later, although he had great difficulty in retaining the food, he was able to do a little work, and during this period he observed gurgling as far as the left nipple. Since that time he has been unable to eat very much at a meal and therefore has frequent smaller meals. He complained from time to time of gurgling in the region of the stomach, especially when doing hard work. Repeated paracentesis of the thorax was performed on the left side without result. Physical examination showed that the interesting symptoms were a dull tympanitic note in the lower portion of the left thorax, displacement of the heart to the right, and the physical signs of a cavity partially filled with fluid and extending from the third rib downwards on the left side. The abdomen was negative. The symptoms were accepted as indicating diaphragmatic hernia, although the difficulty of differentiating from a subdiaphragmatic pyopneumothorax was recognized. In order to decide the question, aside from careful study of the physical signs, the stomach was inflated by giving a divided Seidlitz powder, when it was observed that the left side of the thorax even as far up as the third intercostal space became inflated and the patient had dyspnea and a feeling of extreme anxiety. After the patient had fasted for twelve hours, the gurgling and splashing disappeared almost completely. About a litre of water was then injected into the colon, whereupon the gurgling and splashing reappeared in the thorax, but less intensely. Examination with the Röntgen rays showed a clear transparent area in the lower part of the left thorax which was

more distinct after the patient had been inflated with carbon dioxide. An attempt at gastroduaphony was a complete failure, as the illumination did not appear anywhere. This Struppler explains by supposing that the stomach is situated in the centre of the thoracic cavity and is surrounded not only by the mesentery and omentum, but also by intestines. [J. S.]

2.—Becker has made a careful study of the influence of cold upon the blood when applied to the whole body, including a very careful analysis of the literature on this subject. He concludes from the latter that other authors have reached irreconcilable conclusions, some believing that there is contraction of the blood vessels, and diminution of the number of corpuscles, others, that there is contraction of the blood vessels and increase in the number of corpuscles. It is generally accepted, however, these changes do occur, but they disappear very rapidly. In regard to the leukocytes, some authors find that they are moderately increased in proportion to the increase of the red blood cells; others, that there is a considerable increase disproportionate to that of the red cells. His own investigations were upon various patients to whom a cold douche was administered, counting the blood carefully before and immediately after, and also one hour after the douche. The duration of the cold application was about 4 minutes, and the temperature of the water was 16° to 17° R. that is about 70° F. A second series of investigations was made upon patients suffering from typhoid fever who were placed in water of about 30° gradually cooled to 20° , or 100° down to 77° F. for one quarter of an hour. The results are given in tabular form. He finds under normal conditions the number of the red blood cells and the white blood cells is the same in the capillaries and in the veins. The application of cold produces an increase in the number of red and white cells, especially in the latter, when the blood from the capillaries was investigated. On the other hand, when the blood from the veins was counted, the number of white cells was usually diminished. In the course of an hour there was usually a slight diminution in the number of cells, below the normal. He regards the results as due to the withdrawal of water from the blood and the slight congested condition in the capillaries. The increase in the number of leukocytes is probably due to the fact that they emigrate to the periphery of the body as a result of the action of the cold. Under certain pathological conditions the diminution in the moderate degree of stasis may account for some of the results. [J. S.]

4.—Ketly and Weiss have examined a number of cases in order to determine to what extent the vocal phenomena observed in the intercostal spaces are of value in determining the existence and extent of pleural exudates. The details of these cannot be given in the abstract, but the authors draw from them the following interesting conclusions. That the phonation phenomena in the intercostal spaces may be made a trustworthy basis of physical diagnosis. The lower boundary of the exudate can be determined with considerable accuracy although the phenomena may be partially obliterated by the formation of masses of connective tissue or the reflex contraction of the intercostal muscles. If in the centre of an area of dullness, ordinary vocal resonance fails, it is possible, provided there is not a thin layer of aerated pulmonary tissue between the focus and the ear, to conclude that there is a sacculated exudate. Naturally these physical signs may be carefully corrected by consideration of all the others.

5.—Jendrassik has devised a very ingenious method of recording peculiarities in gait by means of instantaneous photographs. The difficulties that have hitherto existed in all attempts of this kind, are, the expense of the apparatus, its complicated nature, and the time required to employ it. In order to overcome this, Jendrassik employs a single camera with a rather long plate placed horizontally. The lense is of such construction that it gives a short, flat image on all parts of the plate. This camera is set up in a room whose walls are black, but which is, however, well illuminated by a window towards the south, or as in his own case, towards the southwest. However, as direct sunlight cannot well be employed, other exposures are equally satisfactory. The camera is directed away from the window and the patient walks in front of it at such a distance that his image is clearly projected upon the ends of the plate, at either end of a 3 metre promenade. As

the patient walks, an instantaneous shutter is opened and closed from 5 to 8 times, producing that number of images upon the plate. They rarely overlap, or if so, only slightly. The advantages of this method are, of course, its cheapness—4 to 6 photographic plates exhibiting every phase of the step—its simplicity, and particularly the ease with which the results are studied. Reproductions of the results upon the plates are remarkably clear and satisfactory. In order to render these results sufficiently graphic, Jendrassik employs the method of making dots upon the shoulder, hip, knee, and ankle, on the side next the camera. He then connects these by lines which are traced upon the chart, showing both the movements of the legs and the oscillations of different parts of the body. He concludes the paper with careful studies of the normal and various pathological forms of gait. The latter he divides into several types, the hypertonic, which is subdivided into the hemiplegic and spastic, the hypotonic, the myelitic or mixed form, the ataxic, the cerebellar, the gait of paralysis agitans, and the hysterical disturbances. All these forms are illustrated. [J. S.]

6.—Krämer reports the results of his studies upon the epidemic of typhoid fever that broke out in the Fortleth Infantry Regiment, stationed at Aachen. Although 142 men were taken sick; 81 with typical typhoid fever; 31 with the so-called febris typhoid sine gastrica, and 30 with rather indefinite symptoms. The cause of the epidemic was traced to a house in the neighborhood of the parade ground from which the milk for the garrison was purchased, and in which a patient suffering with typhoid fever was found. Some objection was raised to this hypothesis on the ground that this patient was himself a part of the epidemic, and the actual cause extended back at least a year. Ninety-two cases were sent to the Maria Hilf Hospital, of which 43 had typical typhoid fever. Among the complications were bed-sores in three cases; orchitis in one case; otitis media and croupous pneumonia each in two cases; and severe involvement of the larynx in 3 cases, necessitating tracheotomy. He has studied also the Widal reaction in many of these cases, particularly by means of the method of Babanke. This consists in the employment of pure blood in solutions of 1 to 20. He finds that it is quite as efficient as any other method of study, and is much more convenient to carry out. The reaction occurred in all cases of typhoid fever with the exception of 4; but in some of the cases it did not occur until the 24th day after defervescence. In the cases in which there was no reason to suspect typhoid fever, it was invariably negative. Krämer, however, believes that a negative Widal reaction should not be regarded as indicating the absence of typhoid fever, although Widal reaction denotes its presence. [J. S.]

7.—Kollarits, after a brief review of the literature of the pathology of muscular dystrophy, reports a case of a boy, 10 years of age, who clinically presented a typical picture of the pseudo-hypertrophic form. The disease had existed for a considerable time, and for at least two years the patient was unable to walk. He was unfortunately drowned whilst bathing, and at the autopsy fatty degeneration of the muscles was discovered. Some of the fibres were atrophic, and some hypertrophic. The nervous system was carefully examined, and the following changes found. Dilatation of the central canal; diminished number of fibres in Lissauer's zone; in the gray matter surrounding the central canal, in the anterior and posterior commissures, and in Clark's column. The ganglion cells of the anterior cornua were intact, excepting that they appeared to be smaller in size. Kollarits concludes that these changes are not secondary to the muscular condition, but represent an impaired development similar to that which had taken place in the muscles. [J. S.]

8.—Neumann reports five cases of scleroderma occurring in elderly persons, the youngest being 41 years of age, and the oldest sixty. In a critical analysis of the symptoms presented by these he first objects to the tendency to divide the disease into stages. The etiology of the disease is still entirely obscure. It may be infectious; it may be nervous; it may have some analogy to Raynaud's disease. At any rate, in Neumann's cases there were no symptoms of disease of the central nervous system, the changes resembling, to a certain extent, those found in paralysis

agitans. The patients appeared to have seriously impaired nutrition, so that there is some reason to suppose the existence of a state of chronic poisoning. The cases improved occasionally upon treatment, although we do not know what drugs are most efficient. Internal preparations of salicylic acid sometimes proved effective, and locally, in addition to ordinary rubbing, etc., ichthyol has proven of service. Fango was used in one case without result. Tallerman's hot air treatment has proved beneficial in some cases. [J. S.]

9.—Engelhardt has performed a number of experiments upon human blood in order to determine the quantity of fat that it contained. He used for this purpose 10 ccm. of blood obtained from the median veins of various persons, healthy or suffering from some disease. In 8 healthy persons, the average results were .191%; the maximum was .273% and the minimum .101%. In five patients suffering from cachexia the average was .171%; the minimum .112%, and the maximum .284%. The lowest quantity represented the fat obtained from the blood of a vigorous, stout girl. Engelhardt concludes that in wasting diseases no increase in the quantity of fat in the blood can be detected, and that individual variations are very considerable. He calls attention to the difference between his results and those of Bönninger, who found an average of .75 to .85% of fat in the blood. He regards this as due to the errors incident to the methods employed. [J. S.]

WIENER KLINISCHE WOCHENSCHRIFT.

July 25, 1901. (XIV. Jahrgang, No. 30.)

1. Antilytic Serum.
JULIUS DONATH and KARL LANDSTEINER.
2. The Pathology of the Omphalo-mesenteric Duct and Meckel's Diverticulum.
ERNEST VON KARAJAN.
3. The Illness of the Actor Fritz Krastel. O. CHIARI.

1.—Donath and Landsteiner have performed experiments by a new method, to discover the relations between the bacteriolytic and hemolytic substances of the blood and the cells of the same animal. They made three kinds of researches, microscopic examination of phagocytic leukocytes, observation of parallel changes in the leukocytes, serum, plasma, etc., and the production of extracts of the leukocytes. These were made by freezing them and dissolving them in a dilute saline solution. Experiments showed that serum thus obtained resembled leukocytic serum. They consider their leukocytic, erythrocytic, lymphatic, or milk serum to be a "complemental serum." But their cell serum differs from that gained by serum-injection, especially in regard to its specific character in bacteriolytic investigations. Therefore the absolute identity of the two serums cannot be established. The significance of their results lies in the fact that, both in the cells and in the serum, similar substances can be found, which are specific to a certain extent for the species in question. They intend to publish full details of their work later. [M. O.]

2.—Karajan reports in detail three cases. The first was a student of 20, in whom appendicitis with perforative peritonitis was diagnosed. Laparotomy showed diffuse peritonitis with a band from the umbilicus to the small intestine, which obstructed the transverse colon. This band which was inflamed at its intestinal end, was removed and the patient recovered in three weeks. Strangulation was not produced by the persistent omphalo-mesenteric duct, simply compression, like that due to Meckel's diverticulum, when present. In the second case, a man of 38, laparotomy showed a persistent Meckel's diverticulum, which was attached to the mesocolon. This held a fold of the ileum incarcerated. Death occurred the day after operation. An abscess was found at the end of the diverticulum joining the mesocolon. The third case was a man of 30, in which the Bassini operation for right-sided inguinal hernia was done. A band was found in the hernia, which was removed, and the intestine sutured. This was the remains of Meckel's diverticulum. Other similar cases in the literature are cited. [M. O.]

3.—Chiari relates the details of the recent illness of the actor Fritz Krestel. He had a right-sided croupous pneumonia, followed by the occurrence of many small abscesses, with induration. At first streptococci and pneu-

micrococci alone were seen. Later influenza bacilli and staphylococci were seen in the sputum. At no time were tubercle bacilli found. He was ill almost three months, but has now recovered. [M. O.]

August 1, 1901. (XIV. Jahrgang, No. 31.)

1. The Excretion of Chloroform by the Respiratory Organs. KONRAD BUDINGER.
2. The Occurrence of Immune-Hemagglutinin and Immune-Hemolysin in Milk. RUDOLF KRAUS.
3. Aneurysm of the Aorta. ANTON KROKIEWICZ.

1.—It is a well known fact that the odor of chloroform is noted upon the breath of a patient for some time after operation. Budinger has constructed an apparatus by which he can collect the chloroform from the expired air in cold water. This apparatus was used once or twice daily, as long as any chloroform could be found in the breath exhaled. The results are unequal, as some patients could not expire into the tube well. In 20 cases, chloroform was found in the expired breath 24 hours after operation. In some cases it was still present on the fifth day after operation. In four of the cases chloroform was found longer than in the sputum expectorated. Thick pharyngeal mucus seems to hold chloroform longer than thin, watery sputum. It is thus plain that the irritation produced by the chloroform during and right after operation continues for some time longer. [M. O.]

2.—Kraus' experiments upon dogs showed that specific hemagglutinin is found in the milk of dogs treated previously with canine blood corpuscles. His experiments upon goats showed that immune-hemolysin could not be found in the milk of immune animals, in the serum of which immune-hemolysin was present. Kraus concludes that immune-hemagglutinin is excreted by the mammary gland; that immune-hemolysin is not excreted by the mammary gland or kidneys; that immune-hemolysin can be transmitted to the child in utero by the mother; and that immune-hemagglutinin is not transmissible by nursing. [M. O.]

3.—After detailing the differential diagnosis between aneurysm of the ascending aorta and aneurysm of the arch of the aorta, Krokiewicz reports an interesting case of an aneurysm of the ascending aorta in a man of 47, both syphilitic and rheumatic. Pain had existed about the heart for three years, with typical pulsation, tumor, dyspnea, etc. The autopsy showed an aneurysm which had spread out in the pericardium and left pleural cavity. It had been a question, clinically, whether this was not an aneurysm of the right ventricle, from its position, the large amount of dullness, etc. Gelatin injections did not appear to benefit the condition at all. [M. O.]

August 22, 1901. (XIV. Jahrgang, No. 34.)

1. Sudden Death from Myocarditis in Children with Apparently Insignificant Superficial Ulceration. ZUPPINGER.
2. The Etiology of Abscess of the Liver. EGON RANZI.
3. Atypical Psoriasis. ALBRECHT BEYER.

1.—Zupplinger reports three cases of sudden death from heart failure in children with some superficial ulceration. The first case, a boy of three, had an infected wound of the back of his foot, received a week before. He refused nourishment, and grew pale and weak. The wound healed. The heart dullness increased, quantities of albumen appeared in the urine, edema developed with ascites and hydrothorax, and he died just 21 days after the wound occurred. The autopsy showed hypertrophy of the heart, with acute myocarditis and nephritis, induration of the liver and spleen, bilateral hydrothorax and ascites. No bacteria were found. The second case, a boy of 14 months, who had been burned in the inguinal region, died suddenly, on the eleventh day after the burn, in a convulsion which lasted hardly a minute. Here, too, autopsy showed acute myocarditis and nephritis. The third case, a boy of three, had eczema for months, followed by abscesses of the cervical lymph-glands. He died suddenly the day after the abscesses had been opened. In these cases the nephritis shows the severity of the intoxication, which must have been due to infection from the open wound. In none of the cases were there symptoms of sepsis, nor were germs found. Thus Zupplinger believes it possible

for death to occur from acute myocarditis, due to an especial susceptibility of the heart in early childhood.

[M. O.]

2.—Ranzi reports a case of abscess of the liver in a man of 62, who died one week after the first symptoms appeared. These were vomiting, chills, pain in the epigastrium, and jaundice. Dullness developed posteriorly on the right side below the angle of the scapula. Coma, tenderness over the liver, arrhythmia, and chills followed before death. The autopsy showed diffuse purulent peritonitis, subphrenic abscess from perforation of one of the abscesses of the left lobe of the liver, gall stones in the gall bladder and ductus choledochus, which closed the latter, cholecystitis and cholangitis, mitral and aortic insufficiency, hypertrophy of the left ventricle, parenchymatous degeneration of the kidneys, etc. Cultures were made from the three liver abscesses, the subphrenic abscess, the peritoneal exudate, and the contents of the gall bladder. The same bacillus was found in all, with a capsule, but not staining by Gram's method. Cultures and animal inoculations showed this to be the pneumobacillus of Friedländer. Ranzi believes that the infection started from the duodenum, thence spread to the gall bladder, then by the blood, and finally reached the heart. [M. O.]

3.—Will be abstracted when concluded.

September 19, 1901. (XIV. Jahrgang, No. 38.)

1. The Operative Treatment of Double Gastric Stenosis. HERMANN SCHLOFFER.
2. Idiopathic and Symptomatic Myalgia. JAR. ELGART.
3. Two Cases of Stromeyer's "Dislocation-fracture." JULIUS BERDACH.

1.—When either pyloric stenosis or hour-glass contraction of the stomach occurs, gastroenterostomy is to be preferred as treatment, should gastro-anastomosis by the Wölfler method be technically impossible. But Schloffer reports the case of a woman of 54, in whom both hour-glass contraction and pyloric stenosis existed. As gastro-anastomosis was impossible, he performed a gastroplastic operation, making a transverse incision above the narrowed part of the stomach, which he sutured longitudinally. Then gastro-jejunostomy was done, with Braun's anastomosis, the two pieces of the jejunum, going to and coming from the stomach, being joined below the stomach. The patient recovered rapidly, and has kept well since. In only a few such cases will it be possible to perform a pyloroplastic operation successfully. [M. O.]

2.—After a detailed review of the literature, Elgart states that severe muscular pain, often called muscular rheumatism, is felt during the onset of many of the infectious diseases, as in influenza. Less severe myalgia is noted with acute rhinitis, tonsillitis, pharyngitis, enteritis, etc. In both cases the muscle pain is but a symptom. After exercise, especially unaccustomed exercise, severe myalgia may develop. This is a true myopathy, with some exudation of serum or blood, so that the intramuscular tension is increased, and pain results. When the extravasated material is absorbed in the succeeding days, the pain disappears. This condition can be caused at will. Idiopathic myalgia may occur during ordinary work or exercise, to which one is accustomed, from an unusual strain. Symptomatic myalgia occurs with the infectious diseases, intoxications, etc. In all cases some traumatic alteration occurs in the muscles themselves. Wide spread degeneration or atrophy may be found in severe intoxication. If a man is well nourished and always takes sufficient exercise, myalgia will not often occur; but when degeneration or atrophy have already begun in certain muscles, care must be taken not to strain those muscles. The treatment of idiopathic myalgia consists of diaphoretics, laxatives, massage, etc.; that of symptomatic myalgia will be the treatment of the disease with which it co-exists. [M. O.]

3.—Berdach gives the case histories of two cases of Stromeyer's "dislocation-fracture," both due to accidents which occurred during intoxication. In the first case, a man of 40, fracture of the internal malleolus and of the lower end of the fibula occurred with outward dislocation of the astragalus. Extension and fixation for two months produced good recovery. The second case was a man of 30, with the same conditions except that the internal malleo-

hus was intact. He went home after extension for a month, then from improper care, developed marked pes valgus. [M. O.]

September 26, 1901. (XIV Jahrgang, No. 39.)

1. A Congenital Malformation of the Colon. KARL TITTEL.
2. The Etiology of Dupuytren's Contracture of the Fingers. WILHELM NEUTRA.
3. The Diagnosis of Concretio Pericardii and Triensplid Disease. WILHELM TIERCK.

1.—Tittel reports a case of congenital malformation of the colon in a boy of 15 months, born with the face presenting after a difficult labor, the infant being badly asphyxiated. During his first week of life the circumference of his abdomen increased markedly, remaining afterward hard and prominent all his life. Constipation lasted eight or ten days at a time, and strong purgatives then produced but one bowel movement. Very rarely did spontaneous defecation occur. Chills developed suddenly, and the child was unconscious six hours. Rales appeared in both lungs, vomiting occurred, with repeated chills and death. At the autopsy the entire colon was found greatly dilated, the rectum and sigmoid flexure forming large sacs; there were broncho-pneumonia of both lungs and general anemia. Histological examination showed the submucosa and muscular layers thickened; while the mucosa was very much thinner than normal. Tittel believes that the colon was congenitally ectatic. The wall of the ascending colon was very thin, while the sigmoid flexure showed greatly hypertrophied walls. He concludes that operation was not indicated in this case, nor would it have accomplished anything. Tables of the colon measurements and diagrams accompany the article. [M. O.]

2.—From a thorough review of the literature, Neutra finds that Dupuytren's contracture of the fascia of the fingers is often hereditary, and symmetrical, and may occur without traumatism. He reports a case in a man of 46, in whom the contracture began six years before, in the left hand, the right hand becoming affected two years later. He had vertigo, headache, and rheumatoid pains in the right arm. There was slight kyphoscoliosis with some atrophy of the muscles of the left forearm. There was neither syphilis nor traumatism. As no signs of hysteria could be found, Neutra decided that this was a case of syringomyelia. Two other case-histories of patients with syringomyelia and Dupuytren's contracture are given, and several cases are quoted from the literature. Neutra concludes that Dupuytren's contracture is probably a trophic disturbance; that any disease which leads to general disturbances of nutrition can in time cause Dupuytren's contracture; that it is often seen with diseases of the spinal cord, especially syringomyelia frequently being among the first symptoms of the disease to appear; that this contracture of the fascia is often erroneously considered traumatic; and finally, that it is not impossible for the condition to improve without operation even though the disease be incurable. A long bibliography is appended. [M. O.]

3.—This will be abstracted when concluded.

NEUROLOGISCHES CENTRALBLATT.

August 16, 1901.

1. The Question of the Regeneration of the Spinal Cord. A. FICKLER.
2. Recurrent Paralysis of the Face in Migraine. G. J. ROSSOLIMO.

1.—Fickler takes occasion to criticise the description of Bielschowsky, of fibres in the dura mater of the spinal cord after total transverse lesion that he regarded as regenerated fibres from the pyramidal tracts. He discusses these findings, and also those in 2 cases of his own already reported, and reaches the conclusion that such fibres are actually evidences of regeneration, but are merely the association fibres between the individual segments of the spinal cord and not fibres derived from the cells in the brain. Although experimental investigation has failed to indicate how regeneration takes place in the spinal cord, it is possible that this is because all experiments have

hitherto been made by total transverse section. Fickler has therefore performed a number of experiments upon cats by inserting small fragments of celluloid in the spinal column, and removing them after a period of 3 or 4 weeks. The animals at first became completely paralyzed, then after the removal of the celluloid improved very rapidly for a week, and then very slowly indeed. The cats that recovered were killed at intervals of from 2 weeks to 7 months. At the latter period no clinical symptoms of injury to the spinal cord remained. Microscopically the spinal cord showed pictures which resembled very strongly those found in compression of the spinal column, and fibres that may have been newly formed. In the human cords it appeared that these regenerated fibres sometimes served to unite the different segments. Sometimes, however, they apparently missed their aim and formed small genuine neuromas in the perivascular interspaces. [J. S.]

2.—Rossolimo reports the case of a woman 28 years of age, who had begun to have headaches with menstruation at the age of 16. These generally increased in intensity and gradually grew still more severe in time. At the age 19 she had an attack of complete paralysis of the left side of the face. Several years later the right side of the face was exposed to cold while she slept, and this also became paralyzed. After the birth of her second child she again had paralysis of the right side of the face, and finally, at the age of 27, after a very severe attack of migraine on the left side of the face, paralysis of this side occurred. When examined there was complete paralysis of all the muscles, diminished reaction to electricity without reactions of degeneration; hearing was not affected. Taste was somewhat diminished on the left side of the tongue. Rossolimo regards this case as a form of recurrent paralysis of the facial nerve, associated with migraine, and strictly analogous to the recurrent paralysis of the 3rd nerve that occurs in similar conditions. [J. S.]

September, 1901.

1. Associate Nystagmus. E. STRANSKY.
2. Intermittent Claudication. M. VAN OORDT.
3. The Supraorbital Reflex. A New Reflex in the Region of the 5th and 7th Pairs of Nerves. D. MCCARTHY.

1.—Stransky describes a form of nystagmus that he observed and that has not hitherto been reported. If the eyelids of a patient are held forcibly apart, and the subject makes an effort to close them, there will occur a twitching in the upper lid, and in some cases horizontal nystagmus. He reports a case in which he was able to elicit these symptoms by simply lifting the eyelids vigorously. This patient suffered from bradycardia. His musculature was somewhat underdeveloped, and there was some hyperesthesia to pain on the left side of the body. There was some contraction of the vessels. He also mentions two other cases in which the same symptom was present. This reflex is of more physiological interest than clinical. It may, however, be of value to know that a purely functional nystagmus of this nature exists, in order that it may not be considered a symptom of organic disease. [J. S.]

2.—Van Oordt reports two cases of intermittent claudication. The first, a man of 63, who was able to walk for about one-quarter of an hour, after which time he developed severe fatigue in the muscles, occasional cramps in the calves, and, more rarely, a sense of burning in the legs. The symptoms disappeared in the course of a few minutes' rest. He was apparently normal, excepting that the muscles of the legs appeared to be poorly developed. The pulsation of the various arteries in the legs could not be detected. The arteries in the arms and neck were normal; there were no further symptoms of disease of the nervous system. As a boy he had been obliged to stand a great deal, and had taken coffee to great excess. Always after indulging too freely in the latter he felt a curious sense of numbness in the limbs. In addition he had worn a truss for hernia for some time, which had pressed upon the femoral arteries. The second case, a man of 69, who smoked cigarettes to moderate excess, had varicose veins in both legs, and after standing or walking, had severe pain in both legs. This disappeared in a few minutes, upon rest. The legs were quite thin, otherwise the symptoms were normal. No pulsation, however, could be felt in the arteries of the

legs. These two cases apparently indicate that intermittent claudication is usually due to vascular obliteration.

[J. S.]

3.—See editorial, Philadelphia Medical Journal, October 12, 1901, page 580.

CENTRALBLATT FUER CHIRURGIE.

July 27, 1901. (28 Jaargang, No. 30.)

1. Experiences in Cystoscopy. B. GOLDBERG.

1.—Goldberg has made over 150 cystoscopic examinations, 22 of them only in women. The cystoscopy found disease of the bladder in 85 people, and showed that the bladder was normal in 37 cases; 21 cases of tumors of the bladder were seen, in 10 of which the condition was diagnosed by 31 cystoscopic examinations. The examinations were made repeatedly to observe the growth of the tumors. Tumors of the bladder are divided into three groups, the rare cases in which cystoscopy is impossible, the cases which are diagnosed without it, and those in which the cystoscope alone diagnoses the condition. The use of the cystoscope is necessary before operation. In stone in the bladder cystoscopy is not so useful. Of 21 cases only 8 were seen with the cystoscope before operation. It should not be used in tuberculosis of the urinary tract, from the danger of infection. Goldberg used it 7 times, in 3 of which tuberculosis of the bladder existed. It was used in 6 cases of hypertrophied prostate, 14 cases of cystitis, 3 of hypertrophied bladder, 1 bladder with a diverticulum, and 1 case of foreign body in the bladder, 6 times he used the cystoscope to catheterize the ureters, 5 times for intravesical operation. Goldberg believes the cystoscope is never employed in vain. He adds a few details of the technique to be followed in its use. [M. O.]

August 3, 1901. (28 Jahrgang, No. 31.)

1. The Extirpation of the Appendix in the Interval Between Attacks. MAX JAFFE.

7.—Jaffé believes that extirpation of the appendix should not be performed between attacks in all cases of appendicitis. He reports two cases, in which the appendix was adherent to the cecum, and had ulcerated through, giving the signs of perityphilitis. The symptoms were tumor and pain in the cecal region, and some difficulty in the movement of the intestinal contents. In such cases, instead of seeking in vain for the appendix, Jaffé believes that resection of the intestine should be performed, and, when necessary, entero-anastomosis, especially if symptoms of stenosis exist. He operated thus upon his cases, with success. [M. O.]

August 31, 1901. (28. Jahrgang, No. 35.)

1. A Syringe for the Subcutaneous Injection of Anesthetic and Normal Salt Solutions.

ALEXANDER VON ZAWADZKI.

1.—von Zawadzki describes a practical and inexpensive syringe which he has devised for subcutaneous injections of Schleich's anesthetic or normal salt solutions. The syringe is of glass, with a slide attachment to permit the suction of the fluid in, which is to be injected by the syringe. The details are fully shown in the photographs which accompany the article. [M. O.]

September 21, 1901. (No. 38.)

The Extraperitoneal Radical Operation for Median Ventral Hernias. A. HAMMESFAHR.

The author describes an operation which he has successfully performed on various occasions for ventral hernia, and which he first reported in No. 10, 1901, of the *Centralblatt für Chirurgie*. The operation is performed as follows: An oval flap is made extending from the xiphoid cartilage to the symphysis pubis, which is to be as broad as possible at the middle and includes the subcutaneous fat. The hernial sac is then loosened from its envelopments without opening it; this entails careful dissection especially where the sac of the hernia consists of thin cutaneous superficial tissue. If care is taken the hernial sac will not be opened; but if this accident should happen, the opening is again closed with fine stitches. If after dissecting away the flap the anterior sheath of the rectus muscle is not yet entirely exposed, more of the abdominal skin and subcu-

taneous fat is dissected away up to the latter margin of the rectus muscle, and better still a little beyond it. It is essential for the application of the subsequent sutures, that a finger of the left hand can be inserted under the rectus muscle. In his first case the author even separated the parietal peritoneum from the posterior surface of the rectus muscle. But this entails great difficulty especially when cicatrices are present with the hernia. The author therefore proceeds as follows: he opens the rectus muscle at any place in the median line; if the medial margin of the rectus cannot be distinctly palpated, a small transverse incision is made into the area occupied by the anterior rectus sheath, whereupon the part looked for can be found. One finger is now inserted in the incision of the rectus muscle, that is between the posterior surface of the muscle and the posterior sheath of the rectus; the finger then strips the sheath in its entire length. Within a few seconds this can be done on both sides, whereupon the bellies of both muscles are in view and covered by the anterior sheath of the rectus. The first step of the operation is now completed and the sutures can be easily and quickly applied. The recti are so brought together that their median margins are directed towards the abdominal cavity, similar to a Lambert suture. In order to prevent any injury, the needles are not to be too pointed, but strong, and the suture material should be soft, flexible, silver wire or silvered aluminum bronze wire. The needle is inserted at the lateral margin of the rectus, glides along the posterior surface of the belly of the muscle, and between the latter and the inserted finger; then between it and the posterior sheath of the rectus; it then takes the median direction and again emerges through muscle and anterior sheaths between the middle and inner third. Then similar stitches are taken on the opposite side. Superficial sutures embracing fascia and muscle are then applied. A short drain on each side and closure of the skin wound complete the operation. [M. R. D.]

JOURNAL DES PRATICIENS.

August 31, 1901. (15me. Année, No. 35.)

1. Ocular Therapeutics. A. TROUSSEAU.

2. The Treatment of Deafness. A. CASTEX.

1.—Treatment of the eyes is of three kinds, local, general, and hygienic. Among the local means employed are compresses, irrigation, eye washes, caustics, antiseptics, bandages, and glasses. Compresses are indicated in keratitis, or in purulent conjunctivitis, associated with irrigation. Cold compresses are employed for injury, hemorrhage, or purulent conjunctivitis; hot compresses, in blepharitis or keratitis. Several layers of gauze, in water, or a 4% boric acid solution, form the compresses. For irrigating the eye, solutions of mercuric cyanide (1-10,000), corrosive sublimate (1-10,000), carbolic acid (1-200), potassium permanganate, etc. are used in conjunctivitis, traumatism, etc. Eye washes may be anesthetic (cocain, 1-20), caustic (zinc chloride, 1-500), mydriatic (atropin, 3-500), or myotic (eserin or pilocarpin, 1-100). Calomel and other powders are used dry upon the eye, while yellow oxide is employed as an ointment. The caustics used in the eye are silver nitrate and copper glycerole. Aseptic dressings and bandages may be needed, and sometimes glasses. The internal treatment is mercury and potassium iodide in syphilis; sodium salicylate and quinine in rheumatism; cod liver oil, etc. in tuberculosis. Hygienically, baths, exercises, and diet are recommended. [M. O.]

2.—Castex reports the treatment of hypothetical cases of deafness in youth, adult and old age. After obtaining family and personal history, questions should be put about existing discharge from the ear, vertigo, loss of hearing, etc. Then the ears must be examined carefully, to determine upon the condition present. This may be catarrh, otorrhea, sclerosis, syphilis, or psychic deafness. If catarrh exists, the naso-pharynx must be kept clean by alkaline solutions; if otorrhea, the ear must also be kept clean with hydrogen peroxide; if sclerosis, sodium iodide may be given; if syphilis, specific treatment, with pilocarpin locally; if psychic, acoustic exercises and electricity will be beneficial. In an adult, there is generally some buzzing or other noises in the ear. For the rest, hygiene, and bromides will do much. In old age, when the hearing also grows weaker, general supporting treatment is necessary. [M. O.]

PRESSE MEDICALE.

July 27, 1901. (No. 60).

1. The Cause of Death in Mastoid Disease. STANCULEANU and DEPOUTRE.
2. Chronic Pentosuria. R. ROMME.

1.—Behind the mastoid cells, which are easily laid open by operation, are posterior aberrant cells, which, suppurating by continuity, cause meningitis or thrombophlebitis and death, even after the anterior mastoid cells have been freely opened. From 100 temporal bones examined, Stanculeanu and Depoutre conclude that these posterior cells are not found in young children, as they found them but once in a child of 9, but that in adult and old age they are common. They divide these cells into 3 groups, postero-superior, posterior, and postero-inferior, from their position. These posterior mastoid cells were found in 40 out of 100 skulls. In 12 cases all 3 groups existed; the postero-superior in 27; the posterior in 13, and the postero-inferior in 12 cases. In only six cases was there no communication with the anterior mastoid cells. From the position of these cells they advise trephining, removing the bone from the postero-superior angle on the parietal bone, downward $2\frac{1}{2}$ cm. to Henle's spine, and backward 3 cm. upon the occipital bone; or this may be left to follow a less radical primary operation. Thus meningitis and thrombophlebitis may be prevented. [M. O.]

2.—Bial and Blumenthal have shown that pentosuria, which causes the same reactions as glycosuria, except by fermentation and the polariscope, is never found in diabetes. Their researches proved that food did not affect the pentosuria, and that the pentose existed in the blood. While the subject remains obscure, Romme believes, from the work of Bial and Blumenthal, that pentose is formed from nuclein. It is found in the blood and urine of the individual only when, for some unknown reason, it is not oxidized. [M. O.]

July 31, 1901. (No. 61).

1. The Rashes of Smallpox. HENRI ROGER and EMILIE WEIL.
2. Strophanthus. A. MARTINET.

1.—The specific eruption of smallpox is often preceded, accompanied, or followed by other rashes. Roger and Weil have observed 928 cases of variola, 171 of whom had rashes other than the eruption of typical smallpox. These cases were more frequent upon men than women. They were seen both in mild and severe cases, mostly in serious cases. Six varieties of rash were noted, erythematous, morbilliform, scarlatiniform, urticarial, purpuric, and ecchymotic. The morbilliform and ecchymotic rashes alone affected the face. The inguinal regions were affected symmetrically in 68 cases, 25 times by associated rashes, 23 times by purpura alone, while the rest of the body was covered with a scarlatiniform rash. In most cases, however, the eruption was generalized. Next to the groin in frequency, the axilla was affected by a localized rash. Out of 171 cases, 146 showed unassociated, 25 associated rashes. In these 25 cases 51 rashes were seen, making a total of 197 rashes in 171 patients. The rash observed was scarlatiniform in 70 cases, purpuric in 68, morbilliform in 42, etc. As a rule these rashes preceded the true smallpox eruption. Purpura persists a long time. Often the smallpox eruption becomes confluent upon the regions previously attacked by another rash. Generalized rashes are unfavorable. Late ecchymotic, erythematous, or purpuric rashes are almost all fatal. The probable cause of the appearance of these different eruptions is a disturbance in the innervation of the cutaneous vaso-motor system, due to the invasion of the individual by the smallpox. This is due to a congestion of the medulla. The position of this medullary congestion determines whether the rash is generalized or local. [M. O.]

2.—After comparing strophanthus with digitalis, Martinet says that it is to be preferred to digitalis at stated intervals in mitral disease; that it is to be preferred to digitalis in atheroma or aortic affections with hypertension; and that it should be given in increasing doses. He advises extract of strophanthus in doses of 1 mg., (or strophanthin, 0.1 mg.), increasing one dose daily. [M. O.]

August 3, 1901. (No. 62).

1. The Lesions of the Cells of the Spinal Ganglions in Tabes. G. MARINESCO.
2. Hypodermic Injections. P. DESFOSSES.

1.—After a comprehensive review of the subject, Marinesco describes the results of his own work. The variability of the normal cells of the spinal ganglions depends upon three factors, the density of the chromatin, the density of the fibrillar chromatin, and the colorability of the fundamental achromatin. The light and dark cells may have the chromatin arranged in corpuscles, granulations, and very fine granulations, and they may be large, medium, or small. In the spinal ganglions of nine tabetic individuals, cells were found with well defined but very light chromatin corpuscles; with pale, small nuclei; or rarely, with retracted cell walls. These changes are not constant, and seem incongruous, when compared with the degeneration in the posterior columns of the spinal cord. These later researches confirm the opinion already expressed by Marinesco, that tabetic degeneration begins, not in the posterior roots, but in the collaterals of the posterior radicular fibers, especially the reflex fibers. [M. O.]

2.—In using the hypodermic syringe, care should be taken to prevent infection, which may be followed by abscesses, scars, etc., or breaking the needle. The syringe, needle, solutions, and technique of an ordinary hypodermic injection are all described in full. [M. O.]

August 7, 1901. (No. 63.)

1. Paramyoclonus Multiplex. GEORGE CARRIERE.
2. The Transmission of Meningococci by the Respiratory Tract. BUSQUET.

1.—Carrière reports a case of paramyoclonus multiplex in a boy of 10. His father is neurotic and irritable. The child is very intelligent, impressionable, sensitive, and nervous. A year ago another boy hit him unexpectedly in the abdomen. He worried over it all day, and awoke with abdominal pain that night. Three weeks later the pain reappeared suddenly one morning, and has come again almost every day since. Then involuntary movements of the neck, shoulders, body, arms, and legs, developed, appearing in attacks close together, almost every 4 or 5 minutes. Breathing is irregular during the paroxysms. Fibrillary contractions are also noted. Everything becomes exaggerated when the boy goes to bed, he is excited, etc. The involuntary movements in the part disappear during voluntary movement of the part, or when the boy's attention is attracted to the part, but they become worse over the rest of the body. Occasionally there are profuse perspiration, salivation, and polyuria. The sensory reflexes are very lively; the corneal reflex is abolished, and the visual field is concentrically retracted. Carrière believes that this was a case of paramyoclonus multiplex, of which disease only 32 cases are so far reported, three of which Carrière has seen. This condition is due to functional hyperexcitability of the motor neurons, found rarely with an anatomic lesion, sometimes with neurasthenia, but most frequently seen with hysteria. He believes that hypnotic suggestion and careful watching should be the treatment. He reviews the literature of the subject, and gives the differential diagnosis between the different forms of chorea and paramyoclonus multiplex. [M. O.]

2.—Busquet has made experiments upon three cases of epidemic cerebro-spinal meningitis, in Algeria. From the first series of experiments upon different sorts of animals, it was shown that when meningococci are present in the nasal mucous membrane of patients with epidemic cerebro-spinal meningitis, and this nasal mucous membrane is placed upon the nasal mucous membrane of animals, the meningococci will invade the animals and reach the cerebro-spinal fluid. The meningococci remain virulent in rabbits, the nasal mucous membrane of one being capable of infecting others of the same species. Busquet's other experiments show that cerebro-spinal fluid, from patients dead of epidemic cerebro-spinal meningitis, containing the meningococcus of Weichselbaum, is virulent to rabbits. Simple deposition of meningococci upon the nasal mucous membrane of rabbits will cause epidemic cerebro-spinal meningitis. This proves that epidemic cerebro-spinal meningitis can be transmitted by the respiratory tract, especially through the nasal mucous membrane. [M. O.]

August 10, 1901. (No. 64.)

1. The Thyroid Gland in the Treatment of Infantile Myxedema. BEZY and STOIANOFF.

1.—Bezý and Stolanoff believe that the infectious diseases predispose to infantile myxedema, and that the thyroid gland is essential to normal growth and development, especially about the time of puberty. They report the case of a girl of 5, cured by rapidly ascending doses of fresh thyroid gland, up to 24 grains a day. Photographs show the improvement which followed the administration of the thyroid gland. [M. O.]

August 28, 1901. (No. 69.)

1. Echinococcal Cysts of the Peritoneum. GUIBÉ.

2. The Pathogeny of Muco-membranous Enterocolitis.

A. BROCCHI.

3. The Indications for Arsenic. A. MARTINET.

1.—There is no doubt that the echinococcus embryos travel through the cellular tissue or the circulation, from the stomach. This is the exogenous theory. But Guibé believes that the endogenous or auto-intoxication theory occur after the rupture or puncture of a hepatic cyst, found especially in Douglas's pouch. This theory is confirmed by animal experiments, several of which are quoted in full. From an extensive review of the subject, Guibé concludes that the female echinococcus vesicula, set free in the abdominal cavity, may become attached to the peritoneum, develop and reproduce there; that the fluid alone cannot reproduce hydatid cysts, except when scolices or vesicles are present in it; that a fragment of a cyst wall with scolices or vesicles upon it can produce a hydatid cyst; and that echinococcal cysts which have become attached to the peritoneum soon develop an endothelial covering and thus become secondarily extraperitoneal. Therefore, in operation upon such cysts, great care must be taken to prevent the contents of the cyst from touching the peritoneum. [M. O.]

2.—Brocchi reports two cases of muco-membranous enterocolitis in middle-aged subjects in excellent health, in whom the symptoms developed after grave emotion and slight traumatism. As a rule Brocchi believes that intestinal atony precedes all nervous symptoms, especially in neuro-arthritic individuals. In his two cases, on the contrary, the nervous symptoms preceded the intestinal, in people neither neurotic nor lithemic. [M. O.]

3.—Will be abstracted when concluded.

August 31, 1901. (No. 70.)

1. The Side-chain Theory of Immunity. C. LEVADITI.

2. Arsenic. A. MARTINET.

1.—Levaditi explains clearly and fully, with diagrams, the side-chain theory of immunity advanced by Ehrlich. The subject is in most technical language, and is comprehensible only to those well versed in the subject. [M. O.]

2.—Arsenic increases the number of red and white blood corpuscles, augments the body weight, and causes general stimulation of the organism and its various functions, especially assimilation and hematosis. The cacodylates do not cause any symptoms of poisoning, even when continued for some time. They should be administered hypodermically, in aqueous solution, with a few drops of carbolic acid added; more than 5 cg. of sodium cacodylate should not be given as an initial dose, rising gradually to 10 cg., an average dose rarely to be passed. It is well to continue the injections for 8 or 12 weeks, one injection weekly. The same doses may be given to children. Rarely, sodium cacodylate may be given by the mouth or rectum. It is indicated during the first and second stages of phthisis, and in the convalescence from rheumatism, bronchitis, pleurisy, and the infectious diseases. It has been employed with some success, also, in malaria, asthma, neurasthenia, and various skin diseases. The only contraindication to the use of the cacodylates seems to be hepatic insufficiency. [M. O.]

Society Reports.

MEETING OF THE NEW YORK MEDICAL ASSOCIATION.

(Concluded from Page 822.)

Vesical Emergencies—Their Surgical Management. Dr. Eugene Fuller, New York. This was a particularly technical paper, covering operation, instruments, their adaptation to certain cases, catheterization, tenesmus, and spasm, as well as perineal operation with or without a guide, and supra-pubic incision. He surgically subdivided cases of vesical tenesmus into two general classes—those amenable to catheterization and those which are not. Antiseptic precautions should be taken in the catheterization of all patients, especially where traumatism, the result of external perineal violence, is not the evident cause. Harmful traumatism can never be done by a soft rubber catheter. Gum elastic, silk-covered catheters are often of great value. In those cases not amenable to catheterization, the surgeon has to meet the emergency by liberating the retained fluid through the medium of an incision. In case of complete rupture of the urethra, where the operation is undertaken early and gangrene has commenced, retrograde catheterism, after locating the posterior urethral segment and repair of the urethra, should be undertaken immediately after the bladder has been drained supra-pubically. Where prostatic retention occurs in cases not amenable to catheterism, the rule should be immediately to perform prostatectomy, thus effecting and radically removing all obstruction or retention.

Uterine Prolapse. Dr. Frederick Wiggin, N. Y. Of the various local chronic diseases to which women are liable, complete uterine prolapse produces the greatest disadvantages and discomfort. The condition is best described as a reducible hernia through the pelvic floor. Causation: primarily a separation of the tendons of the muscles forming the pelvic floor, where they unite in the median line; this is usually due to the passage of the child during parturition. In the treatment of the disorder, hysterectomy has not been very satisfactory. The writer's treatment is to place the patient in bed, reduction of the tumor, employment of gravity to retain the parts; tampons moistened with glycozone are placed in position and parts treated until all ulcerations on the vaginal wall are healed. The next step is laparotomy. The operation seems to be well borne by old women.

Typhoid Cholecystitis with Report of Cases. Dr. Chas. G. Stockton, Buffalo. The doctor gave a recitation of interesting cases. The gall-bladder is generally infected in typhoid fever, but often so mildly as to escape notice. Sometimes it remains latent. Usually develops within 10 to 30 days, but cases were reported in which it came on respectively 17 and 18 years after typhoid. In the discussion, Dr. Ferguson (Troy) stated that gall stones are not the cause of gall-stone colic, but that the pain is caused by the presence of cholecystitis, that smooth gall-stones are not able to produce pain.

What Percentage of Gouty and Rheumatic Patients Develop Fatal Pulmonary Phthisis? Thomas F. Reilly, N. Y. The doctor's paper was rather an interrogation with no deductions drawn or original opinions presented, and, as there was no discussion, no conclusions were made.

AFTERNOON SESSION, OCTOBER, 24, 1901.

In a contribution entitled **A Durham Tube in the Right Bronchus**, Dr. E. D. Ferguson, Troy, reported the case of a young woman in operating upon whom a tube of the kind referred to disappeared, and after some difficulty was extricated from the bronchus. Considerable hemorrhage took place in removing it, and the condition of the patient for a time was such as to cause anxiety, though ultimately she recovered. The author of the paper exhibited a device which would prevent the recurrence of accidents of that kind.

Indications of Treatment in Uterine Myomata. Dr. George Tucker Harrison, New York. Myomectomy has developed out of ovariectomy. Many myomata remain moderate in size and do not interfere with the patient in any way. It is nevertheless the law that these do undergo retrograde

metamorphosis. A large sized tumor of quick growth is usually regarded as demanding a radical operation. However, this cannot be admitted without qualification. When a woman is more than 50 years of age with a large tumor and suffers no inconvenience, operative intervention is not justifiable. When a woman is comparatively young and myomata grow rapidly, radical operation is indicated. Hemorrhage does not cause death directly, but might do so indirectly by anemia and by tumor on a vein which might create thrombosis. Cystic degeneration of a myoma is an indication for myotomy. When there is a myoma in conjunction with peritonitis, it should form an indication for operation. Reference has been made to the fact that great progressive changes exist at the time of the menopause. The author believed that when myoma was complicated with pregnancy, if birth could be accomplished without endangering the patient's life, natural labor should be permitted. If it interfered, however, with the patient's life, then operation should be performed. Statistics show that the mortality of myotomy is decreasing. Nowhere in the whole domain of surgery is the difficulty greater than in the case of uterine myoma.

Dr. Wilbur B. Marple, New York, read a paper on **Re-section of the Cervical Sympathetic in the Treatment of Glaucoma; Its Present Status.** There were, he remarked, certain methods of treating this condition which were far from satisfactory. In many cases the glaucoma went on without any evidence of having been checked by their efforts. In as many as fifty per cent. of the cases operated on there was said to be no visual improvement, while in ten per cent. absolute blindness was reported to ensue. That being so, he thought ophthalmic surgeons would be pleased to learn of the process which had been adopted by Jonesco of Buda-Pesth. The operation of removing the sympathetic glands for glaucoma had first been performed by that gentleman in 1897, and since then a number of successful cases had been reported. So far it had been almost, if not entirely, confined to simple chronic cases; few observers had suggested its use in acute cases. Some cases unfortunately had found their way into print which had been only a short time under observation, and which were not only valueless but misleading. After carefully studying the literature on the subject, the author had come to the conclusion that the operation of extirpation was a safe procedure in the hands of a skilful operator, but that, while a considerable number of favorable results had been reported, they were not yet in a position to say when the operation was indicated or what permanent results might be expected from it. It was very desirable that cases thus operated on should be watched for a longer period. Dr. James J. Walsh, New York, said he was not an ophthalmologist, and therefore could not discuss the subject from that point of view, but he happened to be with Jonesco when some of the cases had been operated on, and he had since learned from him that he had treated 127 cases in the way described. There seemed to be a future for the operation which justified the watching of future reports with a good deal of interest.

A Report of a Case of Gun-shot Wounds of the Intestines was reported by Dr. H. van Hoevenberg, Kingston, who remarked that he thought it would be interesting, coming as it did so soon after the case of the late President McKinley. The man was shot in the abdomen (median line) with a 32-caliber bullet. The operation described by the author was conducted under very unfavorable auspices six and a half hours after the shooting took place. There were ten perforations of the intestines found, the ascending colon, small intestine and omentum were perforated, and two hours were occupied in exploring the field and closing the lacerations with silk sutures. The patient rallied without unfavorable symptoms, but on the fifth day he complained of localized tenderness, and his temperature rose. This led to the wound being reopened, and the conclusion arrived at that the ball must be the cause of the rise of temperature. A search was accordingly made for it, and it was found in a small pus cavity. After this the temperature dropped to normal, and thereafter there was a history of uninterrupted improvement. No solid food was given until the twelfth day. A feature of the operation which he considered important was the giving of a small dose of morphia for the purpose of restraining the peris-

tafic action of the bowels. He was glad he only gave a quarter of a grain, because he never saw a man so susceptible to the influence of morphia, the pupils contracting to pin-points, remaining so for several hours, but the effect of the small dose was satisfactory, and prevented the possibility of any of the contents being forced through the abdominal wall. Liquid food was given until the twelfth day. From that time on solid food was given and was increased in quantity.

The paper was discussed by Dr. R. H. M. Dawbarn, New York, to whose teaching the author had given credit for the use of morphia. He enlarged on the importance of this feature, which he called the morphia splint. It was, he remarked, in accordance with the dictates of good surgery, which required that the wounded bowel should be put at rest. If this were not done, there was danger of part of the contents being forced out, and causing sepsis. The continuous suture which the reader of the paper had used was also to be commended. When combined with the morphia splint, the continuous suture was safe and ought to come into general use in this class of cases.

Technique of Fixation for Prolapsed Kidney. This was the title of a paper by Augustin H. Golet, New York. The object of the operation, he said, was to fix the prolapsed kidney in a normal position against the muscles of the back in such a manner that there would be freedom from motion until it became firmly adherent. This seemed best accomplished by sutures, and temporary sutures of a non-absorbable material like silk-worm gut were to be preferred. If the gut was prepared by boiling in a solution of lysol it was rendered pliable, and was as easily manipulated as cat-gut. Such fixation of the kidney might not be a normal condition, since the kidneys were normally moveable to a limited degree; but it was much to be preferred to prolapse of the organ and its attendant symptoms and consequences, and it certainly restored the patient to a condition of health and comfort which could not be enjoyed before. Prolapse of the kidney was a surgical condition, because it did not admit of cure by other than surgical means. That it was but one element in a general enteroptosis was no argument against operation. The operation was not one that involved any risk per se, and therefore should not be dreaded by any one obliged to undertake it. It should not be opposed by those who did not choose to endorse it because they did not operate and hence could not observe its results. Summing up, he said: a prolapsed kidney which gave rise to symptoms that produced discomfort or ill-health demanded operation (1) because there was no other means of relief; (2) because there was a tendency to progressive exaggeration of the degree of prolapse; (3) because prolonged prolapse produced congestion and softening of the kidney structure and its fibrous capsule; (4) because the prolapse might at any time interfere with the function of the kidney and entail serious consequences. This paper was discussed by Dr. G. M. Edebohl, Dr. Howard Lillenthal, Dr. Willy Meyer and Dr. Dawbarn, the criticisms being confined to the technic.

A Report of a Case of Glanders, Dr. J. R. Sturtevant, Ithaca, N. Y.

The concluding paper was by Dr. Edward H. Squibb, Brooklyn, entitled, **Brief Comments on the Materia Medica, Pharmacy and Therapeutics of the Year Ending July 1, 1901.** (Read by title).

OFFICERS ELECTED:

Dr. A. A. Hubbell, Buffalo, N. Y., President.
Dr. Wm. H. Biggam, Brooklyn, Vice President.
Dr. Guy Davenport Lombard, New York, Secretary.
Dr. E. H. Squibb, Brooklyn, Treasurer.
Dr. James Taylor Lewis, New York, Counsel.

COMMITTEES:

Dr. E. Eliot Harris, New York, Chairman, Committee of Legislation.
Dr. Alex. Lambert, New York, Chairman Public Health and Medical Charities.
Dr. John W. S. Gouley, New York, Chairman Committee on Library.
Dr. J. Riddle Goffe, New York, Chairman Committee on Publications.
Dr. Charles E. Quimby, New York, Chairman Committee on Nominations.
Dr. Irving S. Haynes, New York, Chairman Committee on Arrangements.

The new office-bearers were installed as follows: President, Dr. Alvin A. Hubbell, Buffalo; Vice President, Dr. Wm. H. Biggam, Brooklyn; Secretary, Dr. Guy D. Lombard, New York.

Adjourned.

MANHATTAN DERMATOLOGICAL SOCIETY.

MEETING HELD FRIDAY, NOV. 1, 1901.

Dr. Gottheil in the Chair.

Dr. Abrahams showed a child of eight weeks with **seborrheic eczema** involving the entire body. There was *coryza*, but no signs of syphilis. Dr. Gottheil remarked that macular lesions were unusual in seborrheic eczema. Dr. Sobel presented a child of 2½ years with **chronic papular urticaria**. Itching was intense, and the inguinal glands were enlarged. Some papules were infected and became pustules. Dr. Bleiman stated that prurigo and scabies could be excluded. Dr. Weiss termed such cases *strophulus infantilis*, often preceding prurigo. He believes this case will eventually develop prurigo. Dr. Gottheil remarked that scabies could not be excluded. Dr. Abrahams advised daily doses of pilocarpin, gr. 1/12—gr. 1/10. Dr. Bloiman presented a boy of 11, with **prurigo**. The eruption began at two years, growing worse in winter. Dr. Sobel hesitated to make a positive diagnosis of prurigo. Dr. Oberndorfer and Dr. Abrahams considered it chronic papular eczema. Dr. Gottheil said there were no positive symptoms of prurigo. Dr. Gottheil then presented a woman of 64, with **rhinoscleroma**. The alae nasi were hard and cartilaginous and ulceration had occurred. Dr. Geyser remarked that radiotherapy would only hasten death. Rhinoscleroma may occur primarily in the tonsil, resembling chancre and cancer. Dr. Weiss presented a man with **keratosis follicularis** of both forearms. Dr. Oberndorfer presented a man with **multiple mollusca contagiosa of the penis**. This situation is rare. The lesions are auto- and hetero-inoculable. Dr. Weiss remarked that as a rule other parts of the body are also affected. Dr. Gottheil reported a case in which there were numerous mollusca on the penis and scrotum. Dr. Abrahams presented a man of 57 with **atrophia cutis propria**. Forty years ago eczematous lesions appeared in the popliteal space; later at the ankle, followed by atrophy, varicose veins and ulceration. Dr. Sobel considers it a tropho-neurotic atrophy. The atrophy and varicosities are probably not related. Dr. Gottheil stated that the erythema seen at the edges of the atrophy points to inflammation. Dr. Gottheil then showed photographs of cellulitis of the lip, *favus corporis*, *sarcoma* of the skin, *lichen planus*, *lichenification* in old eczema, *erythrasma* of the buttocks, *disydrosis* and *erythema multiforme*.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopedic Surgery.

OCTOBER 18, 1901.

George R. Elliott, M. D., in the Chair.

Dr. A. B. Judson presented a baby five months old with **infantile paralysis simulating congenital talipes calcaneus**. A three days' sickness occurred at two months, with fever, trembling, and general hyperesthesia, but no vomiting, diarrhea or convulsions. Dr. W. R. Townsend believed well marked congenital talipes calcaneus to be very rare. Dr. Henry Ling Taylor agreed that the severe forms were rare, but milder varieties were fairly common, usually correcting themselves without special treatment. Dr. Judson presented a case of **crepitus heard in cervical Pott's disease** in a woman of 40. Pain on moving her head and deformity were marked, partly due to a forward displacement of the axis. The width of the neck posteriorly was increased. At one time the head was much flexed and inclined to the left. Six months ago she noticed that motion of the head in rotation was accompanied by a crackling sound. Drs. Townsend, Elliott and Taylor did not agree with the diagnosis of cervical caries, being inclined to consider the case one of *osteoarthritis*.

Dr. Homer Gibney presented six cases of **osteotomy for the correction of bow-legs and knock-knees**, and described

his method of operating. Dr. L. A. Weigel, of Rochester, was somewhat in doubt as to the proper course to pursue. An outline tracing of the leg might show an apparent bowing, while a skiagraph would demonstrate that the shafts of the leg bones were straight. He exhibited skiagraphs of two cases. In one the deformity was corrected by osteoclasis, but the skiagraph showed that the legs were straightened by making the bones slightly crooked. Dr. Taylor called attention to the importance of correcting inward rotation of the tibia in bow-legs. Neglect to correct this rotation meant an incomplete correction of the deformity and the liability of recurrence. He advised breaking the tibia as well as the tibia, well loosening the fragments, and twisting the foot out as much as possible—the resulting eversion would not be too great. Dr. Sayre remarked that in many cases the distortion was found close to the epiphyses, while the shafts of both tibia and fibula were straight. The operation should be performed at the point where the deformity existed.

Dr. Taylor presented a boy of six years with **coxa vara**. He walked at eleven months and had been lame in the left leg since. There was one-half inch shortening of the left leg, the trochanter was elevated a half inch and the head of the femur could not be felt. A skiagraph showed that the head of the bone was in the acetabulum and that the neck was bent downward. There was no rachitis. Dr. Sayre judged from the skiagraph that there had been fracture of the neck of the femur, or epiphyseal separation. Dr. Taylor said that it was evident that coxa vara was present, whether the result of traumatism or malformation.

Dr. Weigel read a paper on **skiagraphy in orthopedics**, illustrated by stereoscopic skiagraphy. The technique was not difficult. An idea of depth was given which was not apparent when viewing the negative alone. By reversing the negatives in the apparatus, the pictures could be viewed from the opposite surface. Dr. Weigel also showed **fractures and dislocations in tubercular joint diseases** with skiagraphs. A boy said to have double congenital dislocation of the shoulders proved to have tubercular destruction of the joints, with partial dislocation. On one side an abscess cavity of large size communicated directly with the joint.

A Case of Unilateral Clubbed Fingers.—Dr. A. Bécélère showed photographs of two hands, upon one of which, the right, typical clubbed fingers were seen, at a recent meeting of the Medical Society of the Paris Hospitals, (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, 1901, No. 11). Röntgen photographs show no difference in the two hands. The patient, a man of 65, with an aneurysm of the right subclavian artery, often shows cyanosis of the right hand upon any motion. The right radial pulse is slightly less in volume than the left. Bécélère compares this unilateral condition with that found in congenital pulmonary stenosis. He believes that the clubbed fingers of the right hand are due to pressure, stenosis, or obliteration of a number of branches of the pulmonary artery from the aneurysm. As certain chronic hepatic affections always accompany clubbed fingers, Bécélère suggests that some relation may exist between them. [M. O.]

Acute Dilatation of the Heart in Acute Articular Rheumatism.—Pierre Teissler, in the *Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, (1901, No. 12), reports two cases of acute dilatation of the heart in acute polyarticular rheumatism. The first case was a girl of 17, who had her first attack of rheumatism. She took 60 grains of salicylate daily for three days. Then the heart dilated rapidly. Two weeks later it returned to its normal size. The second case was in a woman of 30, with her fourth attack of polyarticular rheumatism. Her heart had never before been affected. Dilatation of the heart occurred, but it returned to its former size in 10 days. In both cases the right ventricle dilated, without a sign of endocarditis or pericarditis. This shows plainly that the myocardium alone may be affected in acute polyarticular rheumatism. [M. O.]

Original Articles.

HISTORICAL NOTE ON SMALLPOX.

By JAMES TYSON M. D.,

of Philadelphia

Professor of Medicine, University of Pennsylvania.

It is probable that smallpox prevailed in China many centuries before the Christian era. It is believed to be the same disease as the *pesta magna* described by Galen, in the latter part of the second century. It is known to have prevailed during the sixth century and again during the Crusades. The first accurate description was, however, given in the ninth century by Rhazes, an Arabian physician, and distinguished by him from measles. It is thought to have been introduced into America by the Spaniards early in the sixteenth century. Sydenham's classic description was made in the seventeenth century. In 1796, Juncker wrote that 400,000 lives were lost yearly in Europe by smallpox, and in 1803, King Frederick William of Prussia published an edict to the effect that 40,000 died annually in his Kingdom of the same disease.

Inoculation of smallpox with a view to securing immunity from subsequent attacks was introduced into England in 1718 by Lady Mary Wortley Montague, the wife of the British Ambassador to Turkey. It was, however, practiced for centuries previous to this in China and other Asiatic countries. It was introduced into Germany in 1721, but was not popular until 1740.

As to vaccination the peasantry in various parts of the world, particularly in England, had learned some years before any systematic observations were made that the sores on the hands of a person who milked cows affected with cow-pox conferred immunity from smallpox.

It is said too, that a Dorsetshire English farmer successfully vaccinated his wife and two sons as early as 1774 from a cowpox on himself. In 1791, Plett, a Holstein schoolmaster, vaccinated three children, in one case on the finger-tips. This caused such inflammation that he was deterred from repeating the experiment, but the three children escaped the epidemic in 1794. Edward Jenner, while a student of medicine, learned of the traditions on this subject, and conferred with his preceptor, John Hunter. He settled the question effectually May 14, 1796, when he vaccinated a boy, James Phipps, with matter from a kine-pock on the hand of a dairymaid, Sarah Nelmes, and on July 1, introduced into this boy pus from a smallpox pustule, without effect. Two years later—June, 1798,—he published his celebrated "Inquiry into the Causes and Effects of the Variolae Vaccinae," illustrated by four plates, and within a year or two vaccination became general over the continent of Europe.

Vaccination was introduced into the United States July 8, 1800, by Benjamin Waterhouse, Professor of Physick at Harvard University, who vaccinated his own children, and about the same time into Philadelphia by John Redman Coxe, who vaccinated his oldest child and then tested the experiment by exposing him to smallpox. The re-

liance on the protective power of vaccination in America was strengthened materially by this bold act. President Jefferson was instrumental in introducing vaccination in the Southern United States.

THE CHARACTERISTICS OF GENUINE VACCINIA:
EXPERIENCE WITH GLYCERINATED LYMPH AND
SOME STATISTICS OF THE PRESENT SMALLPOX
EPIDEMIC.*

By WILLIAM M. WELCH, M. D.,

of Philadelphia.

Physician-in-charge of the Municipal Hospital for Infectious Diseases.

and JAY F. SCHAMBERG, M. D.,

of Philadelphia.

Professor of Diseases of the Skin at the Philadelphia Polyclinic; Assistant Attending Physician to the Municipal Hospital.

It is essential for the reputation of vaccination that no misconceptions should arise concerning the criteria upon which a diagnosis of true vaccinia is based. Nothing is so injurious to the cause for which Jenner so conscientiously labored as to give to a spurious or false disease the name of vaccinia.

The following may be regarded as the typical course of the vaccine disease. On the third or fourth day after vaccination a very faint redness may be seen at the point of inoculation. This redness gradually increases, while at the same time a distinct reddish papule is formed which varies in size according to the extent of the abrasion. On the fifth day the lesion begins to assume a vesicular condition. This is usually seen first at the margin of the site of inoculation. The vesicle gradually increases in size, the contained lymph being at first thin and perfectly transparent. On the eighth day the vesicle reaches its greatest perfection. It is then considerably elevated above the level of the skin and presents a pearly or yellowish appearance. When examined closely it will be found to have, even at an early stage of its development, an umbilicated form similar to that seen in vesicles of variola. About this time there appears around the vesicle an inflammatory circle which is called the areola. During the ninth or tenth day the redness increases, the inflamed skin becomes tense and painful, and streaks of redness often extend a considerable distance from the lesion. The neighboring lymphatic glands become enlarged and painful.

At the same time mild constitutional symptoms appear, slight rigors, a rise of temperature of one or two degrees, malaise, anorexia, disturbed sleep, etc. Many children, however, pass through the regular course of vaccinia without any apparent systemic disturbance. Occasionally in severe primary vaccinations a macular eruption, designated as *roseola vaccinosa* and bearing considerable resemblance to measles, may appear.

On the eleventh or twelfth day the pock begins to fade, its contents become opaque and desiccation appears in the centre. By the fifteenth day desiccation is usually completed, although the crust does

* Read at the Philadelphia County Medical Society, November 13th, 1901.

not fall off until the end of the third or frequently the fourth week. The completed crust is of a mahogany color, rough on its exterior, thin at its centre and periphery, with a thick circular ridge between. The scar is at first red, but in the course of a few months becomes paler than the surrounding skin. It is pitted or foveolated, and not infrequently presents radiating bands or striae of cicatricial tissue.

The query is often asked, what constitutes a successful revaccination? This is a question about which there is some diversity of opinion. Many believe that, unless the vesicle and areola observe the course of true vaccinia, the effect is merely local and devoid of prophylactic power. But it is evident on a little reflection that there is no more reason why we should expect the vaccine disease produced by revaccination to be typical than that we should expect smallpox after vaccination to run the typical course of variola vera. If there be modified smallpox or *varioid* after vaccination, so should there be modified vaccinia or *vaccinoid*. From these premises the conclusion may be deduced that, as varioid confers immunity against a recurrence of smallpox, so also does the modified form of vaccinia resulting from revaccination remove from the individual whatever susceptibility to the disease may be present.

As the analogy between cowpox and smallpox is in most respects very close, and as variola frequently differs in the duration and severity of its local manifestations, so also it must not be expected that the local lesions of vaccinia will invariably follow the typical course just described. In some cases, the disease is undoubtedly shorter and milder, while in others it is longer and severer. No deviation, however, should occur in the evolution of the pock; that is to say, it should pass through the stages of papulation, vesiculation and pustulation. It has been known to appear as late as one month after the inoculation was done, and then develop and run regularly through its course. Likewise the constitutional symptoms are not uniform. They may be mild or entirely absent.

There are certain false vaccine conditions which claim attention. The raspberry excrescence when seen usually appears from three to seven days after vaccination, beginning as a red elevation at the site of inoculation, quite similar in appearance to the papule of true vaccinia, but instead of advancing to the vesicular stage it remains hard, dense, bright red in color and nodular in form, looking not unlike a small nevus. It is very persistent, remaining usually weeks or months, and is not followed by a scar. This spurious excrescence is more frequently seen since the general employment of bovine lymph. Experience has proven that this raspberry form of the vaccine disease is utterly devoid of protective power against either variola or vaccinia.

There are some physicians who allege that practically all of the lesions produced by glycerinated lymph are spurious.

Dr. F. J. Runyon, of Clarksville, Tenn. (*Memphis Med. Monthly*, Aug., 1901), condemns glycerinated virus and quotes series of cases in which the lymph, although apparently producing successful vaccina-

tions, failed to protect against successive inoculations and also against smallpox. He says, "When using the glycerinated lymph I had, as I thought, some beautiful results from it, but I now question whether any of these are thoroughly protected from variola. I vaccinated with points (to make sure of protection) those who had recently been successfully vaccinated with the tubes, and observed that in every instance the vaccinia was apparently just as severe as in the primary vaccinations. The converse of the above trial did not hold true, for I found those upon whom the points had been successfully used immune to the glycerinated lymph." The virus was fresh and that largely employed was made by a prominent western firm. (The name is mentioned by the author, but is here omitted.) The physicians in adjoining States to whom these results were communicated also found that in the majority of instances the points would take upon those whom they thought they had rendered immune by the previous use of glycerinated lymph. One of the physicians stated that, of all the vaccinations done by him with tubes, not one that he had seen left a satisfactory scar. Another wrote that of a certain series of vaccinations "the best result he had was in a negro who subsequently contracted smallpox." Similar statements were quoted from a half dozen or more physicians, the consensus of opinion being that the glycerinated tubes were totally unreliable.

Our experience with glycerinated lymph at the Municipal Hospital has been quite different from that above quoted. It has been employed to the exclusion of all other forms of virus, this being the lymph provided to us by the Philadelphia Board of Health, which obtains it from a different source from that mentioned by the paper above referred to. Not one thus far, who has been vaccinated previous to exposure, has contracted smallpox. About fifty individuals, including physicians, nurses and attendants, have been continuously and freely exposed to the disease. Nearly all of these were vaccinated with glycerinated lymph, with a successful result in a considerable percentage of cases. Some had very sore arms and sufficient constitutional disturbance to necessitate rest in bed for a day or two. A number of the unsuccessful cases underwent a repetition of the vaccination. In all of these cases there appeared to be full protection. It should be stated that the vast majority of the number referred to had scars from primary infantile vaccinations. In addition to the individuals above referred to as being exposed, there were some sixty or more workmen, engaged in the construction of a new pavilion, who were in close proximity to the smallpox patients. These were vaccinated with glycerinated lymph, some for the first time, and none up to the present date has contracted the disease. One workman who, by the way, was the only one to refuse vaccination, has within the past week been brought into the hospital with smallpox. He bears upon his arm a good scar from infancy. An unvaccinated garbage-wagon driver and several other unprotected individuals, who were merely exposed upon the grounds, contracted the disease.

The opportunity was also afforded of testing the value of glycerinated lymph in primary vaccinations

in individuals exposed in the wards. One of the nurses who has been employed in nursing smallpox for over two months, and in whom the vaccination was primary, has been found to be absolutely immune. A child of one year, vaccinated with glycerinated lymph about ten days before, was sent into the hospital with a vaccine roseola which had been diagnosed as variola. The child was in the smallpox wards about three weeks and remained perfectly well. A colored child, about two years old, having some fever, was brought into the hospital with a sister suffering from smallpox. The child was successfully vaccinated with glycerinated lymph on admission and did not contract the disease. Several other unprotected children and adults who were vaccinated after admission have been rendered absolutely immune to smallpox.

We have from time to time received in the hospital patients with well-marked and even fatal smallpox in whom vaccination, performed some weeks before, had failed. We recall one patient, a large stout woman of thirty years, who had been vaccinated without result some years before and who was vaccinated with glycerinated lymph one month before admission. There was some local reaction and the physician in attendance was for a time in doubt as to whether there had been a successful "take," finally deciding in the negative. The patient was brought into the hospital with confluent smallpox and died in ten days. From our examination of the patient on admission we were convinced that the result had been spurious.

Such unsuccessful results can scarcely be specifically charged against glycerinated lymph, inasmuch as occasional failures with bovine lymph, more particularly with dry points, have been for years common even in persons susceptible to vaccinia or smallpox.

The striking difference in the experience of different observers, with glycerinated lymph, may be explained in two ways.

It is quite within the bounds of possibility that the virus furnished by the various propagators of lymph may not be equally reliable. If this be true, it would constitute a strong argument in favor of a government vaccine establishment, similar to those existing in England and certain other European countries. The lymph could be gratuitously dispensed to physicians, thus eliminating the commercial factor in the preparation and sale of vaccine virus.

Or the discrepant results may be explained by diversity of opinion, as to what constitutes true vaccinia. Any result which deviates to any considerable extent from the description of primary vaccination given by Jenner should not be regarded as genuine. There are certain local reactions not infrequently met with after the use of glycerinated lymph and perhaps other forms of bovine virus which deviate considerably from the Jennerian delineation. In these cases it is not uncommon to note an abnormal degree of inflammatory action even as early as the second, third or fourth day. Upon this area there frequently springs up with surprising rapidity a more or less conical or globular blister instead of a typical vesicle. This elevation is thin-roofed,

readily ruptured and gives exit to a thin irritating fluid which speedily dries in the form of yellowish brown bulky crusts, the exudation continuing to ooze out at the margins. After shedding of the crusts there is left a faint scar which is devoid of the characteristics of a true vaccine cicatrix. The so-called "takes" which do not protect against smallpox or vaccinia are probably of this nature. Whilst it is impossible to positively affirm that these lesions are entirely devoid of all specific reaction, yet they should not be relied upon to give protection against smallpox. An observation which militates strongly against their being even partial "takes" is that they may develop in individuals who are known to be immune against smallpox. Recently such a lesion developed in a physician who has been steadily exposed to smallpox for a long time. Reactions of the character above described are more common in cases of revaccination.

In many successful vaccinations in which glycerinated lymph is employed, there is an excessive amount of inflammatory reaction. A sort of dermatocellulitis develops, the redness and swelling involving at times the entire arm. The vaccine vesicle spreads considerably beyond the border of the scarification, reaching often the size of a quarter dollar. Not infrequently this area undergoes necrotic change, giving rise to a slough, which, when cast off, discloses to view a large, deep, cup-shaped ulcer which very slowly heals up by granulation. The resultant scar in these cases is apt to be smooth and shining, and devoid of the depressions and bands seen in a typical vaccine cicatrix.

It is surprising that with a virus which is alleged to be free from extraneous micro-organisms such sore arms should be produced. Upon theoretic considerations we would expect such results to be eliminated by the use of a lymph which contained no active principle save the vaccine matter. It may not be out of place to remark that many propagators of virus are to-day violating an important precept of Jenner in the preparation of the virus. Jenner insisted upon the exclusive use of the clear lymph of the vesicle. In the preparation of the glycerinated lymph the entire lesion is curetted, bringing away lymph, vesicle walls and broken-down epithelial tissue, all of which is made into a pulp and mixed with glycerine and water. May not the sore arms be possibly due to the admixture of this tissue debris?

The question is frequently asked, "at what age should an infant be vaccinated?" When smallpox is absent from a community, this may be delayed until the child has reached the age of three months. During an epidemic of smallpox, however, no age is a contraindication to the performance of vaccination. Children born at the Municipal Hospital of mothers suffering with smallpox are vaccinated immediately upon their entrance into the world. Recently a woman with a mild varioloid gave birth to an infant of seven and a half months development. This child was successfully vaccinated in two places, although it later succumbed to a varioloid with which it had been infected *in utero*.

Many physicians hesitate about vaccinating individuals who are suffering from some other disease.

At the Municipal Hospital recently scores of patients suffering from diphtheria and scarlet fever were vaccinated as a precautionary measure. The vaccination did not unfavorably influence the original disease, and on the other hand, the course of the vaccinia was in no case unusual.

Since the beginning of the present year (1901) about three hundred cases of smallpox have been treated at the Hospital. *Of this number not a single patient has been recently successfully vaccinated.* The shortest period elapsing between a successful vaccination and the contraction of the disease was five years. In this case, which occurred in a boy eleven years old, the eruption consisted of only a score or so of papules, which scarcely developed into vesicles but dried up in a few days. It was not found necessary to confine the lad to bed.

Whilst the majority of the patients admitted were unvaccinated, a very large number had been vaccinated in infancy. To our knowledge none, save the boy mentioned, had been successfully vaccinated within the past ten years.

The writers believe that it may be laid down as a rule, that if a child be successfully vaccinated in infancy, and again at the age of puberty, the protection will be permanent. The exceptions to this rule, however, may be sufficiently frequent to warrant a repetition of the vaccination whenever there is exposure to smallpox.

The opinion has been advanced, more especially by Marson of London, that the degree of vaccinal protection in an individual is directly proportionate to the number of insertions made. According to the experience of the writers the *quality* of the vaccine scars is a far more reliable indication of the degree of protection than the *quantity*. A perfectly good vaccine cicatrix presents well defined margins, is reticulated or foveolated, and looks as if it had been stamped into the skin with a sharply cut die. It has been said that genuine pocks are frequently not followed by scars, but without denying this absolutely, we would advise that such assertions be regarded with a considerable degree of skepticism. The general mortality rate from smallpox, as far as we are able at the present time to estimate it, has been about twenty per cent. This is merely an approximate statement, as the ultimate outcome of the two hundred cases now in the Hospital cannot be accurately predicted. The mortality rate among the vaccinated has been about 11 per cent., and among the unvaccinated about 33 per cent. Of the former class the mortality rate of those bearing good scars was about 4 per cent., fair scars about 8 per cent., and poor scars about 20 per cent. In concluding the writers desire to express their condemnation of the use of tight fitting shields. These, by constricting the circulation of the surrounding skin, serve to increase the inflammation and tendency to early oozing. There is no objection to the use of a shield for a few hours, until the vaccine lymph has dried upon the abrasion, but its continuous use during the development of the vaccine lesion is apt to do more harm than good.

PROPHYLAXIS OF SMALLPOX IN CITIES,

By RICHARD A. CLEEMANN, M. D.

of Philadelphia.

The empirical fact established and insisted upon by Jenner a century ago that persons inoculated with cow-pox, an eruptive disease of the udder of the cow, were immune to smallpox, has been amply confirmed by the experience of a hundred years, and the little operation of vaccination performed with the lymph of the vaccine vesicle procured directly from the young cow, the material now almost universally used, holds the first place in the prevention of that loathsome disease.

The duration of immunity from smallpox secured to the individual by a single vaccination is estimated on good authority to be from eight to twelve years. The problem, then, to produce an ideal exemption from the disease would be the performance of vaccination upon every person in the community, with his revaccination at intervals of eight years. The passage of a law compelling this thorough vaccination would be possible under a government of autocratic ideas like that of Germany, and, indeed, an edict almost as sweeping as this has been enforced in that empire for more than twenty years; it provides that every infant must be vaccinated before it is a year old and every child in a private or public institution revaccinated before it has accomplished its twelfth year. Compulsory vaccination, however, is considered inconsistent with the ideas of personal liberty proclaimed in this country; the consent of the individual to the operation must be obtained before vaccinating him or his children. This complicates the methods of prevention to be adopted here; nevertheless they can be made very efficient.

These methods divide themselves into those which are to be pursued continuously, day in and day out; and those special ones, made necessary when a case of smallpox appears in the community, an event dangerous only in proportion to the carelessness with which the other procedures have been carried out.

The continuous methods (assuming the adoption of the usual precautions against infectious diseases in general) provide for as general a vaccination as possible. They necessitate a corps of vaccinators, who should be educated physicians under the order of the health authorities. These should visit every house in the community offering, urging, and performing when permitted vaccination without pecuniary cost upon every unvaccinated person over four months old and revaccination upon any one upon whom the operation has not been successfully performed within eight years; a second visit at the end of eight days, the period at which the vaccine disease should be at its height, should be made to those operated upon, and if the vaccination has been unproductive of the vaccine disease, a second application of the virus should be made and the visits continued at the same period until a successful result has been reached in the primary cases and the vaccinator has been satisfied that the protection in the revaccinated is sufficient. Discretion obviously should be observed with regard to weak children and sick persons, and the operation should be avoided generally in hot weather upon infants less

than two years old on account of the possible complication of cholera infantum.

Experience has shown, however, that the precious boon of vaccination will not be accepted willingly by every one and means must be found to overcome this opposition. It is held that the State has a right to withhold certain privileges from persons who do not accept special provisions made for the safety of the community: under this view a law has been passed prohibiting a child from attending a public school unless it has furnished a certificate of successful vaccination. This is a useful and far-reaching act, and it should be extended to include all institutions, public or private, where children are received. Vaccination should be made a pre-requisite to entrance into the civil service, the army, the navy and the militia. No immigrant should be permitted to land on our shores unless similarly protected from smallpox.

When the disease actually appears in the community, action must be taken with the greatest possible dispatch and thoroughness. The case is reported at once to the health authorities by whom a medical inspector with a vaccinator is sent to verify the diagnosis, and if the sick man is found to be suffering from smallpox or varioloid, all unprotected persons in his environment are immediately vaccinated; a strict inquiry is made into the origin of the attack, the associations of the patient for the previous two weeks, the limit of the period of incubation for smallpox, being strictly scrutinized so that, if any other case exists in the community, it may be discovered. If the disease is found to have been imported from some other locality, that health authorities there should be notified, and any other person coming from the same place is to be treated as a "suspect." The sick man should at once be removed with the rest of the household to a hospital devoted to the care of smallpox cases, those not attacked by the disease to be detained until there is evidence that the vaccinations are proving successful or they remain well for two weeks, the period already mentioned as the limit of the incubation of the disease. All the articles of little value in the room which had been occupied by the patient are to be destroyed. The room itself is to be closed for a few hours to allow for the subsidence of suspected germs; then the crevices of the windows and doors being closely stopped or pasted over with paper, the vapor from a heated mixture of formalin with ten per cent. of glycerin is introduced through the key hole of the door, five hundred cubic centimeters of the disinfectant being used to each one thousand cubic feet of air space in the room; after a few hours of this fumigation the room is to be opened and aired. Owing to the want of penetration of formalin, experiments having shown that it disinfects surfaces only, the mattresses, pillows and any articles, to the interior of which the contagium may have found its way, are removed in canvas bags and disinfected by the thorough application of wet and dry steam. The floors, walls, ceilings and furniture are then to be scrubbed with a solution of corrosive sublimate, one part of

the bichloride to one-thousand parts of water. If the walls and ceiling have been covered with paper, this, previous to the washing, must be stripped off and burned; finally, the room must be ventilated several days by leaving the windows and doors open before it is again occupied.

If, however, the victim of smallpox is found dwelling in his own house, which is occupied by his family alone, he may decline removal to a hospital, as he has the option under the law. Then the situation becomes more difficult; guards, already protected by vaccination, must watch the front and rear of the house day and night and prevent any one except the physician in attendance from entering or leaving the premises; dogs, cats and domestic animals of all kinds are also excluded. Supplies for the household are to be brought and placed before its entrance, from which situation, after the departure of the messenger, they are to be taken in by the inmates of the house. The guards are under no circumstances to enter the dwelling. The patient is placed with his nurse in a room without carpet, or unnecessary furniture; window curtains of material which may be readily washed are allowed. No one but the physician is to enter the room, and he on such occasions must put on overshoes, cover his head with a handkerchief and protect his usual dress with a garment reaching to his heels, these articles to be disinfected before being used again. Within the room should be a vessel of several gallons capacity containing a disinfecting solution; this may consist of the solution of corrosive sublimate, before mentioned, or as A. C. Abbott* recommends, on account of the fixing of the stains of blood and the discharges by the mercurial salt, a solution of three parts of carbolic acid and two parts of common soft soap in one hundred parts of water. Into this all the bed clothes and garments of the patient, when they are changed, should be placed, to remain there for two hours before they are carried out to be boiled and washed; the plates, saucers, spoons, forks and other utensils are to be treated in the same manner, remembering that the corrosive sublimate is destructive to metallic objects. Whatever remains of the food uneaten must be disinfected before its removal from the room. The patient's skin, the supposed source of the infection, is to be sponged from time to time with a disinfecting solution, one of the less poisonous being used, as for instance a five per cent. solution of Labarraque's disinfection fluid; his discharges are to be received in a vessel containing a disinfectant. When the patient has recovered, all the crusts having fallen from his skin, he is thoroughly washed with soft soap to remove the outer layer of the cuticle before leaving the sick room. Should he die, the body is to be wrapped in a sheet, saturated with the corrosive chloride solution, and preferably cremated; if not thus destroyed, the remains are encased in a hermetically sealed metallic coffin and carried without a public funeral to grave.

* Hygiene of Transmissible Diseases, Second Ed. p. 331.

TECHNIQUE OF VACCINATION.*

By DR. FREDERICK A. PACKARD, M. D.,
of Philadelphia.

Physician to the Pennsylvania Hospital and to the Children's Hospital.

What we hope to accomplish by vaccination is the artificial production in the human being of a disease derived from smallpox through the passage of the poison through lower animals whereby its virulence is lessened and its manifestations made local, instead of general. In order to bring this disease about in the human being we make use of material derived from the calf and preserved in various ways. Our object is to so use this virus that it shall gain access to the vital tissues of the body so that the materials manufactured by the active principle of the virus may be disseminated through the body and produce general immunity from variola. By the vital tissues of the skin I mean the portion in direct lymphatic communication with other parts of the body as opposed to portions of the skin whose function is apparently simply mechanical. Another object which we wish to attain is the inoculation of the special virus of vaccinia free from contamination. Still another is the avoidance of everything which would interfere with, and the observation of any precautions that might make more certain, the obtaining of the local results and the general systemic effects supposed to be produced during the life of this active agent in the local lesion. Still further we have to bear in mind that in thus destroying the continuity of the protective surface of the skin and exposing the deeper structures, including especially the lymphatic spaces, to the exterior, we are creating an artificial portal of entry, whereby infectious material may gain ready access to the organism.

It is possibly beyond the province of this paper to discuss the question of the advisability of using virus prepared in various ways. Having, however, made use of two kinds of "points", and having had a personal experience in my youth with the human virus, I feel as though it might be proper for me to briefly state my impressions.

At the present time no one would think of using lymph from human sources. The danger of transmission of disease from one human being to another in spite of all the care that we can exercise, and the danger of infection of the scab while on the original patient and while preserved in the dry state for future use, are themselves sufficient to prevent our employing this method when material can be obtained so directly from the calf. Two ways in which vaccine material is preserved are the drying upon an ivory or celluloid point and the keeping of the material in glycerine contained in a hermetically sealed tube, or, what might be called a combination of these two, where the ivory or celluloid point is kept submerged in a hermetically sealed cell containing a mixture of the vaccine material and glycerine. After a fairly extensive use of the first two of these methods I would unqualifiedly advocate the employment of the hermetically sealed tube containing glycerinized lymph. Theoretically the airtight tube would be supposed to be more free from danger of contamination than would the dried vac-

cine material on a point which is capable of being handled by the fingers of a possibly not overly clean drug-clerk. Practically I have found that fewer sore arms result from the use of the glycerinized vaccine kept in hermetically sealed tubes, while I am sure that my proportion of successful vaccinations is as great if not greater with this than with the method formerly universally employed. There is another difference between the employment of the two methods of preserving vaccine. I feel sure that with glycerinized vaccine we get more irregularity in the period of incubation, some cases, for instance, developing the local lesion at the end of 36 hours while others may apparently fail to develop until even the 10th day. Why this should be it is impossible to say, but I think it is undoubtedly the case. I should also say that the occurrence of generalized eruptions is far more frequent after the use of vaccine preserved in glycerine than after that dried on the quill. Those interested in this question would find it to their advantage, if they have not already done so, to read the report of the Lancet Commission upon glycerinized lymph which was published in the *Lancet*, of April 28, 1900. Objection is made by some to the use of glycerinized lymph because they believe that fewer successful vaccinations were performed with it than with the vaccine dried on points. To this opinion I cannot subscribe as I have never seen the slightest reason to think that I was having less success with the glycerinized than with the older method of preserving the material.

When we intentionally make our patients ill, even though this is done to avoid a greater evil, we are, I take it, more than ever bound to see to it that we do the very least harm that is possible under the circumstances. The production of a sore arm from vaccination with its accompanying two or three days, at least, of malaise and discomfort cannot but make the conscientious physician wish that we had some other way by which we could prevent the occurrence of variola. The production of a sore arm due not to vaccination pure and simple should make us feel that in some way either we had been faulty in our precautions or in the thoroughness of our directions to our patients or else that the patient had not been sufficiently exact in following our directions. He who would vaccinate his patient off-hand with an instrument carried loose in a possibly dirty pocket, or even in a supposedly clean pocket case, and should feel that all that was necessary in the way of paraphernalia for the operation were the scarificator and the vaccination point, runs serious risk of infecting his patient, not simply with the protective agent but with microorganisms capable of producing serious disease, or even loss of life. To properly perform vaccination, a man should have at hand soap and water, alcohol, certainly clean vaccine and some form of protection to apply after the operation is concluded. In my own bag which I use in vaccinating I carry two large bottles of alcohol, in one of which I keep my scarificator; some clean absorbent cotton, a bottle of bichloride tablets and vaccination shields. The vaccine points I put in on leaving my house as I keep them in the refrigerator between vaccinations. I do not believe that with a less elaborate array of

*Contribution to a Symposium on Vaccination. Philadelphia Pollard Society, November 12th, 1900.

apparatus the operation of vaccination is justifiable. Before proceeding to vaccinate a patient, the hands of the operator should be thoroughly scrubbed with soap and water, then thoroughly wetted with either alcohol or corrosive sublimate solution. Then the skin of the patient should certainly be rendered sterile or as nearly so as possible. In our present ignorance in regard to the exact agent of vaccinia we have no antiseptic, of which I am aware, that will sterilize the skin and at the same time avoid danger of destroying the vitality of this agent, except alcohol, which has in addition the advantage that it probably more thoroughly cleanses the skin than do any of our ordinary watery solutions or antiseptics, and that it promptly becomes inoperative against the vaccine virus through evaporation. The skin should be thoroughly scrubbed with alcohol on a pad of absorbent cotton and then either dried with a clean towel or the alcohol allowed to evaporate.

The instrument with which the lymphatic spaces are exposed is unimportant except for the fact that it must be capable of being thoroughly cleansed and also adapted to the exposure of a limited area of deeper tissue without drawing blood. The needle, the scalpel or tenotome, or a special scarificator may be used. My own preference after the use of all three is for the latter. My reasons for choosing it are that it is used for this purpose alone, that it is thoroughly capable of being cleansed and kept ready for use in pure alcohol, that it can make an abrasion sufficiently deep without drawing blood and that the area exposed can be thoroughly well regulated. The one that I have been using measures about a half a centimeter in width and is composed of six prongs, looking very much like a miniature ice-pick. It can be readily sterilized by the use of soap and water and a scrubbing brush, after which it can be dipped in alcohol, ignited from a match, and then after cooling suspended in a bottle of 95% alcohol. I believe that this instrument causes less discomfort than does the scalpel or tenotome, and that we are more certain not to draw blood than we are when we use a needle.

The point to be selected for the scarification is of course of slight importance save for one or two things. No matter what portion be selected, it is, I believe, important to avoid old areas of scar tissue from previous vaccinations or other wounds. If we vaccinate over an old cicatrix we cannot feel sure that the lymph spaces are sufficiently patulous, while after vaccination in the neighborhood of scar tissue the latter may break down and form a nasty sore, if it is encroached upon by cellular infiltration resulting from vaccination. As nearly as possible to the deltoid insertion is, I think, generally allowed to be the most favorable seat in the arm. I hear indirectly that many are vaccinating above the knee, while some are employing the inner surface of the leg. I have been in the habit of choosing a point just below the head of the fibula for the following reasons: If vaccination is done above the knee there is danger that in sitting down the dress will be tight above the knee, whereas below the knee it hangs loosely; while the outer side is selected because of its less liability to rubbing from ac-

cidental interference with the other leg. The only thing that would make me vaccinate elsewhere in the leg would be the occurrence of superficial varices or a bunch of varicose subcutaneous veins at the point which I usually prefer. Whether this is a valid objection or not I do not know, but I have always rather dreaded the possibility of an endophlebitis from contiguity. The area of denudation need not be large, provided only that it is sufficiently large to enable us to be sure that we have opened up the lymphatic spaces. I believe that one of the most frequent causes for failure in producing a successful vaccination is the drawing of blood. Where more than the most minute quantity of blood is obtained, we cannot be certain that we have not in contact with our denuded surface either bloodclot alone or vaccine material so diluted with blood that its activity is either inhibited or prevented. A large drop of blood might be capable of floating on its surface all of the active vaccine material, and in the contracting of the clot it is very likely that all of the serum and vaccinal matter would be squeezed out and allowed to evaporate on the surface. The ideal result of the scarification alone is simply a little pinkish or rosy moisture. With a little practice I think it is possible so to scarify the skin that we can remove all of the epidermis and get a slightly moist surface, then place thereon our vaccine material and finally again scarify sufficiently to thoroughly rub in our infecting material and yet not cause the outflow of any blood. An additional precaution against pyogenic infection is accomplished by wiping the exterior of the tubes with alcohol on cotton before breaking the ends.

After this point we have left behind a surface covered with serum mixed with our vaccine material, a condition of affairs preeminently suited for the retention and growth of microorganisms. The care of such a surface is certainly important. At one time in my eagerness to avoid doing harm I dressed every scarification with several layers of sterile gauze held in place by a bandage. This made my conscience easier, but did not bring physical ease to my patients, as the under layer of gauze invariably stuck to the dressing on its first removal, and I am sure that this contact of material, even though sterile, causes an excessive inflammatory reaction in the already insulted tissues, a reactive inflammation that may interfere with the production of vaccinia. It would seem, however, that we ought to afford some protection, and I believe that this can be done by the use of one of the many shields for the purpose now in the market. I take it the general practice should be that no shield should be used which interferes with the circulation of the lymph and blood to and from the infected area. It also seems to me that it would be improper to use any form of shields which absolutely prevents the radiation of heat from the skin in the immediate neighborhood. The recently introduced celluloid shields have the advantage of allowing the patient from time to time to inspect his arm and derive more or less amusement therefrom, also of permitting the radiation of heat and thereby obviating the poulticing effect that would be

produced by an airtight covering, while no irritating material comes in contact with the wound.

The shield can, I am convinced, be worn too long, and it has been my habit so soon as the vaccine material has evidently produced a specific local lesion to have the shield removed, and then have the arm dressed either with boracic acid ointment or one composed of aristol, one drachm to the ounce of ointment base. The latter gives the best results, although either of the ointments has to be changed upon the filling of the area with granulation tissue, as neither of them seem to be sufficiently stimulating to cause the surface to be covered with epithelium.

In spite of all care in regard to asepsis a few arms will get "sore" from simple intensity of the local process. In cases with much surrounding edema or cellulitis I believe that the rational treatment is to surround the arm with an antiseptic poultice of gauze soaked in (1 to 3000) bichloride of mercury solution. Another point that I would consider of great importance before the vaccinator can consider that he has done his whole duty is proper judgment as to whether the vaccination has been successful or not. I believe from what I have seen during the past few years, that there is by no means unanimity of opinion in regard to the appearance of the successful vaccination, and one of my regrets at being unable to attend this meeting is that I shall not have the opportunity of hearing the discussion upon the standards by which others judge in regard to whether their effort has been successful or has been a failure.

NOTES ON THE SMALLPOX ERUPTION, ITS CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS.

By WILLIAM THOMAS CORLETT, M. D., L. R. C. P.,
(Lond.)

of Cleveland.

Professor of Dermatology, Western Reserve University,
Cleveland.

Smallpox, like syphilis, presents itself in various forms and differs in severity even more than is observed in the latter disease. At the same time it seems almost incredible that a disease manifesting itself so conspicuously on the surface as smallpox does should be difficult of recognition. Even more to be wondered at is the fact that of all diseases, those of the skin are the most confusing to the general practitioner. While concomitant symptoms and the prodromata of smallpox are always associated with the eruption, yet it is the latter that is and must be chiefly relied upon in making a diagnosis. It is necessary, therefore, at the outset to understand the first pathologic changes in the skin to appreciate their true significance.

The Prodromal Rash.

A prodromal rash sometimes appears in variola, for the most part in mild cases, and especially in the variety commonly called varioloid. Again, although more rarely, it is met with in hemorrhagic cases which usually terminate fatally. In position it most frequently appears on the inner regions, as

for example, the axilla, the arms and back. In appearance it resembles the rash of scarlet fever, excepting that its color is duller. On the other hand, in distribution as well as in the order of its appearance, it does not correspond with this disease. At the same time it must be admitted that the presence of a prodromal rash in variola often leads to errors in diagnosis, such cases oftentimes being considered as instances of double infection of scarlet fever and smallpox. Many times the writer has been called in consultation in these cases, and invariably the mooted question was, Is it scarlet fever?

In hemorrhagic smallpox the prodromal rash is liable to appear earlier than in the milder forms, oftentimes late on the first or during the second day. Moreover, this is not infrequently the only rash that appears, the disease terminating in death before the advent of the true exanthem. The prodromal rash in this form has distinctive features which may be recognized as follows: First, by its deep-red color which soon assumes a dark or dusky-bluish tint, and not infrequently actual vibices or hemorrhagic puncta may be made out; second, it does not disappear on pressure. If the patient survive until after the appearance of the true eruption, this gradually subsides, although more slowly than in the simple form as seen in varioloid. Again, in other cases the hemorrhagic features appear during the first day and continue to the termination of the disease. The prognostic significance of the prodromal rash should not be lost sight of. The first or simple form erythema presages that the disease will pursue a mild course to favorable termination, while with the hemorrhagic prodrome a severe and nearly always fatal form—the so-called black smallpox—is sure to follow.

The prodromal rash is due to dilatation of the superficial plexus of the derma, indicating that the nerve-centers are profoundly affected even in mild cases. In hemorrhagic smallpox extravasation of blood through the vessels takes place.

The Eruption Proper.

After a period of fever, pain in the back, headache and vomiting—the prodromal symptoms—the eruption of smallpox appears. Its advent is subject to some slight variations, but usually it may be seen on the morning of the fourth day. The order of its appearance is likewise characteristic and therefore of diagnostic importance, showing first on the areas of the most plentiful blood supply, namely, parts exposed to the external air, as the face, notably about the region of the nose, the forehead, and on the hands. There are occasional exceptions to this order. Thus the eruption may first appear on the trunk; especially when mustard poultices have been applied to relieve the excruciating backache. I recall an instance previously cited (1) in which the eruption first appeared on the legs, from which it extended over the rest of the body, assuming a confluent form on the exposed parts. In this case no reason could be assigned for its anomalous appearance. It is known, however, that a pre-existing inflammation or anything that causes a determination of blood

1. The Writer, "A Treatise on the Acute, Infectious Exanthemata," Philadelphia, 1901, p. 36.

1. The writer, "A Treatise on the Acute Infectious Exanthemata," Philadelphia, 1901, p. 36.

to the part, predisposes to the development of the smallpox eruption.

It is a rule for the palms of the hands and the soles of the feet to be involved, although not always to the same extent as the general surface. The importance of the palmar and plantar eruption in making a diagnosis should not be over-estimated, as it occurs in varicella and in syphilis, diseases oftentimes mistaken for smallpox.

With the appearance of the eruption the constitutional symptoms subside. The fever, which had attained a height of 104° F. or higher, suddenly becomes normal. In mild cases the patient feels that the severity of the disease is past, and he is with difficulty restrained from going about; while in severe cases the system remains profoundly impressed by the variolous poison.

The first changes in the skin that we have been able to detect are irregularly circumscribed reddish areas, lentil-sized, due to capillary dilatation in the superficial papillary plexus of the derma. At first they resemble mosquito bites. The erythematous areas soon recede at the periphery and in a few hours a distinct central thickening or induration may be detected by the touch. This at first resembles a parchment-like stiffening, due to localized edema, which shortly assumes a distinct shot-like feel. *This induration continues throughout the whole course of the disease, one of the most constant as well as the most distinctive feature of the variola eruption.* Shortly, on the second day of the eruption, papules rise perceptibly above the surface, and in distribution the eruption extends to the trunk and extremities in regular order on successive days. Last of all, the palms of the hands and the soles of the feet are invaded. The scalp is oftentimes perceptibly and copiously studded, and finally the *mucous membranes partake of the same changes that are observed in the skin.* From this point great variability in the eruption may be noted, which is mainly dependent on the severity of the disease. In variola vera, late on the first and during the second day, the papules which first appeared show deep-seated serous accumulations, due to exudation and cell-degeneration in the stratum mucosum. By the fifth day of the eruption the lesions have enlarged to split-pea sized areas and the serous accumulation, on account of the invasion of plasma-cells, has begun to assume an opaque or milky tint. In mild cases there may be a general retrocession at this time, in which an abortive eruption would be seen and which so closely simulates the eruption of varicella. Invariably, so far as the writer's experience goes, a few lesions adhere to the variola type from which a diagnosis may be made. At this time, too, resorption and rapid keratinization of the superimposed epidermic stratum giving rise to a wart-like eruption called "horn-pox." Again the invasion of pus organisms may give rise to furuncles, abscesses, and the like. When this occurs troublesome sequelae may be expected, sometimes leading to an indefinite period of ill-health. At this time, during the fourth and fifth day of the eruption, umbilication is met with. It should be borne in mind that umbilication is not peculiar to smallpox, as it sometimes occurs in other affections, although to a less extent. Umbilication is not present during the

whole course of the variola eruption, for as the pocks mature and their walls become tense, usually from the seventh to the ninth day, the umbilication is liable to disappear. Many times has the writer sought carefully for an umbilicated lesion in a well marked case of variola, without finding the slightest trace of a central depression. On the other hand, it has been observed in varicella, although to a very slight extent.

In hemorrhagic smallpox, when the hemorrhagic tendency has not previously shown itself, it is liable to occur at this time, the hemorrhage taking place directly into the pocks and extending to the periphery gives rise to a dark-bluish ring. Petechiae may likewise occur independently of the smallpox lesions.

In the scope of this paper it is impossible to go into the various changes that may take place in the smallpox eruption. An endeavor has been made, however, to bring out the most salient features, those which have most strongly impressed the writer in a clinical way. Having taken up the smallpox eruption and its recognition in a general sense, its differential diagnosis and the affections most commonly mistaken for it may be briefly considered.

Varicella.—In the majority of cases it is not difficult to differentiate between variola and varicella from the eruption alone. The following points, however, may assist the inexperienced:—In variola the prodromal symptoms are always present for several days, usually three; while absent or of a few hours duration in varicella.

Furthermore, the temperature often renders valuable aid in differentiating between the two diseases. In variola it rises rapidly, and even in mild or abortive cases usually reaches 103° to 104° F., when, on the appearance of the rash, a crisis takes place, and it falls to the normal within a few hours, where it may remain throughout the remainder of the disease. Varicella, on the contrary, is seldom ushered in with fever, but the temperature usually rises one or two degrees as the eruption develops.

When the case is seen for the first time after the eruption has appeared, and, as often occurs, no definite history can be obtained, other symptoms must be relied upon. The lesions of variola are deep-seated and show a marked predilection to become indurated, while in varicella the lesions are always when uncomplicated situated quite superficially in the upper strata of the epidermic, at first receiving the pseudonym, "water pock", from its resemblance to drops of water on the surface. Moreover, the distribution of the eruption is usually of great diagnostic importance. In varicella the parts protected by the clothing, especially the back and chest, are mainly involved, while variola finds its special seat of predilection on the exposed parts, face and hands, with a strong tendency to cluster about the nose and forehead. In varicella the lesions first appear as macules, never indurated as in smallpox, and in a few hours develop into prominent, transparent vesicle. As has been said, umbilication is generally present during some period in the development of the smallpox lesion, while it is absent or nearly so in varicella, usually the nearest approach

to umbilication in the latter being the formation of a minute central crust, which does not appear until resolution has begun. Furthermore, the lesions are of more uniform size in variola than in varicella, although this is by no means an infallible test. The age of the patient is important; the writer has in one instance only during a period of many years encountered chickenpox after the age of puberty, and the consensus of opinion bears out the statement that varicella is essentially a disease of childhood. Until all reasonable doubt as to the diagnosis is removed, public safety demands that the worst be prepared for, consequently it is a good rule to treat all suspected cases as smallpox until it is definitely determined to the contrary.

Scarlet Fever.—The prodromal rash of variola which counterfeits scarlet fever is always met with in mild cases, and is accompanied by little, if any, anginal symptoms. Again it should be remembered that the premonitory symptoms are always severe in variola and of two or three days duration, while in scarlatina, on the contrary, they are of short duration, usually but a few hours, often slight, and may be entirely overlooked. The pulse in the latter disease is rapid and out of proportion to the fever, while in variola the fever and pulse lines run nearly parallel. In scarlet fever the erythematous blush appears first on the upper part of the chest, cheeks, and neck. In variola the scarlatinaform rash is best marked on the lower part of the abdomen and on the thighs. Another distinguished feature is the swelling of the lymphatic glands about the lower jaw, so common in scarlet fever and seldom, if ever, seen in an early stage of variola. The conspicuous papillae, or "strawberry tongue," so constant in scarlet fever, is never a conspicuous feature in variola. Here again the age of the patient is often of great assistance, for the prodromal rash of variola seldom occurs in young children, while adults seldom suffer from scarlet fever.

The writer has been very strongly impressed during the last epidemic of smallpox in Cleveland with the frequency with which smallpox in the hospital wards has been mistaken for typhoid fever and syphilis. The gastric disturbances in the former disease, and the distribution of the eruption in the latter are mainly responsible for this confusion. It should, however, be borne in mind that in typhoid fever the disease is insidious, whereas in smallpox it is invariably abrupt, being ushered by nausea and vomiting, severe pain in the back and rapid rise of temperature, and that upon the appearance of the eruption the constitutional symptoms rapidly subside. Recently a case of typhoid fever was admitted into the wards of Lakeside Hospital, and after several days an eruption appeared of a papular nature, rose-red in color, slightly indurated feel and quite generally distributed over the body. The history of the eruption indicated that it had first appeared on the abdomen from which it extended over the trunk and the extremities, as well as the face and hands, although to a less extent. The slow evolution of the eruption even without the history of the case was sufficient to exclude variola, although it occasioned some commotion until a positive diagnosis was obtained.

Syphilis.—It is noteworthy that the first case sent to a newly equipped "political" smallpox hospital in Cleveland a few years ago was a negro—suffering from syphilis. With a pustular syphilide when no trustworthy history can be elicited, some uncertainty may be experienced, and adding to the discomfort in such cases an immediate and positive diagnosis is usually imperative. In both affections the face is liable to be studded with the eruption, the palms and soles are conspicuously involved in both diseases, as well as the involvement of the mucosae.

A careful study of the case, however, will reveal diagnostic landmarks, so to speak, of unmistakable significance. First, the writer has never seen a purely pustular palmar syphilide, without its multi-form character being revealed on other parts of the body. Second, provided the skin lesions were similar, the mucous membranes of the mouth afford even more constant distinguishing features. In variola, pustules or denuded areas corresponding to the sites previously occupied, with a slight induration sometime present, will in many instances be observed. In syphilis, excoriated circular or horse-shoe shaped lesions, sometimes ulcerated, will, when present, afford unmistakable evidences as to the nature of the disease. Third, general adenopathy is always more or less in evidence in early syphilis, and absent, or localized and transient in variola.

That there is a distinguishing odor to smallpox I have never been able to confirm; an equally extensive suppuration of the skin from other causes, with like inattention to cleanliness, will, according to my observation, give rise to the same nauseating stench which is encountered in variola.

SOME EXPERIENCES WITH BLOOD EXAMINATIONS.*

By JOHN H. DEEVER, M. D.,
of Philadelphia.

Surgeon in Chief to the German Hospital, Philadelphia,
and EDWARD KEMP MOORE, M. D.,
of Philadelphia.

Assistant Pathologist to the German Hospital, Philadelphia.

To begin with, it is expected that this paper will not be favorably received by many of the profession. Nevertheless, as the popularity of a paper is the least of its merits, we feel justified in recording our experience with blood examinations, even if they do not verify the extravagant claims that have been made by some of those who have made this subject more or less of a specialty.

During the last few years there have been made at the German Hospital several thousand blood examinations upon the surgical patients and the views given you are based upon the results of these examinations, contrasted with the actual pathological findings at the operating table.

What is said may seem to have the object of discouraging what is sometimes called the scientific side of medicine, but this should not be the case, for if the practical benefits of the laboratory methods

* Read before the Medical Society of Virginia, meeting at Lynchburg, November, 1901.

of diagnosis are not found as great as their originators hoped for, it is their duty to find the reasons for this and place their findings on the firm basis of fact that will make them of the greatest practical benefit to the profession. As an example take the subject of albumen in the urine. When Bright first announced his discovery of this method of diagnosis, after the first wave of incredulity had passed, there was a period when every case with albumen in the urine was expected to die of acute nephritis within a year or so. How untrue that view was we well know, but it was not to those who reported only the cases favorable to that theory to whom credit for advancement was due, but it is to those who reported the cases exactly as they found them, the papers of protest, to which we are indebted for the proper subjugation of this symptom and its establishment as the valuable means of diagnosis that it undoubtedly is.

Just so with examinations of the blood; although not in years, in its development this subject is still in its infancy, and we believe that many of the positive claims made for it must be greatly modified before it is placed on a stable basis and is in proper condition to be of the greatest usefulness to the practical physician and surgeon.

There is undoubtedly much to be learned from examination of blood, and the faults found with its results should not be taken as an effort to hew down the tree, but rather as a pruning to make it take on new vigor and develop into greater usefulness.

With many of the diseases, in which an examination of the blood is said to yield a most gratifying result, our experience has been very limited; and also with some of the different examinations; so that this paper cannot be a complete review of this subject, but only of that part which has been called to notice in a general surgical practice.

Parasites in the Blood.

Undoubtedly examinations of the blood for the hematozoa malariae are of the greatest value, and when found are absolutely diagnostic of the disease. If the only results achieved by the work done upon the blood had been the discovery of this parasite, the labors of the investigators would have been well repaid. There are certain manifestations of malaria that so closely simulate certain septic conditions that without this means of diagnosis their differentiation would be almost impossible. There are for instance irregular types of malaria that simulate gall stone disease so identically, and were it not for the presence of the hematozoa in the blood, a prompt diagnosis would be impossible. However, it has been our experience that the more irregular and atypical the case of malaria, the harder are the organisms to find, and therefore in a case where malaria is suspected, a single negative blood examination should not carry much weight.

The filaria sanguinis hominis is another of the parasites of the blood, the detection of which might be a valuable means of diagnosis, but since elephantiasis is quite rare in this locality, we have never met with a case which was confused with any more purely surgical affection. Indeed, at the

German Hospital there is only one case in which the finding of this parasite is recorded.

With the spirillum of relapsing fever we have had no experience whatever.

In regard to the various pyogenic bacteremias we must say that we have received very little practical benefit from cultures taken from the blood. In the first place the results of such cultures are usually negative, except in such advanced cases that this method was not needed to diagnose the condition. In the second place, a careful bacterial study takes such a long time, that by the time the surgeon receives this report, the patient has often passed on to the care of the Great Physician, and the only object achieved is to file the bacteriological report along with the report of the post-mortem in order to make the records of the case complete.

We have frequently had the blood examined for microorganisms in cases in which malignant endocarditis was suspected, but usually with negative results; and even when successful it is hard to see with what benefit to the patient.

We should like to place ourselves on record as being bitterly opposed to painful, or disturbing examinations of a patient that do not promise him, or her, any benefit, but are made merely because they are interesting. Often too much zeal in scientific examinations has a very disturbing mental effect on a patient and acts very much to his detriment.

Serum Examinations.

The action of the blood serum of a patient suffering from a bacterial disease upon a culture of the specific microorganism has received much attention lately. Of these the Widal reaction for the diagnosis of typhoid fever is the only one with which we are at all familiar.

Undoubtedly a positive Widal reaction can be obtained after the seventh or tenth day of the disease in a very large percentage of cases of typhoid fever, but as a diagnostic aid to a surgeon its results are upon the whole disappointing. Sometimes in the first days of an enteric fever the clinical picture very closely resembles that of acute appendicitis. At this early date the Widal reaction has not been established and in practically all cases the clinical symptoms have made the diagnosis before the Widal reaction has become positive.

There is, too, a certain percentage of cases of typhoid fever in which the Widal is negative all through the disease, until the third or fourth week, or is intermittent. In our experience it is in the cases in which the clinical symptoms are the most perplexing that the Widal reaction most often fails.

Another source of error is that a few patients without definite typhoid give a positive Widal reaction. Our attention has been especially called to two cases of acute miliary tuberculosis and one of tubercular peritonitis, all three of which gave the Widal reaction and occasioned some confusion in the diagnosis. After an attack of typhoid fever the blood will give a positive Widal reaction for an indefinite number of years, a fact that should never be forgotten, as sometimes it is only with the most careful questioning that we can elicit a history of typhoid, if it is possible at all.

From the observations enumerated we conclude

that a positive Widal is rarely of much value to the surgeon, however, valuable it may be to the medical man. A negative Widal reaction, especially after an illness of two or three weeks, seems more often of service; for, if after two or three weeks the Widal is persistently negative, we can be almost certain that the case is not one of typhoid fever.

Value has been claimed for the serum reaction in colon, paracolon, proteus and pyocyaneus infections and Infectious Tropical Dysentery, but personally we have had no experience with these serum reactions and we are not in a position to judge of their merits.

The subject of the coagulability of the blood in jaundiced patients is another of the serum examinations that has received attention lately. In jaundiced patients the blood is certainly much slower in coagulating than is normal blood, and, after the administration of calcium chloride or gelatine, the length of time necessary for coagulation seems to be diminished, but yet at operation there seems to be very little difference in the amount of hemorrhage, whether these substances have been given or not. However, there is no harm in their administration, if the operator should fancy them; but in our experience proper gauze packing at operation and full doses of opium afterward have given the best results in troublesome oozing in gall bladder surgery.

Sugar in the blood can be quite easily demonstrated, but this examination is usually more interesting than valuable. For the urine of all surgical patients is examined for sugar, and tests for sugar in the urine are as reliable and easier of application than are the blood tests.

Examination of Hemoglobin.

Justi's hemoglobin test for the diagnosis of syphilis has proved itself very satisfactory in the cases in which we have used it, and in a doubtful case is well worth a trial.

Oligochromemia in surgery has been considered of great importance. Some surgeons have stated that they would not operate upon a case in which the hemoglobin was reduced below 40 per cent, others take 30 per cent. as the limit of safety. Our experience, however, does not bear out this view. For an acute suppurative condition or after acute or chronic hemorrhages, operation for the relief of the condition may be undertaken, no matter what the percentage of hemoglobin, and we have records of several cases operated with only from 10 to 20 per cent. of hemoglobin that terminated favorably.

In appendicitis there is a marked loss of hemoglobin, usually from 20 to 35 per cent, and this occurs in both the acute and chronic cases. It, however, seems to have very little prognostic importance, for out of 118 cases two had a percentage of less than 40 per cent. of hemoglobin and both of these were operated successfully.

Erythrocyte Count.

This gives the surgeon an index as to the powers of resistance of a patient as well as a guide to the severity of the infection. In a case which appears to be only a moderate infection if the hemoglobin and erythrocytes fall rapidly and markedly, there

are several points to be seriously considered. First, has the patient a very feeble power of resistance due to individual idiosyncrasy, or a complicating disease, such as nephritis and must we therefore make our surgical procedures as limited as possible. Or, secondly, have we misjudged the severity of the infection.

In carcinoma in the advanced stages there is a marked fall in the number of erythrocytes, but this fall is in no way diagnostic and in the less advanced cases with which the surgeon has usually to deal is either absent or insignificant.

There may be in appendicitis a very notable fall in the number of red blood cells both in the chronic and acute forms; and this although interesting, and often apparently out of proportion to the severity of the condition, we have not been able to make of any great diagnostic or prognostic use.

A chlorotic condition of the blood is often valuable in explaining the cause of amenorrhea and leucorrhea in young girls, as well as in other conditions.

Leucocytosis.

This phase of our subject is both the most valuable and the most disappointing part of the examination of the blood. Dr. J. C. Costa, Jr., hematologist to the German Hospital, took 118 cases of appendicitis and tried to define the rules governing the leucocyte count, with the following result.

"In simple catarrhal and interstitial forms the numbers of leucocytes, as a rule, did not exceed 10,000 per cubic millimeter. In a certain proportion of cases, however, exceptions to this rule were noted, for counts of 12,000 or 15,000 and even higher were sometimes made. 36.8 per cent. of catarrhal or interstitial cases showed a leucocyte increase of from 10,000 to 17,100 per cubic millimeter, the latter being the maximum, while in 60.1 per cent. the counts were below 10,000, the minimum being 1,600. Most of these high counts were attributed to a local non-purulent inflammation limited to the peritoneal covering of the appendix, since a circumscribed peritonitis of this sort was very commonly found in this form of the disease. It was tentatively suggested that in some cases the increase represented simply a blood finding of the associated anemia or, perhaps it resulted from blood concentration produced by vomiting or by purging.

In cases with abscess, gangrene or peritonitis a well marked leucocytosis was found in the great majority of cases. In instances of thoroughly walled-off pus foci from which little or no absorption occurred, leucocytosis was often absent; it was also absent in profoundly septic patients in whom the crippling effects of the poison had stifled reaction. Absence of leucocytosis under this latter circumstance was, however, comparatively rare, since in only 16.6 per cent. of fatal cases was a well defined leucocytosis absent, the counts in these two cases being 6,000 and 11,000 respectively. In the other ten the leucocytes ranged from a minimum of 14,200 to a maximum of 58,200, and averaged 19,400 per cubic millimeter.

In three cases extension of the pus focus and general peritonitis was indicated by a progressive increase in the leucocytosis; this increase having been found to vary from 6,600 to 14,000 cells to the cubic

millimeter in excess of the number previously counted. While absence of leucocytosis was observed in connection with small pus collections, it was by no means always true that low counts indicated small abscesses.

Leucocyte counts ranging between 10,000 and 15,000 or 17,000 cannot be depended upon to reflect the nature of the local lesion, since this degree of increase may be found both in mild catarrhal and in purulent cases. Counts of 20,000 or more *invariably* indicate pus, gangrene, general peritonitis, one or all. Absence of leucocytosis means nothing definite.

In operative cases complete evacuation of the abscess is followed within a few days by a decline to normal in the number of leucocytes, provided that the recovery of the patient is uneventful. Persistence of a leucocytosis after the third or fourth day following operation may usually be attributed either to an undrained pus pocket, or pockets, to general peritonitis, or to both.

Attention is called to the fact that as a rule just those conditions which bear the closest clinical resemblance to appendicitis give rise to blood changes identical with those found in the latter disease, so that the blood count as a means of differential diagnosis is greatly limited. Thus, leucocytosis is the rule in such conditions as ovarian abscess, pyosalpinx, ectopic pregnancy, renal abscess, hepatic abscess, gall bladder empyema and malignant disease of the cecum, all of which conditions have been confused with appendicitis. Since renal and hepatic colics are generally associated with inflammatory complications which produce leucocytosis, neither of these conditions can be distinguished with confidence from appendicitis, simply by the blood examination. Acute gastritis may or may not be accompanied by leucocytosis, so that the blood count cannot be relied upon as a clue in distinguishing this disease from appendicitis. The same is true of dysmenorrhea, in which disease inflammatory changes of the uterus may be the factor of a leucocyte increase. Should the diagnosis lie between appendicitis and enteric fever, the former is suggested by the presence of leucocytosis, since in typhoid this sign is practically never observed, except in the event of such a complication as intestinal hemorrhage or perforation. In typical cases a leucocytosis is sufficient to exclude such non-inflammatory conditions as simple enteralgia, lead colic, ovarian neuralgia, ovarian cyst and a movable kidney."

Irregular and inconclusive as these cases are, there are individual cases met with that are still more disappointing. For instance—a young man was admitted to the German Hospital with all the symptoms of a severe attack of appendicitis, the leucocytes on the day of admission numbered 20,000. Operation was refused by the patient. He was treated medically with improvement in all symptoms, the leucocytes gradually fell from day to day, after six days they numbered 7,500. At this time permission for operation was granted and a large abscess was found in the pelvis, containing at least 500 cc. of pus. At the time of operation the temperature was normal, bowels moving freely, pain absent and stomach retentive. The only indications

of the abscess were tenderness and rigidity of the right rectus and a mass discernible upon rectal examination.

In this case the blood examination proved itself entirely unreliable and it does not take a very large number of such cases to severely shake our confidence in leucocytic counts.

In carcinoma there are no marked blood changes, except the anemic and blood destruction of extreme cachexia, which is in no respect pathognomonic. Leucocytosis is absent unless due to the absorption of septic material from an ulcerating area or from some intercurrent conditions.

Our experience with the variations in the leucocyte count have been given in a paper published in the *Philadelphia Medical Journal*, of June 1st, 1901, and we will not infringe upon your time to repeat them here. But in summary we will say that the leucocyte count, although at times very valuable, is often very disappointing.

Quite recently it has been announced that the way out of this difficulty lies in the differential count, in which an increase in the polymorphonuclear leucocytes will show the presence of pus without an absolute increase of the leucocytes. Let us hope that this statement will be verified and remove the discrepancies we have found, but as yet this theory has not been investigated fully enough to be conclusive.

The differential count is very valuable in the diagnosis of pernicious anemia and the various forms of leukemia and these diseases cannot be positively diagnosed or eliminated without a differential count. It is said to be of value in the diagnosis of trichinosis, but with its value in this disease we have had no experience.

With the differential count in suppurative conditions the benefits received have been purely negative in character. The theory of the polymorphonuclear increase already mentioned has not as yet been of any practical benefit to us, yet we cannot say that in the future it will not prove of value.

Although we have made a few examinations of the alkalinity and specific gravity of the blood, their results were entirely inconclusive.

This paper, as we have already said, is in no way a complete review of the value of the blood examinations in surgery, but is only some of the more prominent experiences met with in a general surgical practice. There are many diseases in the diagnosis of which blood counts might be and are of value and also many conditions not mentioned here that interfere with their usefulness.

We have no desire to belittle the real value of blood examinations, for the preceding pages show that they have very often been of greatest value to us. What we do object to is the unfounded claims that have been made for this procedure, which experience does not bear out and which are almost sure to deceive practitioners and lead them into errors likely to sacrifice valuable lives. For instance, the statement that hemoglobin below 40 per cent. precludes successful operation, if followed out would cost many lives by denying to patients the benefits of operation. Then the statements concerning appendicitis that have appeared from

time to time in the Medical Journals that certain operators depend upon the blood count alone to indicate the time and need for operation in this condition. And so with many other inaccurate, though rosyhued, statements, which, unless protested against, are likely to deceive all but the most experienced.

We have mentioned in another communication the many artifacts that may interfere with and negate the value of the blood count, such as physiological and drug leucocytoses, errors in technique, etc., and will not repeat them here.

Therefore, let us make use of blood examinations, but not view the results through such rosyhued glasses that we cannot see their inaccuracies and limits of usefulness.

THE SUPRAORBITAL REFLEX IN FACIAL PARALYSIS.

By JOSEPH SAILER, M. D.,
of Philadelphia.

Medical Registrar to the Philadelphia Hospital.

At the March meeting of the Section on Internal Medicine of the College of Physicians of Philadelphia, D. J. McCarthy demonstrated the supraorbital reflex. This had not been described previously. It consists of a slight, but distinct contraction of the orbicularis palpebrarum when the supraorbital nerve, or occasionally one of its branches, is struck a slight blow. McCarthy regards this reflex as important for the reason that it demonstrates conclusively the sensorio motor mechanism of reflex action; that is to say, mechanical irritation of a purely sensory nerve (the supraorbital) produces contraction in a muscle not immediately in relation with it and supplied by a purely motor nerve, the seventh. In a subsequent communication (*Neurologisches Centralblatt*, Sep. 1, 1901, p. 800) he reiterated his views, and incidentally mentioned that the reflex was invariably lost in facial paralysis.

At the time of demonstration objection was made that it was not possible to exclude contraction as a result of direct irritation of the orbicularis fibres extending above the eyebrow, nor irritation of the periosteum to which the muscle is attached. As the contraction is usually more distinct in the lower lid, the first of these objections seems improbable. As the matter is one of considerable interest, I desire to report some cases* that prove to my mind, that the original explanation of McCarthy is correct.

CASE I.—The patient, K; white, male, 25 years of age, a laborer by occupation, was admitted to the Philadelphia Hospital suffering from tuberculosis of the larynx and lungs, and chronic otitis media. He gave the following history. His parents and other near relatives—all in Germany—were either healthy or had died from unknown causes. He had had an attack of dysentery in childhood, but no other sickness. He had never had venereal infection. Three years ago he had a severe attack of pain in the left ear followed by a discharge which has persisted in considerable quantity until the present time. About one year ago he had lost his voice. Between two and three months ago he noticed that he could not move his

left eye and that food collected between the teeth and the left cheek. He is an ignorant, well-nourished man, with the physical signs of a slight catarrhal inflammation of the left apex. Tubercle bacilli have been found in the sputum. There is only whisper speech. A continual discharge of pus takes place from the left ear which is totally deaf. Hearing is decreased on the right side.

The opening of the left eye is wider than the right; the left side is smooth and expressionless. If the patient puffs out his cheeks, air escapes on the left side. When told to close both eyes, the left ball rolls up and in, but the lid does not droop to cover it. When told to look downward, the lid follows the eye for about half the distance, and then stops. When told to close the right eye, there is very slight drooping of the left upper lid. Mastication is well accomplished. The masseters contract strongly; there is no paralysis of the palatal or pterygoid muscles. The tongue is protruded in the median line. The left platysma appears to be paralyzed; the other muscles of the neck are normal. All the muscles of the right side of the face contract normally to electricity; on the left side only the platysma, masseter and temporal muscles respond. Taste has been tested a number of times on the anterior, and also on the posterior part of the tongue. The patient, although very willing, appears to be too unintelligent to understand that he must answer promptly, and, even with the strongest caution, always hesitates some time, and endeavors to move the tongue after a drop of the solution employed has been placed upon it. As far as can be judged, however, taste is normal on both sides. It appears from this description that the lesion is peripheral, and is probably situated somewhere between the geniculate ganglion and the brain, in all likelihood involving the nerve in its course through the petrous portion of the temporal bone.*

The interesting feature of the case is the behavior of the supraorbital reflexes. When the trunk of the right supraorbital is struck with a percussion hammer, the right eye-lid gives a distinct and vigorous contraction. When the trunk of the left supraorbital is struck, no contraction occurs in the left orbicularis, but there is a distinct contraction of the right orbicularis, not quite as vigorous as when the right nerve is struck. That is to say, there is a distinct crossed reflex, proving beyond any dispute, that the motor nerve in this reflex is innervated from the medullary centre as a result of afferent impulses conveyed along the opposite sensory trunk. The reflex is only elicited when the trunk of the nerve is struck directly. It cannot be obtained by striking the distribution of the nerve filaments in the frontal and anterior parietal regions of the skull.

Two other points deserve notice. Percussion upon the lower edge of the malar bone on the right side produces no response; on the left side there is distinct sluggish, worm-like contraction of the muscles elevating the corner of the mouth. This is evidently not caused by the reflex action, but is simply an evidence of increased myotatic irritability in the diseased muscles which have apparently not lost all contractile power. I have not been able to find any note regarding this phenomenon, in a rather cursory examination of the literature of facial paralysis.

Koster (*Deutsches Archiv für klinische Medizin*, Vol. 68, pp. 343 and 506) has recently called attention to the extreme frequency with which the lacrimal secretion is involved in this condition. In the present case it appears to be equal on both sides. No

*These cases were all observed in the medical wards of the Philadelphia Hospital whilst I was substituting for Dr. Alfred Stengel, to whom I express my thanks for permission to report them.

*Dr. George M. Marshall has since operated upon the left ear, opening the mastoid and tympanum and agrees in the above localization of the lesion.

trophic changes have occurred in the left eye, although lagophthalmus persists during the patient's sleep, and there is marked pyrexia, and general impairment of nutrition.

Krause (*Münchener medicinische Wochenschrift*, Nos. 26, 27 and 28, 1901) does not believe very strongly in trophic ulcers of the cornea after trigeminal resection, but has observed ulceration produced by traumatic irritation (in a miller's wife). It is possible that in this case the active tear secretion had kept the exposed conjunctiva clean, and I think that the rolling of the eyeball may assist considerably.

The second patient presents somewhat similar phenomena, and others that are still more interesting.

CASE II.—W. L., 25 years of age, an iron-moulder by occupation; always healthy with a good family history; at the age of 22 noticed a lump at the angle of the right jaw. This continued to enlarge, others appeared, and two years later an operation was performed, several glands being removed, and others left *in situ* on account of extensive adhesions. The patient has several large scars in the carotid region, and numerous enlarged glands can still be felt just beneath them. Since the operation he had suffered from fever, coughing and occasional sweats. There had been considerable loss of weight, and tubercle bacilli had been found in the sputum. There was infiltration of both apices. Immediately after the operation he noticed paralysis of the right side of the face. This has persisted, with slight improvement, to the present time. Upon examination it was observed that the right corner of the mouth was drawn slightly down; the right side of the mouth was persistently open; and the right palpebral orifice was smaller than the left. There was occasional tic of the muscles on the right side. Sensation to pain and touch were everywhere normal. Motion was very imperfect. The patient was able to lift the right eyebrow slightly; the right eyelids could be approached, but not completely closed. He was not able to show his teeth upon the right side, and upon puffing out the cheeks air escaped freely on this side. Upon repeated effort he was able to draw up the right corner of the mouth, but usually this was associated with drawing up of the left corner, and sometimes, in attempts to draw up the right corner, only the left was moved. The movements of the jaw were not impaired, excepting slight limitation toward the right by the scar. The masseters contracted equally and vigorously. The right platysma did not contract, although the left contracted vigorously. With the exception of the masseter and temporal muscles, none of the muscles on the right side of the face responded to faradic electricity, while those on the left side responded readily. Hearing in the right ear was very much impaired, the watch being heard at 3 inches; in the left ear the watch was heard at 4 feet. Taste was equal and normal on both sides of the tongue. It seemed certain, in spite of the defect in hearing on the right side, which may possibly be accounted for by some local conditions that have not been detected, that in this case the paralysis was due to division of the nerve after its emergence from the skull as a result of the operation, and that a certain amount of repair has taken place.

The supraorbital reflexes when tested gave the following results. Upon striking the left side there was a very marked contraction of the orbicularis, but there was no contraction on the right. Upon striking the right supraorbital, there was only a very slight contraction on the right side, and a moderate contraction on the left, that is to say, a crossed reflex was present in this case also. But the most interesting phenomenon was the apparent extension of the reflex. When the right supraorbital nerve was struck with moderate force, there was in addition to the slight contraction already noted, a distinct lifting of the external angle of the mouth for a distance of about a quarter of an inch. This was entirely involuntary, and appeared to be due to the irradiation of the reflex to several of the medullary motor centers. Why the particular

group of muscles employed in lifting the lip should be especially affected, I do not know.

Striking upon the malar bone and upon the points of emergence of the facial nerve upon other parts of the face failed to produce any contraction, but very slight upward twitching of the lip occasionally occurred upon striking the infraorbital nerve just below the edge of the orbit.

The third case merely serves to confirm the existence of the crossing of the reflex.

CASE III.—J. H., 46, a carpenter by occupation, 4 years ago had several abscesses of the thigh which finally healed. Six weeks ago he began to cough and expectorate freely, and lost his voice. About a month ago the left eye was injured, and shortly after that he developed paralysis of the muscles of the face, giving rise to persistent lagophthalmus. The masseters and temporals still contracted; there was a continual discharge of pus from the left corner of the mouth. The patient was totally deaf in the left ear and the left eye was intensely injected. No tubercle bacilli had, however, been found in the conjunctival secretion; they were numerous in the expectoration. The patient was in such a desperate condition that careful examination was not possible. However, upon tapping upon the left supraorbital no contractions occurred in the eyelids of that eye, but there was a distinct twitching of the eyelids of the other eye. The right supraorbital reflex was apparently normal. Irradiation could not be determined.

These three cases appear to prove, first, that McCarthy's reflex is a true sensori-motor reflex, and that the irritation of the supraorbital nerve may, under certain circumstances, produce contraction of the muscles of the opposite side. Second, that in certain cases the reflex manifestation may extend to the other muscles which are removed to a considerable distance from the supraorbital nerve.

As a subsidiary observation I desire to call attention to the loss of ability to move the platysmā in cases I and II. Babinski (*Gazette des Hôpitaux*, 1899, No 52) regards this as a symptom of organic plegia. It apparently exists also in peripheral facial paralysis.

The Study of Hand Imprints.—In *La Contemporaine*, for March, 1901, Madame A. de Thèbes gives photographs of imprints and models of the hands of Paul Deschanel, President of the French Chamber of Deputies, member of the French Academy, etc., in illustrating a study in palmistry. These are reproduced in the *Gazette Medicale de Paris*, (June 15, 1901) with quotations from her article, though her conclusions are omitted. Here the hands are described scientifically, side by side with the chiromantic description. Should M. Deschanel be arrested or assassinated, he can now be identified by these imprints. A plea is made for a more detailed and more general study of hand imprints, for determining the identity, profession, or trade of an unknown individual, an action which will certainly prove of great anthropometrical value. [M. O.]

Cyclic Cerebro-Meningitis in Adolescents.—Professor P. E. Launois and Jean Camus report three cases of epidemic cerebro-spinal meningitis, benign and cyclic in character. All three patients were boys from 16 to 18 years old. None of them would permit the performance of lumbar puncture. The illness began with gastro-intestinal symptoms, fever, pain in the neck, headache and general malaise. Kernig's sign was intense, persisting until defervescence, when it suddenly disappeared. Patellar reflexes were absent until recovery, when they rapidly returned. Complete paralysis of the bladder occurred temporarily. The temperature fell to normal suddenly upon the ninth day in each case. There was no stage of prodromes or of convalescence. Launois and Camus suspect that the condition was a pneumococcal meningitis, from its cyclic character. The case-histories are given in full. Rendu and Sicard have already reported similar cases. Triboulet has also observed some cases like these. (*Bulletin et Mémoires de la Société Médicale des Hôpitaux de Paris*, June 27, 1901, No. 22). [M. O.]

THE PRESENT STATUS OF THE BOTTINI OPERATION AS A METHOD OF TREATMENT IN OBSTRUCTIVE HYPERTROPHY OF THE PROSTATE GLAND, DERIVED FROM A SUMMARY OF EIGHT HUNDRED AND EIGHTY-EIGHT OPERATIONS BY FORTY-EIGHT OPERATORS.

By ORVILLE HORWITZ, B. S., M. D.,
of Philadelphia.

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College; Surgeon to the Philadelphia Hospital, Jefferson Medical College Hospital and State Hospital for the Insane.

(Continued from Page 829.)

The results of the observations of many surgeons upon patients where complete retention had existed and those affected with a frequent desire to micturate accompanied by the detention of residual urine, is that beneficial results from treatment are very nearly equal; if there be any difference, it is in favor of those cases where complete retention exists. Such has been my experience. In several instances I have been agreeably surprised, after operating upon individuals who had relied upon the daily use of the catheter for several years, to find that soon after the operation they were enabled to partially empty their bladders, the residual urine greatly decreasing in amount until they were finally able to completely empty the viscus. The restoration of the function of the bladder after this operation is probably as Bangs surmises: "Spontaneous urination which follows the operation is due not only to the formation of the grooves, but to the contraction of the cicatrices together with atrophy of the gland." In quite a number of instances, on examining the condition of the prostate some months after the operation, I have been agreeably surprised to find that the organ had greatly diminished in size.

The claim that the Bottini operation may be employed as a prophylactic measure, thereby preventing all the discomfort and danger so frequently attendant upon "catheter life," is based upon an experience of fourteen patients operated upon between the ages of 49 and 61, all of whom were just beginning to suffer from the effects of their prostatic obstruction, residual urine being present in each instance. Twelve of the patients had employed a catheter from two to four months, the remaining two were affected with an increased frequency of micturition, each having about four ounces of residual urine, the catheter never having been resorted to. Not only was the operation in each instance successful, attended by a prompt recovery, but the effect has been permanent, two years having been elapsed since the first operation was performed.

The question as to the length of time that should elapse before operating upon an individual suffering with an obstructing prostate gland is yet in abeyance. The concurrent opinion of those who have had large experience in prostatic surgery is that an operation should be resorted to as soon as it becomes evident that catheter life can no longer be continued with safety to the individual. In other words, the time for the performance of the operation is early, before serious secondary changes take place. I agree with Willy Meyer when he says, referring to the Bottini operation (*Medical Record*, April 28,

1901): "The question when a Bottini operation shall be performed I would answer to-day as I did eighteen months ago, namely, as soon as it will be necessary to give the catheter into the hands of the patient himself. As I have said in a previous paper on this subject, the danger to life begins about this period."

The operation should be performed just as soon as the surgeon becomes convinced that the employment of the catheter is unsatisfactory, and before cystitis, pyelitis or pyelonephritis has been developed.

An operation which is performed early is attended with but little pain and discomfort and promises permanent relief.

More skill and care are required to operate upon a prostate when only beginning to increase in size than on one which has reached considerable dimensions, as in the former condition there is danger of injuring either the bladder or urethra by the blade of the instrument. In operating upon early cases, where but a slight enlargement exists, the incision on the roof of the urethra is a very dangerous procedure, and should not be attempted. The instrument employed, in cases of beginning prostatic enlargement, should be constructed with a much smaller blade than that which is used in more advanced cases. When the operation is performed in the early stage of the disease it is safest to resort to a perineal cystotomy, using for the purpose a modification of Bottini's instrument, devised by Dr. Charles H. Chetwood, known as the "perineal galvano-cautery incisor" (*Medical Record*, May 10, 1901).

The incision into the perineum adds nothing to the danger of the operation and gives the surgeon the advantage of determining by touch the size, configuration and condition of the gland; it also enables him to place the instrument in such a position that the resulting cut will be most effective. The danger of passing entirely through the gland into the membranous urethra is obviated, allowing the operation to be performed with absolute precision.

The results obtained by numerous operators demonstrate that in those cases where prostate obstruction has existed for a lengthened period, the employment of the catheter being required daily, the general health of the patient being still in good condition, that in the majority of such instances galvano-caustic prostatotomy will remove the obstruction to urination, together with the gradual disappearance of the residual urine, with the accompanying cystitis, and the frequent desire for urination, the prostate gland, too, often markedly diminishes in size. Patients advanced in years, in whom the symptoms caused by obstruction have existed for a length of time, who are broken down in health, with blood-vessels atheromatous, bladder and kidneys more or less diseased, retention of urine being a common feature, where a radical procedure could not be undertaken, have in the Bottini operation a method of treatment which is surely palliative, with insured relief to the urgent symptoms. Where an incurable cystitis exists, the bladder being hopelessly damaged, no operation that could be performed would be otherwise than

palliative. As a rule the Bottini operation is followed by sufficient relief to enable one to pass the catheter without pain or difficulty, prostatic spasm disappearing as well as the obstinate constipation from which these individuals usually suffer, together with a marked improvement in the general physical condition. I have several times known individuals gain from 20 to 25 pounds within four months after the operation. The cystitis will persist, but in less aggravated form, and will be amenable to treatment.

The detail of the history of a few cases here submitted forcibly portrays what results may be expected when the galvano-caustic incisor is employed at the outset of prostatic hypertrophy.

G. L. Aged 49. Occupation conductor. Sent to me by Dr. William Miller. Married man. Mild attack of gonorrhea when 20 years of age. For the past year he has been passing water at intervals of every three hours during the day and twice at night. Has no pain, but complains of "an irritability at the neck of the bladder." Examination of urethra and prostate with negative results. By means of the stone-searcher the middle lobe of the prostate was found to be enlarged, observation verified by a cystoscopic examination. Length of urethra normal; residual urine two ounces. Bottini operation performed May, 1899. Present condition; patient perfectly well, all abnormal symptoms having disappeared.

S. L. Aged 62. Married. No venereal history. Has suffered from irritability of the bladder for the past year and a half. Urinates every three hours during the day, twice at night, never feels as if the bladder had been completely emptied. Sometimes suffers from spasmodic pain at the neck of the bladder. Examination per rectum showed the prostate gland to be enlarged and hard to the touch. The urethra half an inch longer than normal. On making a cystoscopic examination found the middle and right lateral lobes enlarged. Three and a half ounces of residual urine. Patient had used the catheter twice daily for the last three months, by the advice of his physician. Urine normal. Operation November 1899. Condition eight months after the operation normal. Patient states that sometimes, though rarely, especially if he has had a hard day's work and is much fatigued, he may have to urinate once during the night. No residual urine was found on examination.

The results obtained from the remaining twelve cases, the Bottini operation having been performed at the outset of the prostatic obstruction, are similar to those above related. I do not think that any further comment is necessary. The lesson that these cases teach is obvious, and justifies Willy Meyer in stating: "I would operate as soon as it becomes necessary to give the catheter into the hands of the patient himself." I think that the results attained in the fourteen cases here referred to fully justify the claim that the Bottini method of treatment may fairly be regarded as a prophylactic measure, and if practitioners would resort to this mode of treatment at the incipiency of their patients' trouble, hypertrophy of the prostate would cease to be a bugbear of old age. The cases now to be recounted illustrate the results of the operation in persons in whom the obstructive symptoms have existed for a lengthened period, on whom the use of the catheter was daily required, the bladder beginning to undergo pathological changes, the physical condition of the patient being good.

S. C. Aged 63. Laborer. Admitted to the Jefferson Hospital October, 1900. Patient states that he had an attack of urethritis when a young man. Never had any urinary difficulty until four years before he came to the Hospital; when he began to suffer from frequency in

passing water, which greatly increased, both by day and night. He has been unable to pass any urine without the aid of the catheter for the past six months. Has been using the instrument for over a year. Examination revealed a much enlarged gland apparently of a mixed type. The urethra was increased one and a half inches in length. There was absolute retention of urine. The urine was acid in reaction, urea 2%, pus, leukocytes and a trace of albumin. He was kept under treatment for three weeks before he was in a proper condition for operation, which was continued for at least four months after the operation was performed. When last seen, nine months after surgical treatment, the patient was able to completely empty the bladder. Had ceased to employ the catheter, passed water about every three hours during the day, and occasionally, though rarely, once at night.

The next case shows the effect of the operation in an advanced case of prostatic hypertrophy complicated by prostatitis, cystitis, pyelitis, polyuria, chronic urethral fever, and retention of urine.

W. F. Sent to me by Dr. E. E. Montgomery. Patient 60 years of age. Gives the following history:

No venereal disease. Began to suffer from frequency of urination at the age of 50. Trouble greatly increased, until efforts to empty the bladder had to be made every two hours day and night. Had employed a catheter for the past four years, and for the past year and a half has been unable to void his urine without the aid of the instrument. He suffers from very violent paroxysms of pain in the vicinity of the neck of the bladder, and at times in the left flank shooting down the course of the urethra, simulating renal colic. Has chills followed by fever about every third day, the temperature reaching as high as 104 degrees. Is weak, emaciated; about 30 pounds below weight; is worn out by fever, pain and loss of sleep. The appetite is poor and he suffers from constipation. On examination the prostate gland was found to be enormously enlarged, apparently fibrous in character. The urethra was over one and a half inches longer than normal. The stone-searcher showed that the enlargement encircled the neck of the bladder like a collar. Owing to the condition of the kidney, the cystoscope was not employed. The urine varied, being sometimes acid, sometimes alkaline, very offensive, filled with gelatinized pus, leukocytes, and albumin; urea 1.1½%. He voids about 65 ounces of urine during the night. Operation performed July, 1900. Repeated September the same year. Condition, as shown by a letter received from the patient, February 13th, 1901, "I am markedly improved. There is no residual urine, spasm, or constipation. Have not had an attack of fever for some time." Report of Dr. Mitchell, his family physician, June, 1901, "Patient has gained in weight and strength, no further need for catheter, no more fever. Spasm has disappeared; still some polyuria and a little pus in the urine. Patient has resumed his usual vocation."

That this individual, in the face of all the complications that existed, should be restored to a very nearly normal condition surely speaks strongly in favor of the Bottini operation.

The next case illustrates well what may be accomplished by means of a galvano-cautery, prostaticotomy employed as a palliative measure.

L. S. Aged 79. Sent to me by Dr. Gartmann. Suffering from prostatic hypertrophy for the past eight years. On admission to the Jefferson Hospital it was found that the prostate was much enlarged; the urethra 1¾ inches longer than normal. Necessary to insert the catheter every two hours day and night. Suffered greatly from prostatic spasm and constipation. Has had occasional attacks of hematuria. Bloodvessels atheromatous; is very feeble, appetite poor, and is below weight. Suffers from loss of sleep, owing to the irritability of the bladder. Urine, alkaline, offensive, full of pus, and contains blood. The bladder was found to be contracted, holding about 3½ ounces of urine. Cystoscopic examination showed that the bladder contained numerous pockets with hypertrophy of the mucous membrane, which was thrown into ridges, the organ being chronically inflamed. Kept in bed for one month with continual drainage and appropriate treatment

preparatory to operation. Operation performed December, 1900. Five months after, during which time the treatment was continued, he gained in strength and weight, pain and constipation disappearing. Catheter can be readily inserted. Cystitis still persists and he is unable to void urine without the use of the instrument, but the use of the catheter is needed but twice during the night.

Owing to the length of time that had elapsed since the initiation of the disease and consequent damaged condition of the bladder, any operation would have been purely tentative. The marked improvement and the relief to the urgent symptoms which followed surgical interference were all that could be hoped for.

The next case demonstrates that the operation may be employed as a curative measure in cases of suprapubic fistula, which, owing to the obstruction caused by enlarged prostate, refuses to heal.

J. B. Aged 67. Sent to me in 1897 by Dr. F. X. Dereum. Suffering from vesical calculus, hypertrophy of the prostate gland and retention of urine. At the time of his admission to the Hospital patient was very ill; he was in the institution six weeks, before it was advisable to have recourse to an operation. A calculus was removed by suprapubic lithotomy. In October, 1900, the individual again came under my care for relief of a suprapubic fistula, a consequence of the operation. The patient was subjected to the Bottini process. As a result the normal function of the bladder was restored, the residual urine disappeared, and at the time of writing this article the individual is in perfect health. A letter received from him January 15th, 1901, says: "I am happy to say that my fistula has entirely closed up and I have not passed a drop of water through the opening for a long time."

D. S. Aged 69. Farmer. Vesical calculus of large size associated with retention of urine due to prostatic hypertrophy. For the last eighteen months has depended entirely upon the use of the catheter to empty the bladder. Suprapubic lithotomy March, 1901. Went to his home three weeks after the operation; returned in the latter part of May, with a suprapubic fistula which had refused to heal. Bottini operation was performed. Five days later passed a portion of his urine per urethra for the first time in eighteen months. At the present time, empties the bladder completely; fistulous tract closed, but has frequent desire to urinate, owing to chronic cystitis. Is enabled to hold the urine five hours during the night; much improved in health and strength.

(To be Concluded.)

1. The Surgical Treatment of Ascites in Atrophic Cirrhosis of the Liver. F. VILLAR.
2. Encapsulated Cavernous Angioma of the Orbit. FELIX LAGRANGIE.

1.—Talma of Utrecht first sutured the omentum to the abdominal wall to establish a communication between the veins of the omentum and those of the abdominal wall, thus withdrawing the blood from the portal circulation. So far only 17 cases have been reported. Villar reports two more. He believes that the method of Schiassi, of Bologna, suturing the omentum between the external surface of the parietal peritoneum and the muscles of the abdominal wall, is the best. A parahepatic incision is made. The case-histories of two such operations follow, with temporary success in both cases. Of the 19 cases, six deaths have resulted soon after operation, while only six patients have been cured. An exploratory laparotomy is sometimes followed by the disappearance of the ascites. [M. O.]

2.—Lagrange reports the case of a man of 35, who had a small tumor of the right orbit since birth. His sight is excellent and the tumor only began to pain him a few months before he saw a physician. The tumor was about the size of a small almond, situated in the deeper tissues of the angle of the orbit. It was diagnosed a congenital venous angioma. After removal, examination showed an encapsulated cavernous angioma. He recovered in a week. [M. O.]

October 6, 1901. (31me. Année, No. 40.)

1. Epithelioma of the Gall Bladder with Cholecystostomy. CHAVANNAZ.
2. Poisoning from Shoes Dyed Black with Aniline. G. CHEVALIER.

1.—A woman of 25 had had pain for three years in both iliac fossae and the epigastrium. She grew worse, jaundice developed, the feces were clay colored, the urine very dark. She was much emaciated and the pain was so severe that she could not lie down. A large tumor was palpable in the left hypochondrium, epigastrium, and right hypochondrium, reaching to the right iliac spine. A sensitive tumor as large as an orange was felt along the edge of the liver, which was also tender. Erysipelas appeared upon her face, in spite of which cholecystostomy was performed. The pain ceased at once. She died ten days after the operation. The ductus choledochus was found closed by a mass of degenerated lymph-glands, while an annual epithelioma was found in the gall bladder. [M. O.]

2.—A boy of 17 had noticed headache, vertigo, and cyanosis of the face and extremities for three days. His heart was irregular, and he was trembling from cold and emotion. There had been no nausea or vomiting. Three days before he had worn a pair of shoes which had just been dyed black, for eight hours, only removing them because of their disagreeable odor. Chevalier found that they had been dyed with a solution of aniline black in aniline oil. He recovered rapidly from the aniline poisoning. [M. O.]

JOURNAL DE CHIRURGIE.

August-September, 1901. (Première Année, No. 8.)

1. Backward Dislocation of the Right Index Finger. A. MOUCHET.
2. Total Hysterectomy for a Uterine Sarcoma in a Child of Three. J. LORTHOIR.

1.—A man of 23 fell two months ago, landing upon his hands. Upon rising he found that he could not move his right index finger, which, bent back, formed a Z upon the back of his hand. All efforts at reduction failed. The first phalanx of the index finger was dislocated upon the metacarpal bone, backward, the ends of both bones being palpable. All movements of the finger were impossible. The efforts to reduce the dislocation moved the luxated phalanx further back upon the metacarpal bone. Radiographs showed the absence of any fracture. Arthrotomy by a lateral incision showed a sesamoid bone which was removed, the head of the metacarpal bone being resected. After a week at rest in dressings, the finger was moved passively; on the tenth day he moved it voluntarily; on the fifteenth day he had completely recovered. [M. O.]

2.—Lorthoir could find few cases of total hysterectomy for malignant tumors of the uterus in young children. He reports a small round-celled sarcoma in the uterus of a girl of three, for which partial vaginal hysterectomy was performed. The tumor had recurred three months after the removal of a supposed uterine fibroma through the vagina. Two months later, as the tumor had again recurred, he performed total abdominal hysterectomy. The child fully recovered. The specimens show that the tumor originated in the posterior uterine wall. [M. O.]

Gynecology.—The opening lecture in the course upon gynecology just begun by Professor Pozzi appears in the *Presse Medicale* (June 1, 1901, No. 44). After mentioning the course of events which led to the creation of the new chair of gynecology in the University of Paris, with expressions of his thanks for the appointment, Pozzi reviews the subject of gynecology in France. Gynecological procedures commenced in 1858. It is only about 25 years ago that Péan and Terrier first performed ovariectomy. Since that time various proceedings have been imported from Germany, England, and America. The first operations, the later methods, the good work of the French gynecologists, are all described. Pozzi concludes by stating his intention to teach gynecology, both medical and surgical. While many operations will doubtless be necessary, some cases will undoubtedly respond to purely medical treatment. [M. O.]

TABLE III.
SIMPLE CHRONIC ABSCESES AND BRONCHIECTASES.

Author	Age and Sex	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Result of Autopsy
Körte, Archiv für Klin. Chir. Vol. 43.	Male, 52.	Pneumonia 2 years before.	Dullness and small and moist rales over middle lobe. X-ray showed distinct cavity, middle of right lung.	None.	Catgut suture of pleu a. Marked dyspnea during operation. Only once small quantity of pus obtained.			3 hours after operation.	Showed a system of bronchiectatic small cavities, surrounded by pneumonic areas. Only the smallest cavity had been opened.
Körte, same.	Male, 21.	Pneumonia 6 months before.	Dullness, tympany and amphoric breathing, with large moist rales over right upper lobe.	Yes.	Pneumotomy. Pus evacuated from a bronchiectatic abscess found in right upper lobe.	In 15 weeks			
Körte, same.	Female	Influenza. Pneumonia 2 years before.	Over left lower lobe marked dullness, bronchial breathing. Resonance decreased, and dry rales over rest of lung. Later amphoric breathing over left lower lobe before operation.	Yes.	Bronchiectatic pus cavity opened. Later a communication with a second cavity established.			3 months later	Stenosis of main bronchus. Extensive cavities in left lung.
Körte, same.	Female, 11	Influenza. Pneumonia of right lower lobe, one year before.	Posteriorly on right side, dullness increased from above down over upper portion; bronchial breathing, from angle of scapula down; light amphoric breathing	Yes.	Small, circumscribed empyema opened. Also opened abscess in right lower lobe.			7 days after operation, of fresh pneumonia of R U L. there were smaller ones present not opened	Showed that operation had opened wall of R U L. right lower lobe, but there were smaller ones present not opened
P. R. Sherwood, Chicago. (Unpublished case.)	Male, 42.	Septic pneumonia, 2 months previously.	Area of dullness from outer border 4th rib and 1/2 inch to right of left mammary line. Large moist rales and bronchial breathing. Icteric fever and 8 to 10 ounces of pus expectorated daily. X ray located abscess accurately.	Yes.	Thoracotomy; found circumscribed empyema corresponding to shadow weeks in X-ray picture. Could not find communication with lung at that time.	Healed in 5 months. Gained fifty pounds			
Carl Beck, (N. Y.), N. Y. Med. J., Aug. 28, 1897.	Male, 31.	Pleuro-pneumonia, one year previously.	On right side in front; tympany and rales, and bronchial breathing.	None.	Resected 8-10th ribs. One ounce pus evacuated. Some odor.	Healed two months after operation.			
Karewski, Arch. f. Klin. Chir., Vol. 57, p. 555.	Female, 35.	Left pleuro-pneumonia 4 months previously.	Dullness from angle of scapula down. High temperature.	Yes.	Opened abscess, size apple, in lower left lobe. No communication with bronchus found.	Recovery.			
Quincke Berl. Klin. W., 1888, No. 18.	Male, 26.	Pneumonia two years before in left lower lobe.	None given.	None.	Zn Cl ₂ paste applied and 4th rib resected. 3 weeks later pus discharged through wound.		Alive 12 years later (1896) with fistula		
Quincke, Mittheilungen aus den Grenzgebieten, 1896.	Male, 25.	Double pneumonia 2 months before, complicating older bronchitic cases.	Periodical expectoration of large quantity of pus. Dullness over sixth space (left). Bronchial breathing, metallic rales. Dullness from 5th left rib down in front. Later amphoric breathing and large moist rales.	Only partially before paste used.	Zn. Cl ₂ paste to cause adhesions. 9th and 11th ribs resected. Opened into cavity communicating direct with bronchus. After operation sputum greatly decreased.	Recovery in 2 months			
Quincke, same place.	Male, 34.	Pneumonia 17 years before, and again 2 years before.	Respiratory mobility decreased on left side. From 7th dorsal spine down dullness; bronchial breathing, metallic rales. Paroxysmal expectoration of large quantities of non fetid sputum.	Don'tful before paste used.	After paste (Zn. Cl ₂) used, pneumotomy, 5 weeks later. Pus evacuated and cavity drained.		Much improved still has fistula		

TABLE III (continued).
SIMPLE CHRONIC ABSCESES AND BRONCHIECTASES.

Author	Age and Sex	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Result of Autopsy
Massachusetts General Hospital.	Male, 61—8.	Four years ago fell upon a stove, striking side and back. Few days later appeared ill, one day unconscious. Then was said to have pneumonia. Was treated at Children's Hospital for nine months, and afterward was aspirated twice, at intervals of three months. No pus found. 2½ years ago was said to have abscess of right lung, but operation was refused for one and a half years. Has had two bad hemorthages.	Evidence of retraction of upper portion of right lung.	None.	Ether given. Portions of 7th, 8th and 9th rib excised. Lung was slightly retracted and honey-combed with sinuses. Tissue friable. A smooth bulging surface seen, apparently the diaphragm. Rounded mass, proved to be thickened visceral pleura, forming a wall of abscess cavity. Pus at once followed incision.			Three weeks after discharge from the hospital.	
Oder and Halstead, Johns Hopkins Hospital Bulletin, Dec. 1891.	Male, 40.	Pneumonia several times. Exact date not known. At intervals left axilla. Loud bubbling rales, hemoptysis and putrid at base of left lung. Resp. 40 expectoration for years. Temp. 104, 3—40°C. fetid expectoration daily.	Loud resonant rales, amphoric breathing, and metallic rales in left axilla. Loud bubbling rales at base of left lung. Resp. 40. Temp. 104, 3—40°C. fetid expectoration daily.	Yes.	Resected 11th and 15th ribs, and opened freely a series of cavities.				Three days after operation, they had opened into a system of large bronchiectatic cavities in left upper lobe.
Kijewski, Centralblatt f. Mith. aus den Grenzgebieten der Inn. Med. und Chir., No. 1, 1901. Also Gazet Lekarska, No. 4, 1897.	Female, 32.	Right - sided pleuropneumonia, followed by severe dyspnea and cyanosis some time before.	Psychic type of fever. Diminished over right lower lobe.	Yes.	Resection of 10th rib after successful exploration had shown pus. Lung curetted and packed with gauze. Fever continued for some time.	Yes.			
Kijewski, same place.	Male, 63.	Broncho - pneumonia (right side) after influenza some time before. cal signs given.	Intermittent fever. Exploratory puncture showed pus. No physical signs given.	Yes. Pleura greatly thickened.	Ninth rib resected. Lung incised, felt very hard, and contained many small abscesses. Curettage, accompanied by considerable hemorrhage. Cavity packed with gauze. Fever disappeared, but abundant pus came from wound.		Ten months later was very weak, had night sweats and there was a fistula.		

TABLE IV.
CHRONIC PUTRID ABSCESES AND BRONCHIECTASES.

Author	Age and Sex	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Result of Autopsy
Körte, Archiv für Klin. Chir. Vol. 63.	Male, 11.	Bronecho-pneumonia, 2 years.	Anterior axillary line on right side. Tympany and amphoric breathing. Gurgling rales. Decreased resonance rest of lung.	Yes.	7th and 8th ribs resected. Musculo-cutaneous flap. Chloroform found encapsulated empyema; also cavity in right lower lobe, 6x8 cm., with dilated bronchi, opening into it. Latter cauterized.			10 days after operation of general sepsis.	
Körte.	Male, 33.	Pneumonia, 10 months previously.	Tympany, gurgling rales, amphoric breathing below right clavicle and in axilla.	Yes.	Curved incision. Pectoral muscles divided. Exploratory puncture negative. With thermocautery opened large cavity filled with cold fluid and gangrenous lung.	Yes, in 18 weeks.			

TABLE IV (continued).
CHRONIC PUTRID ABSCESSSES AND BRONCHIECTASES.

Author	Age and Sex	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died.	Result of Autopsy
Körte.	Male, 29	Pneumonia, 2 years previously.	Tympany in front. Dullness behind, over left upper lobe; no respiratory murmur over entire lung. Many rales over dull area. Typical 3 layer fetid sputum.	None.	Pleura sutured. Marked cyanosis. No further operative measures.			4 days after operation.	Entire left apex composed of a system of communicating bronchielectatic cavities.
Körte.	Male, 23 years.	Duration, 7 years.	From angle of scapula down, bronchial breathing and dullness.	Yes.	Exploratory puncture revealed putrid pus. Pneumotomy. Putrid abscess emptied; left lower lobe near it was encapsulated empyema.	Recovery in 4 months.			
Körte.		Pneumonia, 5 months previously.	Absolute dullness; no respiratory sounds from third rib down on right side. Diagnosis before operation was putrid empyema and gangrene of lung.	Yes.	Thoracotomy, pus evacuated. No communication found with abscess cavities. Patient remained septic.			Death in 10 days.	Showed two large abscesses in right lower lobe, not opened and diffuse bronchielectasis.
F Krause.	Male, 36	Pneumonia, nine months previously, of left lower lobe.	Dullness, amphoric breathing, moist metallic rales, near angle of scapula. Lower down, dullness, diminished respiratory sound and fremitus. Bad odor to expectoration and elastic fibers.	None.	Pleural cavity tamponed, opened 10 days later, when adhesions were found. Cavity in middle of lower lobe opened, size of an apple, containing putrid fluid, and large sequestrum of lung tissue.	Recovery in 3 months.			
F Krause.	Male, 56.	Broncho-pneumonia, 4 months previously.	Dullness and bronchial breathing, on right side; below spine of scapula. Putrid sputum, large quantities. Remittent fever.	Pleura adherent.	Third and fourth right ribs resected on angle of ribs to scapula. Exploratory puncture at adherent area as well as deep cauterization gave negative results.			Death, 4 weeks later.	Autopsy showed abscess cavity in upper lobe, size of an egg and a second in the middle lobe of the same size.
Hadra Centralblatt f. Chirurgie, 1897, p. 103, Supplement.	Female, 38.	Severe pleuro-pneumonia, 8 years previously. Since then invalidism.	Large quantity of putrid sputum. X-ray showed shadow in entire left lung, heart displaced over right lower lobe dullness and when full expectoration, tympany. Exploratory puncture negative.	Yes.	Pneumotomy, abscess cavity opened.	Recovery			
Krause.	Female, 19 years old.	Pneumonia of left lower lobe, and left-sided pleurisy, with effusion, six months previously.	Dullness over left lower lobe.	Yes, at first operation; at second, lung retracted.	At first operation found empyema with greatly thickened pleura. Fever and expectoration increased after operation. Sputum putrid and contained elastic fibres. No physical signs of a cavity. At second operation decorticalized the lung and looked for abscess cavity in vain over both upper and lower lobes. Two abscesses opened spontaneously into dressings.	Healed 5 months later.			
James H. Dunn, Minneapolis, (Unpublished case)	Female, 22.	Pneumonia, 1 years previously.	Expectorated cupful fetid pus daily, unusually at one time. Signs of cavity on right side, posteriorly.	None.	Two operations; one between scapula and spine; other in axilla. Some pus discharged from posterior opening, but no improvement, probably large cavity not opened.			1 year after operation.	
Wiemer, Centralblatt f. Chirurgie, 1896, p. 1183.	Male, 33.	Pleuro-pneumonia, 2 years before.	Dullness over left lower lobe. Tympany in axillary and upper-lateral areas. No respiratory mobility. Putrid sputum in large quantity.	Yes.	Resected 8th to 10th ribs; opened cavity with cautery, size adult fist. Contained large sequestrum. On 11th day after operation found a second cavity.	Healed in 6 weeks.			

TABLE IV (continued).
CHRONIC PURTID ABSCESES AND BRONCHIECTASES.

Author	Age and Sex	Etiology and Duration	Physical signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Died	Result of Autopsy
K. Lichtenauer Deutsche Zeitschr. für Chirurgie Vol. 50, p. 389.	Male, 32	Traumatic pneumonia, 2 years before.	Behind, on left side, dullness, absence of respiratory sounds, above this area. Sharp bronchial breathing. Putrid sputum.	None	Exploratory puncture in 9th space showed pus; pneumothorax; evacuated 130 c. fluid pus. Cavity, size egg, healed in 3 months. Five months later returns of symptoms, ectatic bronchi found. Constructed corset to compress cavity, after cauterizing bronchi.	Healed in 9 months.		
W. W. Keen, W. Joseph Hearn and W. J. Roe. American Medical, July 20, 1891.	Male, 26	Aspiration pneumonia, 20 years previously.	Paroxysmal cough with expecto- ration; large quantities fetid purulent material (1 pint). Vesic- ular murmur absent below line from spine of 8th dorsal vertebra to 7th costal cartilage, with loud gurgling rales over this area on right side. Dullness over this area. Vocal fremitus lost and resonance decreased below above line.	Yes.	First operation, Dec. 19, 1885. Ex- ploratory thoracotomy failed to find abscess. Second operation, Nov. 20, 1886, also unsuccessful, although had cut down alone exploring needle, which had shown pus in 8th inter- space posteriorly. Third operation, Dec., 1888. Resected 6th rib in mam- mary line; lung adherent; separated toward diaphragm; no abscess found. Encountered resistance at dome of diaphragm. Made second resection just beneath angle of scapula (re- sected 4th rib); pleura found adher- ent; opened abscess cavity, into which large bronchi opened. Drained. Pos- terior wound still open. Fourth operation, Dec. 11, 1890. Wall of cavity excised. Since then fistula, but odor and discharge gone.	Greatly improved after 4th opera- tion.		
Williams and Marshall. Lancet, Dec. 30, 1882, p. 1107.		Chronic pneumonia of both lungs, and fetid cavity, expectoration, for one year.	In right lung symptoms of a cavity.	Probably.	Inserted trocar and drained cavity.		Yes, 6 weeks after operation.	Multiple bronchi- ectases in right lung, largest had been drained. Death due to gangrenous cere- bral abscess.
Priestley, Leech Lancet, Jan. 13, 1891		Pneumonia, 6 months before, followed in 2 months by fetid expecto- ration	Dullness from 2nd rib down on left side with absent vocal fremitus and resonance. Resp. mur- mur decreased. No elastic fibers. No signs of cavity.	Yes.	Exploration in 2nd interspace showed pus. With needle as guide, introduced drain. Pneumonia 2 weeks after operation. No ribs resected.	Eight months after opera- tion		
Quinke, Berl. Klin. Woch., No. 19, 1887.	Male, 26	Pneumonia, 2 years before. Since then fetid expectoration	Dullness from 4th dorsal spine down, and as far anterior as axil- la. Loud amphoric resp., and voice. No change with changed position.	None.	Resected 9th rib; found no cavity, but three weeks pus discharged from wound spontaneously. Second re- section 6 months later to close cavity			Dischar- ged with fistula Able to work.
Quinke, Berl. Klin. Woch., No. 18, 1888.	Male, 32	A typical pneumonia, 3 months before.	Dullness on right side, with no sharp boundaries, to spine of scapula and mammary line. Loud bronchial breathing and metallic rales. Very purulent fetid spu- tum.	None.	Zn Cl ₂ paste in 8th intercostal space, followed by adhesions. Resected 8th and 9th ribs, and again applied zinc paste. After days later abscess opened.	In 1 month		
Burgess and White, Lancet, April 16, 1888.	Female, 25	Pneumonia (?), 3 years before.	Hectic fever, large amount putrid sputum expectorated. Lower left lobe dull. Decreased vocal fremitus and resonance.	Yes.	Found circumscribed pleural effu- sion beneath it; abscess drained.	Recovery, two months.		

TABLE IV (concluded).
CHRONIC PUTRID ABSCESSES AND BRONCHIECTASES.

Author	Sex and Age	Etiology and Duration	Physical Signs before Operation	Adhesions Present	Operation and Condition found	Recovery	Improved	Died	Result of Autopsy
Sutton (quoted by Mosler) "Lungen-Chirurgie" 1883, Wiesbaden.		Acute attack pneumonia 5 years before. Two lobes, with fetid expectoration, hemoptysis.	Signs of cavity in left lower lobe.	Yes.	Incision in 4th intercostal space. Drained. Daily irrigation with carbolic solution.			Sudden, on 31st day.	No cause found for death. Cavity occupied entire lobe.
Oehler. Münchener Medizin Woch., 13, Oct., 1891		Three years before had gangrene following pneumonia of left lower lobe. No cavity signs shortly before operation had after influenza a fresh pneumonia.	Chills, dyspnea, dullness, bronchial breathing, and metallic rales.	Not at first, but at second operation (four weeks later).	Exploration negative. Seventh rib resected, followed by pneumothorax operation. Latter soon disappeared. Second operation (four weeks later) found pleura adherent; could not find cavity, but inserted tube. On second day pus discharged.		Still had fistula		
Kümmell. Centralblatt für die Grenzgebiete der Inneren Medizin und Chirurgie, 1891, No. 3.	Female.	Left lower lobe pneumonia, two years before.	Not given.	Yes.	Resection 6th and 7th ribs. Puncture. Thermo-cautery. Very severe hemorrhage. Cavity size of egg, communicating with large bronchus.		Yes, small fistula after six months		
Quincke. Mitt. a. d. Grenzgeb. d. Inn. Med. u. Chir., 1896	Male 31. (Case 6.)	Influenza, pneumonia, one and one-half years before.	Over left apex in front signs of cavity. Dullness behind, marked from 5th dorsal spine down; bronchial breathing, large moist rales.	Yes.	Resected 3rd rib in axillary line incision into cavity, evacuating fetid pus and mucus.			Death 1½ hrs after operation.	Death due to weakness soon after operation. Small bronchiectatic cavity in upper lobe; system of cavities in lower lobe; one opened.
Northrup and McCosh N. Y. Med. Journal, vol. 1, 1897	Female, 23.	Influenza, pneumonia, 6 months before.	Flatness, from 3rd rib down over right lung in front. Absence of respiratory sounds and rales.	Yes.	Resected 6th rib, and opened abscess in lower lobe, containing three ounces of thick and very fetid pus, operation severe shock followed.	Yes, in three months after			
Blunt. Lancet, 1888, vol. 1, p. 622.	Male, 26.	Pleuro-pneumonia of right side; two weeks later fetid expectoration, which continued to time of operation, 3½ months later.	Fetid fever, sweats. Exploratory punctures showed fetid pus.	Yes.	Resected rib one inch below angle of scapula; used needle as guide; and opened gangrenous cavity. Drain ed.	Yes, in six weeks.			
Tuffier. Bull. de la Soc. de Chir., 1883, p. 761.	Male, 41	Pneumonia, with fetid expectoration, 4 months before.	Dullness in front over right lung, amphoric breathing and moist rales. Severe hemorrhage fifth day after operation.	Yes.	Incision in 3rd interspace, opened cavity size of turkey egg. Opened another cavity above it both contained black blood mixed with lung debris.	Yes, in three months.			
Eisendrath.	Male, 60	Right lower and middle lobe pneumonia two years before. Since then over right lung, fever, expectoration of scapula down area of dullness, large quantities of pus, size of palm of hand; also some frequently fetid (three bulging of intercostal spaces pinis daily), emaciation, here. Over this area a few moist rales to be heard. Diagnosis made of gangrene of lower lobe.	Respirations 60; pulse 126. No change in percussion anteriorly from right lung. Behind from fever, expectoration of scapula down area of dullness, large quantities of pus, size of palm of hand; also some frequently fetid (three bulging of intercostal spaces pinis daily), emaciation, here. Over this area a few moist rales to be heard. Diagnosis made of gangrene of lower lobe.	Yes.	Resected 8th and 9th ribs under angle of scapula, entered free pleural cavity, upper lobe collapsed, marked dyspnea and cyanosis. Lower lobe found adherent in front. Resected 9th and 10th ribs in anterior axillary line, pleura adherent, opened a circumscribed gangrenous cavity and beneath it opened gangrenous cavity in lower lobe, and a smaller cavity in middle lobe, containing pus. Drain and gauze inserted.			Twelve hours after operation.	Found cavity size of first in right lower lobe (gangrenous). Adhesions bound lower lobe to chest wall. Had also opened one of a series of bronchiectatic cavities in middle lobe. Some hemorrhage into pleural cavity.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended November 15, 1901.

Empyema Existing Almost Forty Years.—At a meeting of the Medical Society of the Paris Hospitals, (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 20, 1901, No. 21), Faisans and Audistère report the case of a man of 55, who first had left-sided pleurisy at the age of 16. He was ill for almost a year. Then followed four years in the army. At 27 he had another attack of pleurisy; at 29 still another. Paracentesis thoracis was never performed. Since that time he has always had some dyspnea, with a dry cough. This year a severe attack, diagnosed pneumonia with pleurisy, caused his death, after the withdrawal of some purulent fluid from the pleura of the left side. This liquid contained no bacteria of any sort, but showed crystals of cholesterol, fatty bodies, and completely degenerated cellular debris. The autopsy revealed atrophic cirrhosis of the liver which had been diagnosed. The left lung was a tiny flat cylinder, its wall almost of bony consistence. This wall, formed by the hardened pleura, contained a large purulent collection. The lung, though much congested, was still permeable to air.

This encapsulated empyema was only opened with the costotome. From the conditions found, the diagnosis of an empyema of years duration was made. In all, the purulent liquid measured three liters and a half. With this latent pleurisy, he was a soldier for years, performed his work, and drank enough to cause hepatic cirrhosis. Congestion of what little lung was left was caused by the thoracentesis. The empyema had most probably existed for forty years. In the discussion which followed, Barblat recalled having seen a similar case. [M. O.]

Cervical Adenolipomatosis of Tubercular Origin.—Marcel Labbé and Jean Ferrand report the case of a girl of 18, whose mother died of phthisis seven years ago. She had always coughed much, had blepharitis, keratitis, eczema, and chilblains. At the age of 7 a small tumor appeared in the fold of her right elbow. This had later disappeared under treatment. Since the age of 9, her neck has enlarged gradually and progressively, beginning in the left submaxillary glands. During the past few months this has rapidly increased in size. Her neck, from the parotids to the supraclavicular fossae, is a symmetrical, soft, semiliquid, lipomatous mass. There is no pain, and the glands can be felt, hard and nodular, deep in the swollen tissue. There are no symptoms of pressure from the tumor. She had always been stout and well nourished. They consider the condition one of adenolipomatosis, not of multiple lipomata. Its localization is unique, as it is absolutely limited to the neck. During childhood the cervical glands became tubercular; following this, periglandular lipomata formed; then rose a localized adenolipomatosis. Three conditions seem responsible for this, the tuberculous transmission from her mother, her lymphatic temperament, shown by the blepharitis, keratitis, coryza, eczema, chilblains, etc., and a tendency to obesity marked even in childhood. (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 20, 1901, No. 21). [M. O.]

The Lymph-Glands in Cancer.—At a meeting of the Medical Society of Paris, Dr. Courtois-Suffit said that cancer affects the lymph-glands in the same way that the infectious diseases do. But from the external appearance of the lymph-glands, the nature of the anatomic alterations within cannot be guessed. For they may become enlarged and still be free from carcinoma. He divides the lymph-glands into three classes, those which are healthy but hypertrophied, producing leukocytes, a precancerous or paracancerous condition; those which are infected secondarily with either pyogenic or tubercle bacilli, from the ulcerating tumor, or from the lungs, etc.; and the true cancerous glands, with epitheliomatous cells, from near by lymph-glands, through carcinomatous or healthy lymph vessels. The lymph-glands play to some extent a protecting role. Courtois-Suffit divides cancer into three stages, the local, glandular, and blood vessel stages. Youth favors the occurrence of the glandular stage. Either near by or far off lymph-glands may enlarge. The inguinal glands are generally affected with abdominal cancer; the subclavicular, with gastric cancer. When the subclavicular glands are affected, the cancer has spread through the lungs or mediastinum, through the thoracic duct, or there may be no connection at all between the stomach and the enlarged subclavicular lymph-glands. Finally the fact must not be forgotten that all the enlarged glands found in carcinoma are not cancerous.—(*Journal des Praticiens*, 1901, No. 21). [M. O.]

Acute Pneumococcal Meningitis in an Infant of Six Weeks with Hereditary Syphilis.—Dr. Louis Guinon reported a case of acute meningitis in an infant aged six weeks, covered with syphilitic roseola. Examination of the purulent cerebrospinal fluid after lumbar puncture showed polynuclear leukocytes in great numbers. The child died the next day. The brain was covered with greenish pus and there were no serous effusions. From the brain and the blood of the heart, pure cultures of pneumococci grew. Guinon reported this case to remind us that meningitis in a syphilitic must not necessarily be specific, and to show that pneumococcal infection easily becomes generalized in a very young child. The point of entrance of the pneumococcus in this case is unknown. (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 20, 1901). [M. O.]

VOL. VIII, NO. 22

NOVEMBER 30, 1901

\$3.00 PER ANNUM

The St. Louis Catastrophe.—We feel it to be our imperative duty to call attention to the fact that incalculable injury will be done to the cause of preventive medicine if the exact truth about the recent spread of tetanus in St. Louis is not revealed. Many facts have come to light, but we are not assured that *all* the facts are yet known. The coroner's jury rendered a verdict on the 18th instant, in which it blames the Health Department of the city of St. Louis for "negligence," but this luminous verdict proves nothing that was not already known. More to the point is the report of the committee of bacteriologists, published in *The St. Louis Medical Review*, and republished in this number of the *Journal*, to the effect that they arrived at the positive demonstration that the toxic serum dated August 24 and that dated September 30, were "identical." This is in direct contradiction to Dr. Ravold's statement that all the latter serum was destroyed. This discrepancy is vital. If the serum of September 30th was used, there is no longer any mystery about the epidemic, for the horse from which this serum was taken was shot on October 3d, because it had tetanus. The grave questions to be determined are, who is responsible for this fault, and how did it happen?

The statement that the work was done by the almshouse "janitor" in a stable on the almshouse property; and the absence of evidence that the horse had been immunized from tetanus, and that the serum had been properly tested on lower animals—all these points leave a most unsatisfactory impression on the mind and must be cleared up.

That this accident will have the effect of causing distrust of all municipal laboratories (in any and every city) is more than probable. We do not constitute ourself the final judge on this subject, but we recognize that the fault of one municipal laboratory should not be visited upon the heads of all the others. We wish, however, to point out most seriously to all municipal authorities that the cry is already being raised that the attempt has been made in several cities to mix politics with antitoxin serum. We do not know how just this is, but it behooves all municipal authorities who have gone or intend

to go into the manufacturing business, to take heed of this St. Louis disaster, and see that it is not repeated.

The private manufacturing firms which produce antitoxin are naturally not silent in this crisis. They claim that they have never had such disastrous results follow their work (in which respect, however, they have no better record than some of the municipal laboratories) and they point out that the reasons are that they immunize their horses, employ only expert workers, and observe scrupulously the laws of cleanliness. They are entitled to full credit for their success, and we gladly accord it to them. But the lesson to be drawn from this grave calamity is renewed vigilance; and no manufacturer, whether a Board of Health or a private firm, can afford to ignore this lesson.

The St. Louis authorities are to be commended for the promptness with which they have conducted the investigation; and the committee of bacteriologists, as well as the medical profession in St. Louis, are deserving of the highest praise for their conscientious efforts to unravel this dreadful problem.

Gunshot Wounds of the Pregnant Uterus.—Gunshot wounds of the pregnant uterus, although of somewhat rare occurrence, present a subject full of interest to the surgeon and obstetrician, involving, as they do, many delicate points of diagnosis and treatment, and requiring the most careful judgment on the part of the operator. The subject is interestingly brought before us by Dr. George Gellhorn, of St. Louis, in the *St. Louis Medical Review* of November 2nd and 9th. He has collected eighteen unclassified cases of gunshot wounds of the pregnant uterus. These cases show that the contents of the uterus greatly diminish the force of the bullet so that complete perforation of the organ is not the rule. Symptoms of hemorrhage and shock usually set in after such an injury, but in Gellhorn's eighteen cases there are two notable exceptions to this rule. In each of these cases the uterus expelled its contents and the child died shortly afterwards, but the mother recovered. In neither of these cases did any serious symptoms present themselves prior to the emptying of the uterus. Hemorrhage from the wound in the

abdominal wall varied greatly, in some cases being very slight, in others profuse, and in still others mixed with amniotic fluid. In many of the cases intestinal perforation complicated the uterine wound. In those cases which recovered from the immediate shock general peritonitis usually manifested itself. Labor pain setting in a few hours after the infliction of the injury, was the rule. An exact diagnosis of the condition is oftentimes difficult. The absence of fetal heart sounds after the injury is supposed by some to be indicative, but in a case reported by Prichard the fetal heart sounds continued to be heard, and yet when the abdomen was opened the uterus was found to be perforated and the intestine wounded in six places. In discussing the mortality, Gellhorn excludes one case in which death occurred from a cannon-ball injury. Of the remaining seventeen cases five died and twelve recovered. Six of the patients were not operated upon and only one of these died. In nine cases submitted to operation three died. This mortality corresponds very closely to that of other statistics. Gellhorn thinks, however, that it is misleading, since many cases of gunshot injuries of the pregnant uterus which terminate fatally are never reported. The effect of the injury upon the fetus was reported in fifteen cases; in eleven of these death occurred. Gellhorn urges early operation in all cases, in which advice we feel sure all surgeons will concur. Gellhorn inclines to the view that in most instances a better result will be obtained by the Porro operation, although in a few cases in which the uterine wound is small it may be closed and an expectant plan of treatment carried out. We are hardly prepared to agree with the writer in his suggestion of always removing the uterus in these injuries. In the early months of gestation and where the uterine wound is not extensive, we cannot but feel that the more conservative treatment of emptying the uterus and closing the wound, is not only more likely to result in recovery, but is also the most rational form of treatment.

Gastric Wounds during Pregnancy.—In this issue is published a most interesting report of a gunshot wound of the stomach and intestine, occurring during pregnancy. The promptness and skill of Dr. Gloninger in opening the abdomen and suturing the wounds are worthy of great praise. He saved not only the life of his patient, but also that of the fetus, which was born a few months later. The case is eloquent testimony to the accuracy of the views expressed in these editorial columns, that such injuries should have, in the majority of cases, immediate operative treatment. An incidental deduction from this instance of successful surgery is the great value to

the public of the hospital in small cities and towns. It is not probable that Dr. Gloninger would have had this brilliant result, had he not had the advantages of hospital environment for his patient. A hospital in a community trains the local medical profession to do great deeds, and gives the citizens, whether poor or rich, the possibility of the benefits of modern surgery in urgent emergencies.

Decortication of the Lung.—The question of priority in medical discovery is one of the most perplexing of those that concern the student. Discoveries in medicine, even more than in any other branch of knowledge, seem to be made when the time is ripe for them. Thus, bacteriology can scarcely be said to have developed until the microscope had reached a state of perfection to enable it to be possible. And in many surgical operations we are obliged to wait until perfection of technique, anesthesia and antisepsis have reached such a point that we can safely explore cavities and attack organs that were previously inaccessible.

So much for the scientific aspect of the question, but there is another which is entirely human, and most exasperating; that is to say, the so-called patriotic side, which prevents the German from recognizing the priority of a Graves: which arrays the continent of Europe against England, and the Eastern Hemisphere against America. Of all people, among the least patriotic in this respect are our own; due, perhaps, to a too assiduous cultivation of Teutonic medical literature, and a habit of speaking contemptuously of the indigenous product, because there are unquestionably some very disreputable medical journals published in America, just as there are in France, Germany and Switzerland, only, fortunately for us, they are rarely transported.

We are impelled to these reflections by having had our attention called again to the dispute between Fowler, of Brooklyn, and de Lorme, of Paris, regarding the possibility of stripping the pleura from the lung and thoracic parietes for the purpose of curing empyema. So far as originality goes, in this case as well as in many others, both appear to deserve equal credit. The idea occurred to de Lorme in April of 1893, and at that time he made some experiments upon dogs, but these experiments were not reported in such a manner as to obtain any wide circulation. When Fowler, in October of the same year, actually performed the operation upon a patient and succeeded in curing a very chronic and intractable condition in the left lung, he was entirely unaware of de Lorme's work. It was not until several months later that de Lorme actually performed the operation, and we think, therefore, that the credit is entirely due to our American colleague, and that the operation, if it

is to be decorated with a proper name, should bear his. "Fowler's operation" then, or pulmonary decortication, consists in stripping the pleura from the lung, diaphragm, ribs and pericardium and removing it together with all granulating tissue and sinuses that it may contain, with the object of promoting re-expansion of the lung, and completely extirpating the infected focus. In a recent paper, in addition to the report of an exceedingly interesting case operated upon by spinal anesthesia with most brilliant results, Fowler analyses the statistics to be obtained from the literature. In 30 cases in which the functional results had been stated with sufficient clearness, he finds that there have been 11 cures, 3 deaths, and the remainder were either improved, not improved, or doubtful. If, however, we consider only the effect upon the empyema, we find that it was cured 17 times. As 6 of the other cases were suffering from advanced tuberculosis, no permanent effects could have been expected under any circumstances. The final statistics should be 17 cures in 24 operations, with only one death. A very satisfactory result indeed. An interesting point is, that of all the cases recorded, Fowler's were the only ones in which total pleurectomy was performed, so that the operation when carried to its full extent is most emphatically and exclusively his own.

The Administration of Anesthetics.—Probably few things outside of the operation itself give the surgeon more anxiety than the administration of the anesthetic. Until quite recent years in most of our hospitals the important part of giving ether, or even chloroform, devolved upon the youngest and most inexperienced of the resident staff. It is a comfort to observe, however, that this custom is being changed in a number of our larger hospitals. It is to be regretted that practical instruction on anesthetics and their administration receives so little attention in our medical colleges. Great strides have been made in late years to acquaint the student with the practical methods of diagnosis and treatment, both medical and surgical; he is given bedside instruction in percussion, palpation, auscultation, etc.; he is obliged to attend one or more cases of confinement, and occasionally he is made to assist at operations. But how many of our colleges give to their students practical and personal instruction in the immediate duty of administering anesthetics? The rôle of the anesthetist has recently come into considerable prominence, due to the improved methods of producing anesthesia, and we are pleased to see that here in America this heretofore more or less neglected subject has lately been given much more consideration. It would seem to us that the student should be personally instructed how to

administer an anesthetic just as he is taught how to examine a chest, and not allowed to graduate without having once had an opportunity of anesthetizing a patient under the direction of an experienced anesthetist. To one interested in this subject it is a disappointment to examine the lists of textbooks recommended to students in the various college catalogues and find no mention made of a work on anesthesia. To appreciate the importance of this question one has but to refer to his own first experience in the giving of an anesthetic, to observe the manner in which the administration is frequently carried on, or to consider the many complications, immediate and post-operative, arising from the careless and ignorant use of anesthetics. Much might also be said in this connection regarding the importance of choosing the proper anesthetic in the presence of various organic lesions. It is undoubtedly true that most surgeons devote too little time to a choice of the anesthetic. When a careful consideration is given to the condition of the kidneys, lungs and heart prior to operation and the anesthetic chosen which promises the least interference with the functions of these organs, it is our belief that fewer cases of post-operative pneumonia, bronchitis, suppression of urine, etc., will be reported. The combination of nitrous oxide and ether has done much to prevent these post-operative complications, and can be substituted in many, if not all, of the cases in which ether alone is generally used.

The Surgery of the Mind.—We published some months ago in this journal a highly suggestive paper by Professor Pick, of Prague, in Bohemia. The author is an eminent German physician, and his paper should have made a deep impression on the minds of our readers. The purport of the essay was, in brief, to show that surgical operations done primarily for the sake of their effect on the mind, in cases of neurasthenic, hysterical and insane patients, were often disastrous in their results, seldom successful, and hardly ever justifiable. This position will be considered extreme by some neurologists, and by not a few surgeons, but in the main Professor Pick is probably right.

If Shakespeare lived at the present time he would not ask in dubious numbers "who can minister to a mind diseased?" The trouble with Shakespeare was that with all his legerdemain he never fathomed the mysteries of suggestive therapeutics. The answer to him nowadays would be that anybody with a few surgical instruments and an antiseptic training can minister to a mind diseased. The problem reduces itself sometimes to within the narrow limits of dilating the cervix uteri or adjusting a pessary. Even medical experts fall into the temptation of treating

the mind through the solar plexus—and we recall the case of an elderly lady who promptly got better after having a stomach-tube passed into her insides for the purpose of securing a test meal.

In fact, there are probably few of us, in any domain of practice, who have not sinned sometimes in trying to break into the mind by way of the cellar door. It has been said that the wisest physician is he who is the most suggestive, and that every truly honest physician has in him an histrionic element. When Sir William Gull said that people liked to be humbugged, one of his friends retorted that they liked to be *gulled*; and the truth of the saying was seen in the fact that Sir William left a large fortune.

But there is a serious duty involved in this risky kind of practice, and the ethics are not more conspicuous than are certain questions of policy. As Professor Pick showed, many of these patients are not permanently benefited by suggestive surgery, and their last end is worse than their first. A reputation built upon this kind of hypnotism is like a house built upon the sands.

It is too soon to pass judgment on the enterprise of the Paris doctors who, on the 21st instant, went up in balloons for purposes of physiological investigation. They took an assortment of dogs, rabbits, guinea pigs and scientific instruments, and results are promised later. Their observations on the blood appear to have been of great interest—especially on the corpuscular strength of that fluid. The red blood corpuscles are said to have shown an increase up to 10,000,000 per cubic millimeter at an altitude of 4,000 meters. The enterprise was peculiarly Gallic in its main features.

One of the diversions of the day is to observe the lay journals discuss seriously the latest deliverance of Tolstoi on the subject of matrimony. The Russian novelist has become the expatriated apostle of much that is impracticable and absurd, and his preachment to the effect that "marriage is sin" is logical and characteristic. The father himself of a large family, Tolstoi has discovered his own matrimonial sins rather late in the day. His doctrine, of course, is contrary to physiology, ethics and common sense, and physicians certainly would suppose that such a doctrine was not worthy of grave criticism. Charity should prompt us to ignore the illusions of the poor, distracted mind of this Russian mystic, who in his old age thinks that the sublimest virtue and wisdom consist in turning monk.

Current Comment.

THE PLAGUE IN CALIFORNIA.

The report of the special health commissioners, appointed by the Governor of California, adds another humiliating chapter to the already long drawn out discussion of the existence of bubonic plague in this State. It is not proposed to enter into any detail in refutation of this bold, defiant, and stupid document. * * * It seems superfluous to tell the reader that this lucid exposition of supposed facts is quite sufficient in itself to convince any thinking man of the truth it attempts to deny. It is contradictory throughout, and bears openly on its face the imprint of desperation and despair. A sense of distrust and suggestion of falsehood scents every page, and permeates every sentence.

PRAYER HEALING IN GERMANY.

The latest fashionable form of quackery in Berlin is said to be prayer healing. This has for some time prevailed in aristocratic circles in Berlin and Potsdam, and it has also invaded the ranks of the financial aristocracy. A pharmacopœia of prayers to be used against special forms of disease has been prepared. However beneficial to patients this new method of spiritual therapeutics may be, it does not appear to be likely to enrich its professors. The practitioner of prayer healing most in vogue is a lady doctor whose fees are at the rate of 2 marks an hour.

ADAMI ON KOCH.

In the current issue of the *Canadian Journal of Medicine and Surgery*, Professor J. George Adami writes at length on the same subject (the non-identity of human and bovine tuberculosis), and shows that Koch must have known that the investigations made by himself and Schütz were simply a repetition of those of Frothingham, Theobald Smith, and Dinwiddie. Adami, in August, 1899, read a paper on this subject before the Canadian Medical Association, in which he reviewed the work that had been done, and discussed the arguments *pro* and *con* at considerable length. It is hardly conceivable that Koch failed to see this paper, for the German Consul at Montreal asked for and received copies of it for transmission to his government. It is a serious fact that it was just about this time that Koch and Schütz began their inoculation experiments at Berlin.—*The Medical Record*.

VANITY IN A GOOD CAUSE.

A good story has been rescued from a South German paper by the *Westminster Gazette*. One of the hospitals in Rio de Janeiro bears on its front, in letters of gold, the inscription, "Human Vanity to Human Misery." The history of this strange sign is instructive. The Emperor Dom Pedro, of Brazil, who was the friend of the poor and the suffering, wished to erect a hospital for the benefit of the indigent invalids in the capital of his empire. Hence the public were invited to subscribe to such an institution. But there was hardly any response. Then the Emperor made it known that the title of "baron" was to be conferred on every subscriber of 100,000 milreis, and that of "count" on every subscriber of 250,000 milreis. And lo! and behold, a stream of money began to pour into the coffers of the building fund. The misery of the poor had not touched the wealthy, but the appeal to their vanity had not been in vain. The great day of the opening of the hospital came. An enormous crowd was gathered together. Everybody was gazing up to the gable of the new building which was to be "unveiled." When the cover was withdrawn the newly-made "aristocracy" read their Emperor's estimation of themselves in the inscription, "Human Vanity to Human Misery."—*The Sanitary Record*.

Correspondence.

TRANSPLANTATION OF THE URETER.

By J. F. BALDWIN, A. M., M. D., Columbus, Ohio.
To the Editor of the Philadelphia Medical Journal:

In your issue of October 19th, in an article by Dr. A. Laphorn Smith, he states that the operation of ureteral transplantation, which he had made on the 17th of August, was the eleventh which had been made in this country and in Europe, and he names as American operators Baldy, Kelly, Boldt, and Fullerton. You comment on this article editorially in your issue of October 26th, and add to the list of American operators the names of Penrose and Krug.

If you will turn to the files of your journal you will see that in the issue of November 26, 1898, I reported a case of uretero-vesical implantation which I had made on the 25th of the preceding August, while in the *American Gynecological and Obstetrical Journal*, of May, 1901, I reported two additional cases, making three in all.

In truth, the operation is so easy of execution that I suspect, were all the cases recorded, the number would be very much larger than Dr. Smith's article and your editorial would lead us to infer.

I wish to call attention to two or three points in transplantation technique. I see no reason for ligating the little remnant of ureter attached to the bladder. We would certainly anticipate no reflux of urine from that portion, while if any did occur it would readily escape through the fistula already existing into the vagina. Moreover, the chances of a ligature becoming infected at that point would be very great, and once infected it would of course make trouble until removed.

Since a fistulous opening already exists between the field of operation and the vagina, it seems to me better practice to enlarge this opening sufficiently to permit a drain to be passed from the field of implantation into the vagina instead of putting the drain through at the lower angle of the incision and thus inviting the occurrence of a weak point for a future hernia.

I fail to see any advantage in making the implantation without opening the peritoneal cavity. The extra-peritoneal operation is much more difficult, while at the same time there is necessarily left a large flap of peritoneum having a poor vascular supply and with a dead space between it and the transversalis fascia. The risk of infection in such a dead space is well understood, while the danger of sloughing of such a flap is by no means theoretical. This sloughing is alluded to, with cases, by Alban Doran in his paper on Cysts of the Uraebus, in Volume 81 of the *Medico-Chirurgical Transactions*. So great is this danger that in his paper Doran states distinctly that "the operator should never run risks through extreme anxiety to leave the peritoneal cavity unopened."

UNUSUAL AFTER EFFECTS OF A SNAKE BITE.

By LAWRENCE E. HOLMES, M. D., of Biltmore, N. C.,
To the Editor of the Philadelphia Medical Journal:

In reply to Dr. John G. Sheldon's suggestion, published in the *Philadelphia Medical Journal* for October 12, 1901, with regard to the case I reported in the same journal for September 14th last, under the heading, "Unusual After Effects of a Snake Bite," I would say that, though the carbolic acid theory of the paralysis may be considered as a remote possibility, it seems to me that the explanation on the ground of hysteria is much the more probable. It is hard to understand how carbolic acid applied to a superficial wound on the anterior surface of the forearm, could, several days later, reach the nerves of the back of the forearm in sufficient strength to produce a toxic neuritis before being absorbed, and carried into the general circulation and without causing any injury to the intervening structures. (This argument may be applied, only with less force, against the theory of a toxic neuritis produced by the serpent venom.) If carbolic acid could have such a local circumscribed effect, it would not be delayed five

or six days, for the local anesthetic effect of the drug occurs in a very few minutes and passes off in a few hours at the longest, unless permanent injury to the tissues is produced. There is no reason whatsoever to suppose that the local symptoms of inflammation—pain, redness, swelling, etc.—were, in this case, produced by the acid, for I have seen the same condition, only in a more marked degree, occur as the result of a snake bite, when no carbolic acid or any similar substance has been applied.

The gangrene, which occasionally follows the prolonged local use of carbolic acid is, according to Honsell, the result of "excessive transudation into the cellular tissues, so choking the circulation." This explanation is much more plausible than the nervous theory, for it does not seem possible that the acid could reach the nerve trunks in sufficient strength to paralyze them before being destroyed or absorbed. Though the case is not typical, yet, taking everything into consideration, there can be but little doubt that the editor of the *Philadelphia Medical Journal* was correct in his opinion, expressed editorially in the number of the *Philadelphia Medical Journal* in which the case was first reported, when he pronounced the case an unusual manifestation of hysteria.

Actinomycosis of the Superior Lachrymal Canal.—I. I. Ginzburg (*Medicinskoje Obosrenie*, May, 1901) quotes Aphanasieff's classification of actinomycosis into four groups: (1) Actinomycosis of the head and neck. Infection takes place through the mucous membrane of the oral cavity and the organs contained in it (carious teeth, tonsils, tongue and pharynx); also directly through the skin. (2) Actinomycosis of the thorax and the thoracic organs. Infection takes place through the healthy or injured mucous membrane of the respiratory tract. (3) Actinomycosis of the abdominal wall and organs. Infection takes place through the mucous membrane of the intestinal tract. (4) Actinomycosis of the skin and subcutaneous tissue. Infection takes place through bruises, ulcers, wounds, etc. To these groups the author adds a fifth, namely actinomycosis of the lachrymal apparatus, where infection takes place through the exposed conjunctiva. To the 39 cases of the last group recorded in literature he adds another observed by him. The patient, a woman of 30, had her upper tear-duct completely occluded by a substance resembling closely granulation tissue which, when removed and examined microscopically, proved to be a ray-fungus possessing long filaments, but without the clubbing observed by other authors in such cases. [A. R.]

Muco-membranous Enterocolitis.—The fundamental symptoms of muco-membranous enterocolitis, says Maurice de Langenhagen (*Presse Medicale*, 1901, No. 38) are mucous casts, (false membranes), in the stools, constipation, though this may alternate with diarrhea, and pain, colicky or occurring in violent paroxysms. Besides, there are the various signs of dyspepsia, some degree of nervousness, functional disturbance of the liver, intestinal lithiasis, etc. Anatomically the lesion is generally catarrhal and superficial, in the colon, and accompanied with marked atony. It is mainly seen in nervous and lithemic women. Out of 600 cases seen, 435 were female, 141 male, and 24 in children. There were among the women very few cases of metritis or salpingitis. In 32 patients Langenhagen noticed a typical diarrhetic form of the affection. Marked enteroptosis was found in 41; meteorism and hemorrhoids occurred in almost all cases. Emaciation is the rule. The liver is generally small; the stomach dilated. The right kidney was movable in 136 cases. Langenhagen believes that muco-membranous enterocolitis is a frequent cause of appendicitis. Diet is absolutely necessary; enteroclysis should be practiced for a time; and baths at Plombières, Chatel-Guyon, or Vichy complete the treatment. [M. O.]

Reviews.

Pathological Technique. A Practical Manual for Workers in Pathological Histology, including Directions for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By Frank P. Mallory, A. M., M. D., Associate Professor of Pathology, Harvard University Medical School; and James H. Wright, A. M., M. D., Instructor in Pathology, Harvard University Medical School. Second Edition, Revised and Enlarged. Octavo, 432 pages, with 137 illustrations. Philadelphia and London: W. B. Saunders & Co., 1901. Cloth, \$3.00 net.

We gladly welcome the second edition of this admirable manual which was designed originally to fill a definite need, and has filled it to perfection. The universal favor which the first edition received at the hands of students, teachers and laboratory workers should be a source of pardonable pride to the able authors. This second edition has been thoroughly revised and brought up to date. The very latest methods are given, and a few new chapters and some very fine illustrations added. On the other hand, the chapter on the examination of urine has been almost entirely omitted. However, there is one urinary test that should have been included, and that is the diazo-reaction which is a very important adjunct to the Widal test. We were somewhat surprised not to find pure beechwood creosote mentioned among the clearing agents. In the hands of those who used it, it has proved a most valuable clearing agent, either alone or in combination with oil of cloves. It does not dissolve celloidin, has only a slight action on the stain (hematoxylin) and clears rapidly from 95 per cent. alcohol. It also flattens out the sections as no other agent does. The rapid method of staining with hematoxylin is not given in a manner which would insure the best results. As practised in some laboratories, the method is: (1) strong hematoxylin, 2 to 3 minutes; (2) acid alcohol, $\frac{1}{2}$ minute; (3) alkaline water (ammonia or lithium carbonate), until blue; (4) distilled water, one or two changes; (5) 95 per cent. alcohol, $\frac{1}{2}$ to 1 minute; (6) creosote, until clear. Eosin or Van Gieson's may be used as counter stains. The staining occupies only a few minutes, and yet splendid preparations are obtained. This, however, is in no way a criticism of the book which in our estimation deserves nothing but praise, and can be highly recommended. [A. R.]

A Laboratory Course in Bacteriology. For the Use of Medical, Agricultural and Industrial Students. By Frederic P. Gorham, A. M. W. B. Saunders & Co., Philadelphia.

This small volume contains the elementary principles of bacteriology and is mostly devoted to methods. It is brief, comprehensively written, very well illustrated and conveniently arranged. The methods are carefully selected and brought up to date. It is evident that most, if not all of them, were tried by the author who is himself an experienced laboratory worker. Useful features are a comprehensive classification of bacteria according to Migula's system and a glossary of terms employed in the description of cultural characteristics.

As seen from the title, the book is too general in its scope, or rather too elementary, to be of any great use to medical students, unless as a convenient laboratory aid to the beginners. [A. R.]

A Text-Book of Diseases of Women.—By Charles B. Penrose, M. D., Ph. D., formerly Professor of Gynecology in the University of Pennsylvania. Fourth Edition, Revised. Octavo volume of 539 pages, handsomely illustrated. Philadelphia and London: W. B. Saunders & Co. Cloth, \$3.75 net.

The fourth edition of this well-known book preserves its original excellent form in an up-to-date garb. Dr. Penrose has had the happy faculty of clearness of expression,

and this, supplemented by a large experience in gynecologic practice and teaching has given him a directness of diction that is convincing, to say the least. The methods of treatment advocated in the book are those employed by him in his own work, and are those which in the hands of skilled gynecologists give the best results symptomatically with the lowest mortality-rates. In a close examination of this volume we see much that is new, including a summary of the latest knowledge on kraurosis vulvae, the more recent methods of treatment of uterine prolapse, the latest statistics on ventral suspension, and the accepted management of tubal pregnancy. Wilms's theory of the origin of dermoid cysts is mentioned, but the reader is left in doubt as to the author's stand upon this as yet disputed question. The important subject of gonorrhea in women receives ample attention, and the chapter on this subject is one of the most interesting in the book. The technique of gynecological operations, the text of which is filled with excellent illustrations, is clear and concise, leaving nothing to be desired in the way of asepsis and mechanical maneuvers. A number of the newer illustrations are the work of Miss Margaretta Washington and are equal to the best of the products of that distinguished medical artist. Dr. Penrose's book is a valuable one, of interest to the younger aspirants after surgical standing and of value to the older established surgeons. It must have a continuance of its well deserved popularity.

[W. A. N. D.]

The Physicians' Pocket Account Book. By J. J. Taylor M. D. Published by the Medical Council, Philadelphia, Pa.

A concise, convenient, and labor saving little book of 200 pages, embodying some practical suggestions, based upon strict business principles. It obviates the necessity of more ponderous stationery and can be employed at a moment's notice. In addition to the business suggestions, it would not have been amiss if the author had also included some suggestion as to the reciprocal duties of practitioners, and their professional responsibilities to each other as based upon definitely recognized ethical principles. The paper is excellent for the purpose, and the compilation accurate. [M. R. D.]

Beitrag zur Pathologischen Anatomie der Graviden Tube. Von Dr. med. August Peterson, Berlin. Published by S. Karger. Pages 84.

In this brochure of 84 pages Peterson gives us an interesting contribution on the pathological anatomy of tubal pregnancy, founded upon the study of 14 cases which occurred in the clinic of Professor Leopold Meyer. The specimens were submitted to careful microscopic examination, the object of the author being to discover, if possible, the relationship existing between a pre-existing salpingitis and the pathogenesis of tubal pregnancy; also to discover the relationship existing between the tubal mucosa and the attachment of the ovum. The subject is scientifically treated, there are interesting tables and clinical reports attached and the subject matter cannot fail to be of interest to gynecologists. [W. A. N. D.]

Tuberculosis of Both Suprarenal Capsules Without Addison's Disease.—Charles Le Roy, in the *Journal des Sciences Medicales de Lille*, (June 1, 1901), reports the case of a man of 39, who had had a fistula in ano. Tuberculous meningitis developed, and death followed. The autopsy showed an old phthisis and adhesive pleurisy, intestinal and meningeal tuberculosis, and total tuberculosis of both suprarenal capsules. He had never complained of pain, nausea, vomiting, etc., nor had his skin been at all bronzed, nor had he been weak or unable to do hard work. Le Roy believes that Addison's disease is a cachectic state resulting from cancerous or tuberculous degeneration; while the pigmentation of the skin, the asthenia, and the other symptoms are due either to fatigue, or to a lesion of the central nervous system, which may produce trophic disturbances, with pigmentation, sensory and motor disturbances or functional troubles. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Jewish Hospital.—It is announced that Meyer Guggenheim, of New York, formerly a resident of Philadelphia, intends to donate \$60,000 to the Jewish Hospital Association to erect a building for the treatment of private patients. He has already given the Mount Sinai Hospital, New York, \$200,000 for a similar purpose, and \$25,000 to the Denver Hospital for Consumptives.

University of Pennsylvania.—In memory of Dr. William F. Norris, who died November 18, all exercises in the Medical Department of the University of Pennsylvania were suspended during the afternoon of November 20th, when the funeral services were held.

Society Meetings Next Week.—The following societies will hold meetings next week at the College of Physicians, Philadelphia, at 8.15 P. M. Monday evening, December 2, Academy of Surgery; Wednesday evening, December 4, College of Physicians; and Thursday evening, December 5, Obstetrical Society.

Scarlet Fever.—It is reported in Washington, Pa. that scarlet fever prevails to an alarming extent in Canonsburg, a small town near this place, and all efforts to check its ravages have proved futile. The disease broke out in a negro settlement, and nearly every family in the town has a case. The public schools have been closed, and aid will be asked from the State Board.

Water Measles.—A disease called water measles, supposed to have been brought from the Philippines, has appeared in Stroudsburg, Pa. A number of similar cases is reported a few miles away, in New Jersey. The patients had fever and eruptions formed, like water blisters, which eventually burst.

Kensington Hospital for Women.—Dr. Ellis McDonald, recently substitute resident in the Royal Victoria Hospital, Montreal, has been appointed resident physician in the Kensington Hospital for Women, replacing Dr. S. E. Tracy, who has gone to San Francisco.

Decrease in Smallpox.—Forty-six cases and seven deaths was the smallpox record for Philadelphia for the week ending at noon, November 23. The total of smallpox cases for the year is 655, and the deaths 97. Smallpox patients discharged from the Municipal Hospital cured now number 345. In the city there are now 213 smallpox victims. City Councils at Chester have adopted resolutions expressing a desire to join with the United Health Boards and municipal authorities of Delaware county to secure a hospital for contagious diseases. The resolutions express the belief that such a hospital is needed at once to properly protect the health and lives of the citizens of the county. Deaths are occurring in the smallpox hospital, Norristown, and new cases are reported daily.

NEW YORK AND NEW JERSEY.

Immigrant Detained Because He Has Tuberculosis.—In deciding the case of Thomas P. Boden, now being argued in New York, the courts will rule whether or not a man suffering from tuberculosis can be excluded from this country. The decision which would send Mr. Boden back to Ireland would permit his wife and child to remain here. Mrs. Boden insists upon sharing the lot of her husband, and if he is deported, she and her baby will accompany him. This is the first case in which the constitutionality of the treasury ruling that consumptives be prevented from landing as immigrants will be passed upon by the courts.

Smallpox on a Ship.—The Hamburg-American Line steamer "Graf Waldersee," which arrived in New York November 22 from Hamburg, was detained at Quarantine by the health officer because a woman steerage passenger developed smallpox. The patient was sent to North Brothers Island and the steerage passengers who occupied the compartment with the patient were sent to Hoffman Island for observation. The steamer, after disinfection, was released.

Hospital Building Opened.—Governor Voorhees formally opened the new building at the State Hospital for the Insane, at Morris Plains, N. J., November 21. Three hundred prominent men from all parts of New Jersey attended the services. The new building is of red sandstone and granite, three stories high and covers about an acre and a half. It cost about \$500,000, and is fitted with all the latest improvements. Addresses were made by the Rev. J. M. Buckley, Governor Voorhees, Dr. Britton M. Evans, medical director of the hospital, and Patrick Farrelly, president of the Board of Managers.

New York Orthopedic Dispensary and Hospital.—The Trustees of the New York Orthopedic Dispensary and Hospital announce that Dr. Russell A. Hibbs will give a course of clinical lectures on Orthopedic Surgery at the Institution, Monday and Thursday afternoons, at five o'clock, from December 2nd to January 2nd (both inclusive). The course will be free to the medical profession and students.

Sing-Sing a Disease Spot.—"A jail like the woman's prison on Raymond street, Brooklyn, does not reform, but is a source of contamination to its inmates," says George McLaughlin, secretary of the State Board of Prisons, in his report to the New York State Conference on Charities and Correction. He believes the institution at Sing-Sing to be the most objectionable of the State prisons. "It is a hotbed for the culture of the bacilli of tuberculosis and a distributing centre of the seeds of disease, not only among prisoners, but among the families and the communities to which they return after their discharge. A modern prison should be constructed so that every cell should be open to the sunlight and air. The workhouse on Blackwell's Island may be cited as a good example of the modern prison."

Koch's Theory Substantiated.—Dr. G. D. Barney's attempt to demonstrate that Professor Koch was in error in stating that tuberculosis germs were not communicable from a cow to a human being appears to have resulted in a demonstration that the German scientist was right, as Miss King, the young woman whom Dr. Barney inoculated with germs taken from the mammary glands of a tuberculous cow was reported by him to be in good health two weeks after inoculation.

Consumptive Hospital.—The Board of Trustees of the New York State Hospital for the Care of Consumptives, after inspecting many sites, believe that Ray Brook, on the west side of the Adirondacks, is the best suited for the proposed institution. While Governor Odell has not fully approved of the selection, he thought it was the most available of those he inspected.

Horses to Test Vaccine Virus.—An experiment which will interest the medical profession is to be made in Burlington, N. J. Dr. Glasgow and Dr. Bunting, a doctor and veterinary surgeon, both graduates of the University of Pennsylvania, have secured ten horses, and it is proposed to inoculate each of the animals, using virus secured from a druggist. The animals will be carefully watched and their condition noted from day to day. As the horse is most susceptible to tetanus, if impurities exist in the virus, it will surely develop in one or more of the animals.

Tetanus in Camden.—The special committee of the Camden Board of Health has written to General Sternberg, Surgeon General of the United States Army, asking results obtained in the army by vaccination, and the history of any tetanus cases that have come under his observation. Although more than a week has elapsed since the inoculation of the fifteen white rats with virus at the Cooper Hospital, the rodents have shown no bad effects and the physicians are sure that the vaccine is not the carrier of the tetanus germ, but that it is propagated by insufficient care of a wound. Vaccine lymph used in the process of inoculation at Camden has been examined at the State bacteriological laboratory at Princeton, and has been found free from contamination. The samples were forwarded to Princeton early last week by the health authorities at Camden, and since then State Bacteriologist Baldwin has been making careful analysis. The examination was completed November 25th. Dr. C. F. Brackett, president of the State Board of Health, said that the investigation did not show any evidence whatever that the vaccine contained germs of tetanus.

Death of Acting Assistant Surgeon Stuart Eldridge.—The Surgeon-General of the U. S. Marine Hospital Service has received the sad intelligence of the death of Acting Assistant Surgeon Stuart Eldridge, who was on duty in the office of the United States consul-general at the port of Yokohama, Japan. Dr. Eldridge was a native of New York State, but had resided in Japan for many years. At the time of his appointment in the U. S. Marine Hospital Service, July, 1894, he was a member of the imperial board of health of Tokio, and sanitary adviser to the Japanese Government. He was an honorary member of the New York State Medical Society, an honorary member of the Alumni Association of Bellevue Hospital Surgeons, etc.

An Appointment.—Dr. Smith Ely Jelliffe has been appointed visiting neurologist to the City Hospital, New York City.

WESTERN STATES.

May Destroy Chinatown.—The president of the San Francisco Board of Health recommends the destruction of the Chinese quarter. He says that Chinatown cannot be rendered sanitary except by total obliteration. It should be depopulated, its buildings leveled by fire, and its tunnels and cellars laid bare. Its occupants should be colonized on some distant portion of the peninsula, where every violation of sanitary laws could at once be detected. The day has passed when a progressive city like San Francisco should feel compelled to tolerate in its midst a foreign community perpetuated in filth for the curiosity of tourists, the cupidity of lawyers and the adoration of artists. Dr. Williamson's recommendations are in line with those made last May by Dr. Geo. F. Shrady, of New York, who was sent out to investigate the circumstances that led to the widespread reports that bubonic plague existed in this city. Dr. Shrady was amazed at the filth he discovered in the Chinese district, and, to avoid the possibility of infection, advocated resorting to the radical measure of burning.

McKinley Hall.—The new chapel and amusement hall at the State Hospital for the Insane, Massillon, Ohio, which was dedicated November 21, is to be called McKinley Hall.

Infectious Diseases in Wisconsin.—There are thirty-six cases of smallpox in Oconto, and nearly as many of scarlet fever, according to the report of the Board of Health. None of the smallpox cases have proved fatal, but there has been one death from scarlet fever. Several cases of smallpox have broken out in Hollandtown, one case in the postmaster's family. Two new cases of smallpox have developed near Hayton, and for the first time in a long number of years an epidemic is prevailing near Juneau to more than ordinary extent. Thirty-five cases of scarlet fever are reported, and the chances are that a larger number will develop before long. Cases of diphtheria have also been reported.

Suicides in Kansas.—Owing to an epidemic of suicides in Emporia, Kansas, the Mayor and Board of Health have forbidden the publication of details of suicides or attempts in local papers.

A Removal.—Dr. E. W. Lee, formerly surgeon of the Burlington Railroad in Omaha, Nebraska, who for some time practiced medicine in St. Louis, Mo., and was one of the surgeons who assisted in the operation upon President McKinley, has recently moved to New York.

No Smallpox in Chicago.—Attention is called to the interesting fact that, while smallpox is now more or less prevalent in all sections of the country, and particularly in the great cities, Chicago is entirely free from it. No other city of the first class in this country can make the same boast. This exceptional exemption is ascribed by the Chicago health authorities to the thoroughness with which vaccination has been performed there, no less than 950,588 persons having been examined within the past thirty months. Probably this record is something unequalled in the line of guarding against smallpox in a great city, and the benefit that is now being derived from it should furnish a lesson to other great centres of population. Yet 15%, or over a quarter of a million, are yet unvaccinated.

\$35,000 Verdict for Injuries.—A jury in a Chicago court

returned a verdict of \$35,000 in favor of a physician, against the West Chicago Street Railroad Company. It is alleged in the declaration that while the physician was alighting from a Blue Island avenue cable car he was thrown in such a way that his hand and wrist were crushed, necessitating amputation.

Inter-County Medical Society.—The Inter-County Medical Society met at Eau Claire, Wis., November 19th, Dr. W. B. Lyman, president. Several technical papers were read.

Chicago outclasses all other large cities in the number of deaths from railroad accidents. Its total for the census year is 330, while the combined total for nine other big cities is only 486.

Dr. Nicholas Senn, the famous Chicago surgeon, has just returned home from a tour of the world, which included a trip over the plains and mountains of Siberia, via the new Russian railroad now operating from Moscow to Vladivostok.

The Plague in San Francisco.—There occurred in San Francisco during the month of September six cases and four deaths from the plague. During October there were three cases and three deaths, and in November, up to the 4th, one case and one death.

SOUTHERN STATES.

Smallpox in Kentucky.—The secretary of the State board of health of Kentucky publishes some startling figures in regard to the prevention of smallpox during the last four years. Out of the 119 counties, only nine have been free from smallpox during the present epidemic, and those are remote from the main lines of travel. According to his figures, a total of 398 distinct outbreaks has been reported, eighty-five of which were imported from other States. In four years 11,269 cases were reported, with 184 deaths, giving the remarkably low mortality of 1.63 per cent. Sixty-three counties and municipalities were obliged to erect special hospitals, and, even with these accommodations, the health board thought that the majority of patients had been treated in their homes. During this four-year epidemic, 392,280 persons were vaccinated and 408,825 were found protected by previous vaccination. As the total population of Kentucky is 2,147,174, more than 60 per cent. of the people were either unprotected or not examined. The actual cash expenditures from the municipal treasuries amounted to \$308,000, or more than \$27 for each case of smallpox reported. This makes no account of the loss of money due to interference with business, which must have totalled very close to \$1,000,000. The health board was confident that many lives lost might have been saved and a large part of this money need not have been expended, had the people paid more heed to warnings urging vaccination. Even after a four years' crusade, Kentucky is but a poorly vaccinated State, and until there is a change in that condition, further serious outbreaks of small-pox may be expected.

Maryland Public Health Association.—The regular semi-annual meeting of the Maryland Public Health Association will be held at Rockville, Md., December 3 and 4. Details of the meeting have not yet been completed. The president of the Association, Mr. Henry Brauns, says, however, that instructive and interesting addresses by well-known men and women interested in public sanitation will be made at this meeting.

Delaware Nearly Free From Smallpox.—The State Board of Health has announced that every case of smallpox in Kent County except one has been stamped out by rigid quarantine. Wilmington also is free from the contagion and there are but few cases in Sussex County.

Skipper Also a Doctor.—A barge was towed to Baltimore the other day with her rudder gone, having lost it in a storm. The skipper of the barge, the only skipper on Chesapeake Bay who has the privilege of hanging an "M. D." to his name, is the manufacturer of several remedies. The skipper's laboratory is on the barge, and while traveling he makes his medicines. Upon the arrival of the barge, he hurriedly makes his charter, and then opens up his medicine business. He makes his home at Ches-

penke City, and, while he carries freight up and down the bay, rarely comes to Baltimore.

The North Texas Medical Association will hold its semi-annual meeting in Greenville, December 10th, 11th, and 12th. The officers are: Dr. R. F. Miller, Sherman, president; Dr. J. B. Sheldahl, Dallas, vice-president; Dr. S. B. Moore, Van Alstyne, secretary; Dr. C. A. Gray, Bonham, treasurer. The sections are in charge of the following: Surgery—Dr. Bacon Saunders, Fort Worth; Practice—Dr. R. W. Baird, Dallas; Obstetrics and Gynecology—Dr. J. B. Garrett, Galveston.

Winchester Memorial Hospital.—In the presence of a large throng of people, the cornerstone of the Winchester Memorial Hospital was laid November 18th at Winchester, Va. A parade preceded the ceremonies at the hospital building. Fifteen thousand dollars have been subscribed to the hospital fund.

Southern Surgical and Gynecological Association.—The annual meeting of the Southern Surgical and Gynecological Association has just been held in Richmond, Va. The attendance was very good, while the number and quality of the papers presented were much above the average. The following officers were elected for the ensuing year: President, Dr. W. E. B. Davis, Birmingham, Ala.; vice-presidents, Dr. J. Wesley Boyce, Washington, D. C. and Dr. J. W. Long, Salisbury, N. C.; secretary, Dr. W. D. Haggard, Jr., Nashville, Tenn.; treasurer, Dr. Floyd W. McRae, Atlanta, Ga. The next meeting will be held at Cincinnati, Ohio.

Yellow Fever Institute.—Drs. Formento, Veazie, Salomon, and Prof. Beyer, of New Orleans, have been appointed members of the Yellow Fever Institute created by Congress last Spring.

Youngest Newspaper Reader.—A despatch from Bridgeville, Del., says that the 21 months old son of Prof. Wiley, of the Bridgeville Academy, is a phenomenon. When given toy blocks recently, he arranged them to form words. Prof. Wiley recently found the baby sitting on the floor with a newspaper in his hands, apparently reading. The professor questioned the child, when, he says, he found that the baby knew what the paper contained.—*Public Ledger*.

Maryland State Medical and Chirurgical Society.—The semi-annual meeting of the Maryland Medical and Chirurgical Faculty convened in Elkton, Md., November 19th. Several members of the Delaware State Medical Society were also present. The session was opened by Dr. V. Wallace, of Chesapeake City, president of the Cecil County Medical Society. The papers were of a highly interesting character, and called forth spirited and witty discussion. The officers of the association are: President, Dr. J. McPherson Scott, of Hagerstown, Md.; vice-presidents, Drs. Harry Friedenwald and Brice W. Goldsborough; secretary, J. Williams Lord, Baltimore; treasurer, T. A. Ashby; executive committee, Drs. William Osler, J. D. Blake, L. McLane Tiffany, H. B. Jacobs, the president, secretary and treasurer. The society has 680 active members and 17 honorary members.

Maryland Health Report.—In the annual report of the State Board of Health, Dr. W. H. Welch, of Johns Hopkins University, president of the Board, said that among the preventable diseases he particularly directs attention to the overshadowing importance of tuberculosis, which Maryland should single out for direct attack. The epidemic of smallpox which has been steadily increasing in the United States since 1898, has inflicted no great injury upon Maryland. The Secretary, Dr. John S. Fulton, said that among preventable diseases, tuberculosis is shown to have caused in 1900 12.7 per cent. of all the deaths in Maryland; pneumonia 5.9 per cent.; infantile diarrhea 10.2 per cent.; typhoid fever 4.5 per cent. The ratio of deaths from preventable diseases to the total mortality is 39.4 per cent. Among the counties, Baltimore had the highest apparent mortality—16.3 per 1,000.

MISCELLANY.

Leper Settlement at Darcy Island.—Dr. M. H. Foster, assistant surgeon, U. S. M. H. S., reported that on October 27th he visited Darcy Island, which has been set aside by

the British Columbia authorities for the isolation of lepers since 1892. The island is well suited for this purpose, being about 14 miles from Victoria, and having a good supply of spring water. At one time seven lepers were detained there, but now there are four, all Chinamen. Both the tubercular and anesthetic types of the disease were seen, and the duration ranged from three to four years. They occupy small frame buildings and have a garden, in which they grow vegetables, which keeps them occupied. Every two weeks supplies are sent from Victoria. There are no clean persons on the island, the lepers who are able to be about looking after those who cannot care for themselves. But one white man has been sent there, who came from Alaska, where he was supposed to have contracted the disease, possibly from Chinese in the canneries.

Jamaica.—From Port Antonio comes the news that vessels arriving from Philadelphia are being quarantined on account of the prevalence of smallpox there.

Insusceptibility to Vaccine.—The editor of the *Polio-clinic*, answering a young woman who had been vaccinated sixteen times without ever having taken, who had no scar on her arm, suggested that her first vaccination, in infancy, may possibly have been effective; and that even if all vaccinations have failed, she could not consider herself safe from smallpox, and should carefully avoid all risk of contagion.

Notes.—154 out of every 10,000 convicts are constantly in hospitals.—On an average, 1,700,000 of the world's population are constantly afloat.—Only 900 people in a million die of old age.—Malaria has been bound in Honduras at an elevation of 4,000 feet, far above the mosquito level, where there is good water, natural drainage, and salubrious climate. The flea, it is said, is responsible for this.—The island of Java, which is 673 miles long and 125 miles wide, only three degrees off the equator, supplies practically all the cinchona bark from which quinine is made. There are about 25,000 acres of this island used in growing cinchona.

Yellow Fever Suppressed.—Surgeon General Sternberg has received a report from Major W. C. Gorgas, chief sanitary officer of Havana, showing a great improvement in the sanitary condition of that city. There has not been a single case of yellow fever in the city during the month of October, usually the severest month for that disease. During the past ten years the average number of deaths during the month of October of yellow fever was 66.27. In October, 1896, there were 240 deaths and 25 in 1899, the lowest previous rate in the past decade. In October, 1900, there were 308 cases and 74 deaths. This year there were no cases and no deaths. This result is undoubtedly due to disinfection on the lines commenced in February by the Military Governor to kill infected mosquitoes. It has only occurred a few times since yellow fever became epidemic in Havana, about a century and a half ago, that an October day has passed without a death from yellow fever. The present condition cannot be due to chance and cannot be entirely due to the general sanitary improvement. The only change from last year is that since February all infected mosquitoes have carefully been killed. In Havana they have worked on the hypothesis that the mosquito is the only way of transmitting the disease. They have not considered fomites in any way. Clothing has not been disinfected nor any effort made except to kill the mosquitoes which had bitten a sick person, and to prevent any more mosquitoes from biting after the case was discovered.

Obituary.—Dr. J. W. F. Best, at South River, Md., November 16.—Dr. Dwight Washington Day, at Eau Claire, Wis., November 19, aged 60 years.—Dr. Thomas J. Barron, at Baltimore, Md., November 20, aged 58 years.—Dr. Louis B. Pacetti, at Baltimore, Md., November 20, aged 53 years.—Dr. James P. Jackson, at Kansas City, Mo., November 22, aged 57 years.—Dr. William J. Wright, at Brooklyn, N. Y., November 20, aged 49 years.—Dr. Philo H. Banks, at New Orleans, La., November 23.—Dr. Howard W. Shaffer, at Ponca, Okla., November 14.—Dr. Fred. J. Oelschlaegel, at Cincinnati, Ohio, November 11, aged 46 years.—Dr. Barton W. Stone, at Louisville, Ky., November 13, aged 57 years.—Dr. George B. Robson, at Staunton, Va., November 25, aged 80 years.

GREAT BRITAIN.

Vaccinated Veal.—It has recently been found in London that calves which had been inoculated for the production of vaccine virus were slaughtered and sold as veal after the lymph had been produced. A careful examination was made of the meat, and when any ailment or disease was found, both meat and lymph were destroyed, but when the calf was healthy the meat was sold for veal. The doctors claim that there is no danger in this, as the inoculation gives the calf merely a surface skin cover, and the animals chosen for inoculation are always the healthiest that can be procured. In fact the calves were in such good condition, that vaccinated veal commanded a high price.

Birthday Honors.—On the King's birthday, knighthood was conferred upon Dr. G. A. Critchett, recently president of the Ophthalmological Society, honorary oculist to the King. Medals and insignia were given Drs. W. R. Henderson, of the Gold Coast, R. Allman, of Southern Nigeria, G. H. D. Gmlette, of Indore, T. H. Hill, H. E. Deane, T. E. Dyson, J. McColgbry, and E. Wilkison, in India.

Isolation Hospital, Devizes.—It was decided November 4 to erect an isolation hospital, at an approximate cost of \$47,000, in Devizes for the use of the joint urban and rural districts.

Hospital Sunday at Bath.—Over \$1000 was collected in Bath on November 3 for the Royal United Hospital. At the last meeting of the Birmingham Hospital Saturday and Sunday Funds it was announced that over \$86,000 had already been collected this year.

Gartnavel Asylum, Edinburgh.—Dr. Oswald, formerly medical superintendent of the Glasgow District Asylum at Gartloch, has been appointed superintendent of the Edinburgh Royal Asylum in the place of Dr. Yellowlees, who recently resigned.

Obituary.—On November 5th, Dr. R. B. McKelvie, a graduate of Glasgow University, died in Oban, aged 65 years—A. H. Smee, a graduate of St. Bartholomew's Hospital, chief medical officer of the Gresham Life Assurance Society, died in London November 8th, aged 57 years—On November 11th, Dr. J. S. Taylor, former health officer in Liverpool, a graduate of Aberdeen University, died, in his 80th year—Sir J. W. Agnew, a graduate of Glasgow University, surgeon of the East India Company, died November 8th, aged 86 years—The death is also announced of Dr. John Connel, a graduate of the University of Edinburgh, in Peebles, Scotland, on November 4—On October 30, Dr. M. Ledwith, of Mullingar, died of pneumonia.

CONTINENTAL EUROPE.

France's Big Reformatory.—One of the most remarkable of the foreign institutions in which the reformation and education of juvenile criminals is combined with punishment, is the Agricultural Colony of Mettray, in the Loire country a few miles from Tours. There, with ten inmates, began in 1839 the great institution which served as model for at least five of its kind in France alone. There are from twenty to twenty-five chalets, a church, schools, farm buildings, stables, dairy, cow sheds, bakery and pretty little houses with small gardens for the staff, a large establishment of from 1200 to 1500 acres, where every kind of agricultural product is cultivated. Every requisite for the colony is grown and manufactured on the premises. In one feature Mettray has no parallel in any institution. This is the Paternal Home, entirely apart from the rest, in which children of well-to-do people, not criminals, but idle, insubordinate boys are brought to their senses. The French law permits the father to send his child to a place of detention for six months. The Paternal Home consists of thirty or forty rooms grouped around a circular gallery. The pupil, who is designated by a number during his sojourn in the house, is not permitted to see any one except the director and his teachers. He never sees any other boy undergoing treatment. The reason for this is the desire that no disgrace be attached to a boy temporarily an inmate, as these boys in many cases rise in after life. On his arrival the boy is taken to his room and the programme laid down for his instruction explained to him. He is then locked in and has time to reflect on the course that he intends to take. Sometimes he remains obdurate for several days; but as a general rule sheer ennui causes him to give in and he asks permission to study and work. Ex-

cellent masters are then provided for him, the choice of subjects being left to his parents. A father can put away an unruly son in this manner in France and have an excellent education forced into him at a cost of about \$30 a month. The institution is primarily to educate and reform children of the poor. The life is one continuous round of study, work, clock-like regularity of habits, and attention to duty. They get up at 4.45 A. M., at 5.15 breakfast; 5.40, work begins; 7.50, lunch; 8.30 to 11.30, work; 11.30 to 1, school; 1 o'clock, dinner; 2 to 7.15, work; 7.30, supper, then prayers and bed. The boys sleep in hammocks, with an overseer constantly in the dormitory. The school is divided into groups called families. The head of the house, who makes a special study of the group of boys under him, is called the *chef de famille*. In addition there is in each family an "elder brother," chosen by the boys themselves for his general good behavior. During the sixty years this institution has been in existence it has reclaimed and made good and successful citizens of thousands of young criminals. Statistics show that only 5 per cent. of those who have passed through the institution ever go back to crime. Before its foundation 75 per cent. of France's juvenile offenders went back to crime after being punished.—*The Humanitarian*.

The Plague in Russia.—Up to November 17th three deaths had occurred in Russia from bubonic plague. One case was reported in St. Petersburg, while two deaths were recently certified in Odessa as due to the bubonic plague. The health authorities took vigorous precautions against the spread of the disease, and no further cases have been reported.

Tuberculosis at Menton, France.—Hotel keepers at Menton are uneasy at the number of tuberculosis patients who flock there, and have decided not to take advanced phthisical subjects, but to send them either to private villas or to the sanatorium at Gorbio.

Contagion on Railways.—A petition calling for legislation, requiring separate coaches for children suffering from whooping cough, is being circulated in Paris. As practically no cure exists except change of climate, much travel with the little sufferers is necessitated. It is hoped that this may lead to general legislation calling for the isolation of coaches for the use of adults suffering from other contagious diseases.

Crematory in Russia.—The first crematory in the Russian empire will soon be built by the Japanese. Permission has been granted to them to construct the institution at Vladivostock.

Continental Notes.—In the churches of Warsaw notices are being posted to prevent spitting on the floor.—A new leprosarium is being established near Moscow. It is estimated that the cost of maintenance of each patient will be about 500 roubles (\$250) a year.—Horses killed for food in France yield on an average 450 pounds of meat each.—The abuse of absinthe in France is said to be responsible for 15,000 crimes or misdemeanors, 16,000 cases of lunacy, 1800 suicides, and 30,000 cases of tuberculosis.—Moscow University is giving special instructions in the application of light in the treatment of nervous, skin and other diseases.—Professor A. Koch, of Heidelberg, suggests that the question of employment for the blind should be solved in accordance with the precedents of Japan, where they are much in demand as experts in massage.—Nearly one-half of the students at Switzerland's six universities last Summer—1990 out of 4046—were foreigners. Of the 748 female students only 98 were Swiss, the vast majority—560—having been Russians.—German surgeons say that the delicate membrane which covers the contents of an egg shell will answer as well as bits of skin from a human being to start the healing of open wounds. This discovery has already been successfully tested.—The City Council of Odessa has decided to give up 5000 roubles, almost \$2500, to the family of a physician in the city employ who succumbs to an infectious disease. Should the physician not have children, the brothers, sisters, or parents of the deceased can only get the interest upon the money.—Dr. Vinogradski, director of the bacteriological laboratory of the Institute of Experimental Medicine, St. Petersburg, has offered to give 5000 roubles annually toward the new laboratory buildings, as long as he remains connected with the institution.

1.—An accurate prognosis of disease is well-nigh impossible, and even an approximate forecast presents great difficulties which are perhaps more prominent in relation to diseases of the nervous system than to diseases affecting other parts of the body. Now, if we have to speak so cautiously about the course of diseases produced by poison, the effects of which have been so carefully studied as those of syphilis, how much more caution is necessary in speaking of the action of poisons whose effects are so little known as those which we assume to be the exciting agents of disseminated sclerosis, of Landry's paralysis, and of many other forms of nervous disease. The mere size of a lesion appears to have but little influence on the progress of disease. It may be accepted as a general law that, other things being equal, lesions of the peripheral nerves are more quickly and completely recovered from than lesions of the central nervous system, and that lesions of the brain, at least as regards the degree to which function is impaired, are less serious than those of the cord. Bury believes that each poison has its own point of attack, and that the earliest change of each disease has its own peculiarities, minute enough, no doubt, and still invisible to our present methods, but which, if visible and thoroughly recognized, would enable us to diagnose the condition and to foretell its probable developments. It is, then, the symptoms that testify to active phases of disease that, for purposes of prognosis, require to be carefully studied. They have a natural history of their own which calls for independent investigation, and which is not as yet adequately explained by morbid anatomy. If the author is right in assuming that a poison is the most common exciting cause of diseases of the nervous system, prognosis will vary with knowledge of the proper treatment for elimination of the poison, and of the effects produced by it. But in most cases we know neither the nature of the poison nor the manner in which it enters the circulation, hence treatment is purely empirical and often fails. In addition to remedies for the elimination of poisons we want others to aid us in counteracting their effects, and here we must hope for fresh discoveries regarding the effects of glandular extracts and the nature of toxins and antitoxins. In this connection, the influence of one disease upon another is worthy of renewed investigation. We have, further, to study the influence of one part of the nervous system upon another part. [J. M. S.]

2.—Of the systemic disease in which **throat and nose complications** occur and which may require **local treatment**, tuberculosis, syphilis and affections of the central nervous system are the most important. Lesions of the nose and throat may develop in the course of leprosy, diabetes, general anemia, chlorosis, Bright's disease, typhoid and other acute fevers, influenza, gout, rheumatism, urticaria, pemphigus, actinomycosis and smallpox. But the throat and nose complications in many of the affections just named are rare, and some require no local treatment whatever, except an occasional palliative; while in other instances they must be treated exactly as if the affections were purely local. Laryngeal tuberculosis, however, should receive intelligent and energetic local treatment. [J. M. S.]

3.—Clarke reports the case of a man, aged 19 years, who

complained of a sensation of heat or burning in one upper extremity; a marked intentional tremor in the same limb, absent during rest, and exactly resembling, during movement, the tremor of disseminate sclerosis; hemiplegia of the opposite side of gradual onset, affecting the upper extremity only for a considerable time and predominating in this limb throughout. A diagnosis of tumor of the thalamus was made. Cases of this kind also, although not invariably, present loss of the emotional movements of the face, whilst the voluntary are preserved. At the necropsy, a tumor was found occupying the right thalamus, and extending downward and backward into the subthalamic region, where it invaded the opposite side and pressed on the right internal capsule and crura cerebri. [J. M. S.]

4.—Potter reports a case of enteric fever commencing with and complicated by an attack of influenza. [J. M. S.]

5.—Sympson reports a case of recurrence of laryngeal papillomata in a child after tracheotomy. [J. M. S.]

1.—See Abstract of *British Medical Journal* in this issue of the *Philadelphia Medical Journal*.

2.—Buckworth delivered an address before the Liverpool Medical Institution on October 24th, 1901, on the **personal factor in tuberculosis**. The author maintains that the personal factor of the disease is often overlooked and that "if we treat the disease and not the person, we may be scientists but certainly not physicians." The author holds the view that the scrofulous habit or strumous diathesis is a condition of the body susceptible to tuberculous infection. He differs from Osler whom he quotes: "Scrofula is tubercle, as it has been shown that the bacillus of Koch is the essential element." He fully agrees with Mr. K. W. Treves of Margate, who sustains the view that "scrofula is synonymous with tuberculosis in some form or other." Treves believes that there is a class of individuals who are especially liable to tuberculous disease, in whom it is difficult to stop and especially prone to recur. They are inclined to stoutness, with thick coarse skin, much cellular tissue, of purplish or dusky complexion, and have a poor circulation. Treves does not believe that such persons can be called scrofulous before they manifest tuberculous disease and therefore these individuals possess a scrofulous or strumous habit of body as yet untainted by infection with the bacillus of Koch. The author states that pathologists lose sight of their host. With regard to the development of tuberculosis two factors are essentially concerned, (a) the parasite, (b) the nature or condition of the health of the individual through inheritance or acquirement, or as a result of various debilitating conditions. There is a class of persons who are delicate and frail, and endowed with the specific proclivity to become affected by various irritants and especially prone to tuberculous infection. Some of these individuals may be pronounced scrofulous before the invasion of tubercle bacilli. [F. J. K.]

3.—Ogston discusses the freezing point of the blood and secretions as an aid to diagnosis. The freezing point of normal blood is 0.56° C. below that of distilled water and

does not vary more than one-hundredth of a degree up or down. The freezing point of urine varies from -1°C . to -2°C . in proportion to the solid which it contains in a state of solution. He quotes the conclusions of Kümmell and other observers who state that the normal freezing point of the blood varies within one one-hundredth of a degree or less: If elimination becomes defective, the freezing point decreases markedly. Kümmell has observed the freezing point at 0.7° to -1°C . He believes that the value of cryoscopy promises to furnish definite and satisfactory evidence in regard to renal disease in a patient requiring operation to determine how much disease exists; whether enough healthy kidney substance be sufficient to purify the blood; and whether the lessened kidney elimination which follows operations especially when performed under an anesthetic, superadded to the existing kidney defect is likely to endanger the life of the patient; and finally where the kidney itself is to be operated on, whether the other organ be healthy enough to take over the eliminative work of the two kidneys. Beckmann's apparatus for the determination of the freezing point of the blood is described and an illustration of this apparatus is included in the article. It consists of a jar into which dips a large test-tube surrounded by ice and salt. In the mouth of the test-tube is inserted a perforated cork and a smaller test-tube about an inch in diameter. In the inner tube is placed the fluid to be frozen. The thermometer employed is Beckmann's thermometer which has a scale possessing a range of 6°C ; each degree is divided into one-hundredths. The author states that "the freezing mixture cools the fluid and the mercury first goes down to, and then descends a couple of degrees or so below, the freezing point. At the moment at which congelation begins, the mercury rises again quickly and within a few minutes attains a steady maximum which is the true freezing point. During this observation the fluid is kept constantly stirred by a ring-shaped platinum stirrer that passes down between the inner tube and the thermometer." The calculation of temperatures below zero is made by subtracting from it, for instance, the zero were 4.01° , then the normal freezing point of the blood is 3.45° , that is 0.56° lower. The author reports 12 cases illustrating the value of cryoscopy of the blood. He further mentions that possible and unusual purity of the blood may exist, giving higher freezing points than normal. [F. J. K.]

4.—Allbutt read a paper before the British Congress on Tuberculosis on the sanatorium in the treatment of tuberculosis. He remarks that not only is the modern sanatorium method curing the individual but it is the chief method of prevention. He does not view with favor home treatment of a phthisical patient by a physician unversed in the sanatorium method, or by a patient who has not had at least a month's treatment in a sanatorium. The most suitable climatic condition for the patient he defines as follows: "For the most general terms in which climatic conditions can be put is that the coldest air which the individual can tolerate, if it be dry, clear, and still, is the best, as it calls for more food and thus stimulates the appetite." Allbutt considers it highly important to have a laboratory connected with the sanatorium. A fixed term of residence in the sanatorium for each individual case cannot be given; some maintain that a stay of three months is sufficient but Allbutt thinks that a mean term of this duration is too short. He also outlines the dietetic and medicinal treatment. Educational pursuits should not be neglected at the expense of the medical drill; patients should have their minds occupied. [F. J. K.]

5.—Box and Wallace contribute an article on acute dilatation of the stomach with an account of two cases. The first case occurred in a male, 29 years of age. This patient developed acute gastric and duodenal dilatation after amputation of the thigh; the disease terminated fatal. A post-mortem examination revealed the condition. The second case occurred in a man, 24 years of age, during the course of pleuro-pneumonia. At autopsy dilatation of the stomach and duodenum was found. These authors point out "that in producing the train of symptoms met with in acute dilatation of the stomach two factors came into play. There is

first a paralytic condition of the viscus which leads to distension, and then, at a certain stage of the distended stomach, actually produces obstruction by pressing on the duodenum on the front and to the left of the spinal column." They emphasize that early recognition is of no little importance, as the condition does not yield to treatment when advanced. Repeated physical examinations of the abdomen, with an attempt to elicit the succussion splash, are of great importance in arriving at a diagnosis. Strychnine injections, stomach lavage, rectal feeding, and intravenous or rectal injection of saline solution, are the measures which are advocated in the treatment. They do not recommend the postural method of treatment and should surgical interference be determined upon, gastro-jejunostomy would appear to be the ideal procedure. [F. J. K.]

6.—Charles Bell Taylor gives some brief notes regarding seven exceptional cases of cataract extraction. The first case was that of a man with congenital cataract which however differed from the ordinary variety in that the opacity affected the lense throughout. The patient had been blind for 35 years in the right eye, and the left was little better. The vitreous was fluid in both eyes, the iris was tremulous and whenever the head was moved the lense would also participate in the commotion. Other surgeons had strongly advised against an operation, but the author succeeded in extracting the lense in both eyes with the result that the patient now possesses excellent visual acuity. The moment the corneal section was completed, the eyeball collapsed, the vitreous exuded and the lense sank to the bottom of the chamber. The lense was extracted with a wire spoon, which the author considers as an invaluable instrument on account of its mechanical assistance without adding to the bulk of the lense that is to be extracted. The second case had also been considered hopeless and was certainly an unpromising one. The patient, who was 42 years of age, had been struck in the right eye by a piece of steel 15 years ago, and had a similar accident a year ago in the left eye. The author operated four times extracting the lense in each eye and producing an artificial pupil in both eyes, with the result that accurate vision both for distance and for close work was obtained. The third case resembled somewhat the first one except that iris forceps were brought to the assistance of the extraction of the lenticular mass and capsule. A perfectly black pupil resulted with useful vision. The fourth case illustrates the usefulness of the author's bent knife, by means of which the left eye may be operated upon with the left hand with even greater facility than on the right eye. The fifth case illustrates a successful operation upon an eye previously considered hopeless. The sixth case resembled somewhat the third case as far as the operation was concerned, except that the operation was followed by an attack of acute glaucoma which was arrested at once by a sclerotomy and puncture of the hyaloid fossa with a result that excellent vision was obtained both for reading and for distance. The seventh case was that of a man, 86 years of age, upon whom the author had performed a successful cataract extraction without iridectomy upon the right eye. When the patient reached the age of 96, the author operated upon the right eye with excellent results, the patient now being 101 years of age with excellent sight both for reading and for distance. [M. R. D.]

7.—Yonge believes treatment of ozena by cupric electrolysis may be looked upon as the best remedy that has yet been found. While this treatment does not restore the sense of smell or repair the shrunken turbinates, it will however, in a certain percentage of cases, so reduce or even banish the tendency to crust-formation as to give the patients a state of wholesome comfort. He gives a report of 15 cases treated by this method which consists of first cleansing the nasal cavities with a mild antiseptic wash, then cocaineizing and in a few minutes the copper needle attached to the positive pole is introduced into the middle or inferior turbinate, and the steel needle into the septum. For about ten minutes a current of from 10 to 20 milliamperes was employed. The number of applications used depended on the improvement manifested; as many as five were em-

ployed. Two cases were cured, five were much improved, six were temporarily improved and two did not improve.

[F. J. K.]

MEDICAL RECORD.

November 23, 1901.

1. Is Itabes a Specific Disease? D. E. SALMON.
2. Some Facts Learned in the Management of Typhoid Fever in Central West Virginia. W. W. GOLDEN.
3. Rupture of the Urethra. A Report of Cases. JAMES R. HAYDEN.
4. Operation for Caries of the Mastoid, Secondary Opening of the Lateral Sinus, and Ligation of the Internal Jugular Vein. JULIUS ROSENSTIRN.
5. The Value of the Widal Reaction in the Diagnosis of Typhoid Fever in Children. MILTON GERSHEL.

1.—D. E. Salmon contributes an article with the title, "Is Itabes a Specific Disease?" A reply to the article on "Hydrophobia and the Pasteur Methods," by Charles Winslow Dulles, which appeared in the *Medical Record*, July 13, 1901.

[T. L. C.]

2.—W. W. Golden discusses the management of typhoid fever in West Virginia. He states that fully one-fourth of the medical practice in Central West Virginia consists of attendance upon cases of typhoid fever. Within the last few years, however, a very noticeable abatement in the disease has taken place. This he ascribes to the measures of sanitation and prevention which have been adopted. In his series of cases constipation has more often been observed than diarrhea. The eruption is only seen occasionally. An unduly high temperature at the beginning is frequently seen, but is mostly due to the heavy diet indulged in by the patient with the hope of overdoing his growing weakness before the physician is consulted. This author regards diet as of prime importance in treatment, and he believes that cows' milk is the safest article of food, preferring this to any of the various substitutes. He thinks that the majority of cases of typhoid is over-fed. In a case of a patient with a fair degree of energy and flesh in reserve, a dry mouth and a high temperature indicate a minimum of food. Such cases will do better when the quantity of milk does not exceed one pint in twenty-four hours, if a larger quantity of water be given along with alcohol in doses so small as to produce no perceptible stimulation, but frequently administered. He remarks that tympanites is practically an unnecessary symptom if a correct diet is followed, and recommends the daily use of enema of saponified water, holding in emulsion 1 drachm of oil of turpentine. [T. L. C.]

3.—James R. Hayden reports three cases of rupture of the urethra. His conclusions upon the treatment of this condition are of interest. There is a choice between the operative and non-operative treatment, depending upon the nature and extent of the injury. If there is a severe hemorrhage from the meatus with a complete retention of urine, or difficult and painful urination and bloody urine, associated with difficulty or inability to enter the bladder with instruments, together with the presence of a fluctuating perineal tumor, with a rise of temperature, then immediate perineal section and bladder drainage are indicated. If, on the contrary, there is slight hemorrhage and urination is free, but somewhat painful, the urine tinged with blood, or containing light bloody flakes, and catheterization can be performed normally and there is no perineal fluctuation, then catheterization, irrigation, and urinary antiseptics should be resorted to, the patient being kept in bed, and carefully watched for the first sign of extravasation. In the event of which external urethrotomy with vesical drainage should be immediately resorted to. Partial suture of the urethra, but not complete suture must always be employed in case of complete rupture, in which the divided ends of the canal are widely separated; otherwise it is not essential. [T. L. C.]

4.—Julius Rosenstirn reports a case of mastoid disease

with infectious thrombosis of the lateral sinus and extension of the process into the jugular vein. An operation was performed in which a secondary opening was made in the lateral sinus, and ligation of the internal jugular vein resorted to. The patient recovered. During the operation unusual hemorrhage was encountered, due to a very large intraosseous vein filled to its utmost on account of the sinus thrombosis. The patient was a boy of 15 years. No bacteriological examination was made in the case. A brief résumé of the literature of the condition is given. [T. L. C.]

5.—Milton Gershel has studied the Widal reaction in the diagnosis of typhoid fever in children. He concludes that the main facts concerning the Widal reaction in children are the same as those that hold true for adults. In 84 cases of typhoid fever in children, ranging from one and a half to fourteen years of age, eighty-one cases gave a positive result. In 115 cases that were fevers other than typhoid, the positive reaction was never obtained. The reaction did not occur later in children than in adults, but on the contrary, somewhat earlier. However, he would not lay too much stress on this point. The Widal test is of greater importance in children than in adults, owing to the frequent atypical character of the diseases in the former, and the greater frequency of cases resembling pneumonia and meningitis. He believes that the routine performance of the Widal reaction, as pointed out by Morse, will aid us in establishing the frequency of typhoid fever in children.

MEDICAL NEWS.

November 23, 1901. (Vol. LXXIX, No. 21).

1. Traumatic Stricture of the Esophagus. F. E. BUNTS.
2. "What is the Use of Making a Diagnosis in Nervous Diseases, Since Nothing Can be Done Anyway!" THEODORE DILLER.
3. A Preliminary Note on the Sterilization of Catheters: A Bacteriological Study. C. B. NANCREDE and W. H. HUTCHINGS.
4. Hygiene and Hygienic Legislation. W. SCHEPPEGRELL.
5. On Primary Sarcoma of the Liver: Critical Observation and Contribution of Two New Cases. BINDO DE VECCHI and GUIDO GUERRINI.
6. Note Upon a Case of Pretended Expectoration by Myriapods. ALLEN J. SMITH and R. R. CURTIS.

1.—F. E. Bunts reported eight cases with stricture of the esophagus in which the opening was so small that the esophageal bougies could not be passed. He used and advises for such cases a graded double-bulbed olive shaped bougie. Two bulbs are placed on each staff, the first being one size of the French scale smaller than the second bulb. This served to permit one to follow up the advantage gained by passing one bulb by the immediate passage of one a size larger. The frequency varies in the passage of the bougie in all cases; in some cases it can be passed daily, while in others two or three days will elapse before another attempt is made. Force should never be used, and it is better, if not successful, to wait a day or two before trying again. In children it is necessary to use a gag. The patient should sit upright, the head thrown back somewhat, in order to straighten the line of introduction of the bougie. It is better to pass it into the pyriform sinus at the side of the larynx, which affords a funnel-like aperture that will allow the bougie to slide into the esophagus without encountering the bodies of the cervical vertebrae or the cricoid cartilage. The author believes that the use of this instrument will in a great many cases render the necessity of gastrostomy and retrograde dilatation unnecessary, even in some of the most serious cases.

[T. M. T.]

2.—T. Diller gives the following reasons why a diagnosis of nervous diseases should be made as soon as possible, although in very many instances nothing can be done: (1) physically; (2) mentally; (3) socially; (4) financially. In the first division can be classed those cases in which an early diagnosis will arrest or alleviate the disease. In

the second class the effect on the chronic invalid is of import, when he sees the physician hopefully fighting the disease with all possible means; he is comforted as can be done in no other way. It is often important to know just what the benefit would be if the patient were allowed to mingle with other persons. This cannot be decided until a positive diagnosis is made. The most important of them all is financially, as it has often happened when a patient is only in moderate circumstances that the family use all his money to send him away when he would be just as well at home. [T. M. T.]

3.—C. B. Nancrede and W. H. Hutchling report sixty-five experiments in which different sterilizing agents were used in sterilizing catheters: (1) It was found that soft rubber catheters could not be completely sterilized by boiling under four and one-half minutes; (2) mechanical cleansing will render sterilization easier and will take a shorter time to be effective; (3) boiling elastic and soft rubber catheters five or more minutes will roughen or diminish their elasticity or strength; (4) immersing for five minutes in bichloride solution does not sterilize any catheter which is infected, at best only inhibiting the growth of the germs, as it was found by experiment that, if the mercuric salt be precipitated by ammonium sulphate, the germ will grow freely when implanted in culture media; (5) chemical sterilization should never be used for catheters which are to be retained in the bladder for any length of time, unless subject to a very prolonged action of the mercurial salt; a mere washing with a chemical solution is not sufficient for an infected instrument; (6) formalin vapor will sterilize infected instruments in twenty-four hours; (7) all methods of sterilization commonly employed should be continued for much longer periods than the minimum time required for destruction of germs in a laboratory; (8) English web catheters can be more readily sterilized by heat than can soft rubber ones, probably on account of their interior construction. [T. M. T.]

4.—W. Scheppegegrell gives two reasons why the laity do not exert themselves in demanding stringent legislation for the control of the spitting habit: (1) because they believe that tuberculosis is due entirely to inheritance, not realizing that inheritance in these cases may mean simply a susceptibility, and that infection is the main cause of one member after another of a family being afflicted by the disease when once it has developed in a household; (2) that the incubation of tuberculous disease is so long that the connection between cause and effect is difficult and sometimes impossible to trace. He also gives the ordinance which is in force at New Orleans at the present time: (1) Hereafter it shall be unlawful for any person to spit on the floor of public halls, theatres and other places of amusement, and on the sidewalks; (2) Any person convicted of this offence shall be fined a sum not exceeding five dollars or imprisoned in the Parish Prison for a term not exceeding ten days or both in the discretion of the Recorder. [T. M. T.]

5.—B. de Vecchi and G. Guerrini report two cases of **primary sarcoma** and after closely examining forty-five reported cases find that the majority of them are not primary sarcomas of the liver. They also give various authors' opinions of the origin and development of the disease: (1) Arnold considers two possibilities, viz: proliferation from the connective tissue of the vessels or of the acini; (2) Delépine admits a proliferation of the cellular elements of the vessels by the irritating action of the substances elaborated by the metabolic activity of the hepatic cells; (3) Byrom regards the tumors as starting from the perilymphatic connective tissue; (4) Kahlden looks upon the tissues around the vessels as the origin; (5) Cesar Demel believes that the growth begins in the normal connective tissue of the liver; (6) the authors give another opinion and consider the neoplastic tendency to be attributed to a preceding cirrhosis. [T. M. T.]

NEW YORK MEDICAL JOURNAL.

November 23, 1901. (Vol. LXXIX, No. 21).

1. On the Advantage of a Trace of Albumin and a Few Tube Casts in the Urine of Certain Men above Fifty Years of Age. WILLIAM OSLER.
2. Modifications in the Methods of Operative Surgery resulting from Laboratory Research. JOSEPH D. BRYANT.
3. Vesical Emergencies; Their Surgical Management. EUGENE FULLER.
4. Leucoplakia. JOHN V. SHOEMAKER.
5. Pelvic Inflammation in the Female; Its Diagnosis and Management by the General Practitioner. ABRAM BROTHERS.
6. Cyst of the Appendix Vermiformis. W. C. WOOD.

1.—William Osler emphasizes the importance of basing one's judgment less on the urine than on the general condition of the patient after the age of fifty. It is quite a frequent occurrence to find albumin and casts, but this is not always a serious condition. He states that it is probably due to the expression of presenile changes in the kidneys, the result of arterial degeneration and is often a renal inadequacy. The points one should lay stress on as indicative of serious diseases are: (1) Persistent low specific gravity of the urine, 1.008 to 1.012; (2) the state of the heart and arteries; (3) the presence of albuminuric retinitis. It is not always easy to make a diagnosis, and two conditions have to be carefully differentiated: (a) A primary sclerosis, discovered at the fortieth year in which the kidney changes are secondary, and are expressed by a transitory albuminuria and a not very low specific gravity of the urine which is not in very large amount; (b) the granular contracted kidney. Here arteriological factors are all important. It is met in young persons consecutive to scarlet fever and other infectious disorders, also in middle-aged persons who have had gout, in workers in lead; while in others in whom no definite factors can be determined. Cardiovascular changes are very much the same as in the first division. Uremic symptoms are more frequent, as is persistent headache. Renal changes are very much more common. [T. M. T.]

3.—E. Fuller states that vesical retention can be subdivided surgically into two general classes: (1) Those amenable to catheterization and (2) those that are not. In the first class one of the most important points is gentleness in instrumental manipulation. Much damage can be done with a sharp and rigid instrument, and the author advises the gum-elastic silk woven catheter with bulb or olivary pointed end. In the second class the only thing to do is to liberate the retained fluid. The two routes are either the perineal or the suprapubic, the former being the most frequent. When prostatic retention occurs in cases not amenable to catheterization, the rule should be immediately to perform prostatectomy. [T. M. T.]

4.—J. V. Shoemaker gives the symptoms of leukoplakia as follows: It begins upon the tongue or inner surface of the lips, or cheeks, in the form of a red circumscribed hyperemic spot, or spots. Around the spots or on the surface some of the papillae may be swollen. This is the erythematous stage. After an uncertain duration of weeks or months, its aspect changes. The redness is succeeded by a pearly white, bluish or gray color. The epithellum at this time becomes thick. These spots at length become confluent and form a single lesion, which at first remains red at its periphery. In shape the patches are round, oval or oblong. Shallow, transverse or longitudinal grooves divide the surface into a series of polygonal patches. In certain cases the disease assumes the form of a bend, from half to three-quarters of an inch in breadth, sometimes rough and slightly elevated; at other times smooth, and upon the mucous membrane of the cheek. There is flaky desquamation due to successive reproduction of epithellum (very diagnostic). The surface of the patches gradually becomes cornified, hard, rough, and the constant movements of the tongue may produce fissures, especially on the borders. In the

later course of the disease papillomatous growths may develop from the affected locality, and finally it is very apt to degenerate into epithelioma. An existence of twenty years is not uncommon. If the tongue is involved, its movements are clumsy and speech is embarrassed. Its venous circulation becomes obstructed, especially at the lower surface and lower border. [T. M. T.]

THE BOSTON MEDICAL AND SURGICAL JOURNAL.

November 21, 1901.

1. An Investigation of the Boston Ice Supply. HUBBERT WINSLOW HILL.
2. Lesions of the Bladder During Abdominal and Vaginal Hysterectomy. CHARLES GREENE CUSTOMS.
3. Suggestions for the Improvement of Training Schools for Nurses. RICHARD C. CABOT.
4. Some Deductions Concerning Mild Modification. R. C. MACDONALD.

1.—On theoretical grounds the danger of infection through ice is very small. Practically, and under the conditions of the present Boston supply, danger of infection through natural or artificial ice is almost nil. Careful search of the records has shown that but one presumably authentic case of transmission of typhoid fever through ice is on record. Snow ice contains a fairly large number of bacteria. Bubbly and clear ice contain a much smaller number. Artificial ice contains, especially in the center and bottom of the cake, about as many as the average in natural ice. The outside of the cake is likely to contain very few. The bacteria present are, except in the extremely rare cases where typhoid bacilli may exist, practically harmless. "Dirt" is found in both natural and artificial ice, usually more abundant and in coarser particles in the former, finely divided in the latter. Artificial ice made from exhaust steam shows at times a slight oily scum after melting. [J. M. S.]

2.—Wounds of the bladder during abdominal or vaginal hysterectomy are not of frequent occurrence. Out of some 300 abdominal sections for gynecological affections Cumston wounded the bladder but once, and he had only one case out of 74 cases of vaginal hysterectomy. If the bladder has been wounded, the wound should be immediately sutured. When permanent drainage of the bladder is employed in the female, it is better to change the catheter every 4 or 5 hours and to insert a new one each time. If a permanent catheter is used, the Pezzer instrument is by far the best. Infection of the bladder, following the use of a permanent catheter, may be avoided if the latter be put in connection with a sterilized rubber tubing, which extends under the bed and dips into a glass receptacle which is plugged with absorbent cotton. After suture of the bladder following suprapubic cystotomy, from 5 to 6 days is usually enough to continue drainage. If the sound should be left without removal for a week or 10 days, it is well to use intravesical injections with a 1:2000 solution of either lactic or phosphoric acid every other day, this will prevent a deposit of urinary salts on the outside or in the lumen of the catheter. The urethritis that follows the use of the permanent catheter in the female will cease spontaneously after the instrument has been removed. If the bladder is opened during vaginal hysterectomy, the best treatment is permanent drainage of the bladder. [J. M. S.]

4.—Any modification of milk which reduces the total casein must reduce still further an already greatly deficient lactalbumin. No modification of milk, as now given, can change the inorganic to organic combinations of phosphorus. MacDonal suggests that both of these deficiencies may be somewhat overcome by a judicious use of whole egg. Egg albumin approximates quite closely to lactalbumin, and in the egg yolk we have a veritable storehouse of organic phosphorus compounds. [J. M. S.]

6.—Moyer discusses the psychoses of chorea. He states that the occurrence of well-marked psychoses in the progress of Sydenham chorea (excluding chorea of advanced life) is exceptional. He reports a case which occurred in a fairly well developed girl, 15 years of age, who, so far as could be gathered from the study of the family history, did not show neurotic heredity. Choreic movements involving the upper extremities and later becoming general, developed in the spring of 1900. After the illness had existed for about three weeks, she became acutely maniacal, restless, sleepless, and constantly dancing about, and knocking against furniture and other objects. Nutrition rapidly failed and the skin became bruised in many places. Under treatment she made a complete recovery from chorea, and with it the mental symptoms disappeared. The condition recurred in the spring of 1901. The author reports a number of cases collected from literature. From the present state of knowledge on the subject, the author advances the following conclusions: "1. A well-marked alteration of the character and mentality can be noted in the majority of cases of chorea, usually preceding by some weeks the onset of the choreic movements. 2. Distinct hallucinatory phenomena are present in a considerable number of cases, which are not, however, of sufficient severity to merit being classed as a distinct psychosis. 3. The mental disturbance in chorea usually comes on after choreic movements, but it may precede them. 4. The type is usually maniacal, though it may occasionally be melancholic or present the character of an acute delirium. 5. Mental disturbances are commoner in older children; they are rarely observed before the twelfth year. 6. Chorea which are accompanied by mental disturbance later in life, are almost always accompanied by organic changes in the central nervous system. 7. The prognosis is favorable when the mental disease complicates the simple, acute chorea of Sydenham. Insanity associated with chorea in the middle and advanced life is almost invariably associated with organic diseases of the central nervous system." [F. J. K.]

8.—Byrne gives an account of school medical inspection in Chicago. In that city a corps of 50 medical inspectors is employed. This work was begun on January 8, 1900, and from that date to April 12, 1901, these medical inspectors examined 76,805 pupils. Of these 4,539 were found suffering from contagious diseases and excluded from school. During the time while school inspection has been in progress there was no marked decrease in the number

of diphtheria cases and a very decided decrease in the number of scarlet fever cases, with a lowering of the mortality of each disease. The school inspectors of Chicago do not make daily visits, but are required to respond to special calls from school principals when in their opinion local conditions demand attention. [F. J. K.]

7. Epidemic Meningitis—The History of an Outbreak. JAMES McKENTY.

1.—John Guiteras contributes an article on experimental yellow fever at the inoculation station of the Sanitary Department of Havana. This authority states that the experiments were undertaken with the hopeful view that the results of the cases would be favorable on the following grounds: (1) The series of mild cases obtained by the Commission (referring to the United States Army Commission in their experiments with yellow fever; the continued series of mild cases resulting from these experiments without a death); (2) the control over the number of bites; that is, the subject would be bitten but once by infected mosquitoes, whereas in an infected house the subject accidentally infected would be exposed to successive bites; (3) the patient would be cared for during the period of incubation, and immediately upon the invasion of the disease; and, finally, the patient would be treated from the beginning in a mosquito-proof house, where he would be a source of danger to no one. The immune station was opened in February, 1901, when a large number of larvae of the *Aegomys laevis* (the *culex* of Finlay) was secured, and breeding jars were started in order to have a constant supply of young insects. Guiteras takes up the manner in which the mosquitoes were propagated and infected. He furnishes in tabular form the series of trials in experimental infection made in the station. Of the 42 cases included in this table, in but 8 was experimental yellow fever successfully produced. This may be partly explained on the ground that the insect to become infected must bite the patient having yellow fever on the first, second, or third day of the disease. A mosquito so infected cannot carry the disease until a period of more than 12 days has passed since the insect became infected. However, these facts were well borne in mind in the experiments, and Guiteras believes that there was a possibility of a mistake in diagnosis in the original cases from which the mosquitoes were supposed to be infected. He also suggests that the failure may be due to variations in the number of parasites found in the peripheral circulation of the infecting patient. Charts of 10 of the experimental cases are furnished, which supplies us with the history of the initial rise of the temperature of the disease. Of 24 cases with experimentally produced disease which he has collected, there were three deaths, a percentage of 12.5. He concludes with Dr. Gorgas, therefore, that "when a nonimmune is going to be exposed to yellow fever, it is better to be inoculated, and have the disease under circumstances where he can be put to bed early and be treated from the beginning, than to take it accidentally." He makes the recommendation that not more than one mosquito should be employed for more than one inoculation, and that when a group of mosquitoes infected from one case

should show a very decided virulence, their use should be abandoned. [T. L. G.]

2.—W. L. Rodman reports a case of perforating typhoid ulcer in a child of 12 years in whom laparotomy was performed. Recovery followed. The case was an unusually severe one, and the pulse and temperature were high from the onset. Gastrointestinal irritation was marked and vomiting and diarrhea were present early. The patient was admitted to the hospital June 18th, and the operation was performed on July 19th. [T. L. C.]

3.—William J. Gies presents a paper on a new constituent of bone, in which the chemistry of bone is discussed, and a statement made that the author has recently shown the presence of mucoid in bone, thus establishing a closer chemical relationship between mature bone and cartilage than has been supposed to exist, and demonstrating, further, that, as far as mucoid contents is concerned, osseous tissue is not an exception among connective tissues, as previously it seemed to be. To this substance he has given the name of *osseomucoid*, and he presents the method by which its presence in bone is determined. [T. L. C.]

4.—Scott remarks that in operation for ovarian disease hematomas are frequently found. A few of these, usually involving the entire ovary, depend upon the twisting of the pedicle of the ovarian tumor, but more frequently the hematoma is confined to one of the cysts, being located in a sessile tumor. Local disease of the arteries and general constitutional disease will account for some of these cases, but for the majority there is no satisfactory explanation. Scott advances the hypothesis that at least part of the hematomas are due to an ovarian impregnation with early death of the fetus. It is now proved that rarely an ovarian pregnancy will occur, one authentic case being that of van Tussenbroek, of Amsterdam, reported last year. Granted then that there is such a thing as ovarian pregnancy, Scott inquires why is its proven existence so rare? He believes that in many cases of ovarian conception the Graafian follicle is located superficially in the ovary immediately under the ampulla of the tube and eventually emerges into a tubo-ovarian pregnancy. He gives the report of a case examined by Professor Welch of Johns Hopkins Hospital, and concludes as follows: Hematomas of the ovary are comparatively common and we have no explanation of their occurrence. Ovarian pregnancy is a proven possibility. Continued development of the ovum in ovarian pregnancy causes changes in the organs and tissues such as to render the demonstration of its ovarian origin impossible. The most natural consequence of the early death of the ovum in ovarian pregnancy is its gradual transformation into an ovarian cystic tumor; added to this, retrograded changes obscure its origin, and a hematoma is the final result.

[W. A. N. D.]

5.—Francis P. Morgan furnishes a paper containing suggestions upon the use of the metric system and prescription writing. The author shows the advantages of the metric system, and makes a plea for its universal adoption. He presents a formula which is to be memorized, and he believes that it contains all the information necessary for the conversion of one system into the terms of the other: 1/60 gr. = 0.001 one milligram. 1/6 gr. = 0.01 one centigram. 1 gr. = 0.06 six centigrams. 15 grs. = 1.00 one gram. 1 dr. = 4.00 gr. 1 oz. = 32.00 gr. [T. L. C.]

6.—Theodore Tieken reports a case of annular pancreas which caused constriction of the duodenum with sacculization of the intestine above the narrowed portion, dilatation and hypertrophy of the pylorus and hypertrophy of the wall of the stomach. The author states that the chief points of difference between this case and those previously reported are: (1) The more extensive dilatation of the duodenum above the restriction; (2) the greater narrowing of the lumen of the bowel; (3) the more extensive development of the annular portion of the gland; (4) the absence of dilatation of the stomach, and (5) the greater hypertrophy and dilatation of the pylorus. He states the following genesis of annular pancreas; if the ventral and dorsal diverticuli

lums did not unite as they normally do, but each developed independently, there would be pancreatic tissue on either side of the intestine, and as growth proceeded, the bowel would soon be completely surrounded by glandular tissue. In the semiannular type the condition might be due to an overdevelopment of the head, which sends out processes, partially surrounding the bowel. [T. L. C.]

7.—James McKenty gives the history of an outbreak of epidemic meningitis occurring in the winter and spring of 1893 and in 1894-5-6 in North Dakota. The brief reports of 8 cases are appended. In only one case was the petechial eruption marked. In two cases the pain over the spine was markedly worse on pressure, especially over the lower cervical vertebrae. In the beginning of the epidemic in 1893, the majority of the victims were adults. During the recurrences of 1894-95, children were more frequently attacked. In his series of cases there was but one evidence of personal contagion, but he states that the house was probably infected from the time of a previous case six months before. He agrees with Osler who states: "That the disease does not seem to be directly contagious, and is probably not transmitted by clothing or excretions." Pneumonia was not often associated and when it did occur was never so extensive as to add to the gravity of the case. Many children seemed to suffer from what seemed to be a combination of the two cases during 1895-96. Joint complications did not occur in any case. Permanent mental impairment occurred in one case. [T. L. C.]

1. On Combined Bromethyl-Chloroform Anesthesia. I. F. ZEMATSKI.
2. Should the Medicinal Application of Hypnotism be Restricted? P. LA. ROSENBACH.
3. The System of Rendering First Aid in Berlin. I. E. GAGEN-TORN.
4. The Medical Report of the St. Petersburg City Maternity Hospitals, for 1900. E. L. PUSHKINA.

1.—Zematski has used a combination of bromethyl and chloroform in producing anesthesia in 2000 cases and has seen it employed in 1000 more. This extensive personal experience leads him to the conclusion that this method of anesthetization is far superior to any other and merits a more general application. The superior merits of bromethyl-chloroform over pure chloroform are set forth in the following table:

Pure chloroform anesthesia.

1. First stage prolonged: minimum 8, maximum 20, average 12 minutes.

2. A prolonged oppressive sensation of gradual constriction (prolonged period of nightmare.)

3. There is always a period of excitement, occasionally amounting to a violent delirium.

4. Anesthesia progresses in the following order: (a) first a dulling of perception (the patient talks excessively, is delirious); then (b) a lowering of sensibility

Bromethyl-chloroform anesthesia.

1. First stage very brief, 45-55 seconds; in rare cases 20 seconds; maximum, also in rare cases, 2 minutes.

2. Anesthetization takes place so rapidly that the patient has no time to realize the subjective sensations. Complete absence of prolonged nightmare.

3. With proper administration excitement is absent. If present, it is either because the patient is an alcoholic or too much anesthetic has been used.

4. Anesthesia progresses in the following order: (a) first, there is a loss of sensibility to pain (analgesia); (b) loss of sensibility to touch (anesthesia), and

ly to touch (anesthesia), and only the last manifestation is that of (c) analgesia.

only as the last manifestation; (c) psychical anesthesia or general insensibility.

The method employed by the author is very simple and readily acquired. On an Eschmarch mask 8, 10, 12 or 16 drops of bromethyl, according to age, sex and condition of the patient, are dropped. The inhaler is held at first at a distance from the face. In proportion to the temperature of the room; the higher the temperature the greater the distance. After two or three whiffs, the inhaler is placed closer to the face and at the expiration of 10 seconds 20 to 30 drops of bromethyl added. Generally, from 2 to 5, rarely 10, grms. of bromethyl are used. After 1 minute, chloroform is substituted for the bromethyl. By this time the patient is already in a state of narcosis, and the effect of the chloroform is much more rapid and less likely to produce excitement. During the bromethyl anesthesia, the pupils are slightly dilated and the corneal reflex remains present for a considerable time; when chloroform is added the pupils become contracted. Contraindications to the use of bromethyl-chloroform are: (1) Atheromatous condition of the blood vessels and (2) alcoholism. In the latter the anesthetization should be preceded by an injection of morphine. In none of the cases observed by the author did any accidents occur, thus pointing to the comparative safety of the anesthetic. [A. R.]

2.—Rosenbach criticizes the medical law restricting the free use of hypnotism by physicians. He argues that the ill effects observed after hypnotism, which served as the foundation for the law, are due not to the hypnotism but the hysterical condition of the patient. If an hysterical woman, who was subjected to hypnotic suggestion, becomes worse despite the hypnotism, the latter is blamed, although it would be just as rational to blame the drugs for the conditions which they failed to ameliorate. He sees little danger in hypnotism becoming a factor in crime. As a rule, a person in a hypnotic or post-hypnotic state will not commit an act which is in striking discord with his or her established moral conceptions; and with regards to the offences which might be committed by the hypnotizer, there can never be any assurance that the victim will not remember the nature of the crime and the circumstances under which it was committed, even if a suggestion is made to forget everything that transpired during the *seance*. It is this fear that has kept and will keep the criminally inclined from utilizing hypnotism as a means of committing a crime. The author agrees with the foremost alienists in Europe that while the unscientific use of hypnotism should be prohibited, no restriction should be placed on its use by physicians for therapeutic purposes. His own experience leads him to look upon hypnotism as a most valuable aid in the treatment of cephalalgia, local spasms, fixed ideas, morbid fears, insomnia, chronic alcoholism, masturbation, psychical impotence, sexual perversion, nocturnal enuresis, and other conditions dependent on neurasthenia, hysteria or a general mental unbalance. [A. R.]

1.—See Philadelphia Medical Journal, Vol. VII, No. 23, p. 1071.

2.—See Philadelphia Medical Journal, Vol. VII, No. 23, p. 1071.

3.—One of the greatest dangers in a case of scarlet fever is the invasion of the nasopharynx by the streptococci and their associates. A superficial disinfection of the visible pharynx may be accomplished by the use of teaspoonful doses of the following mixture, given every hour: Tincture of iodine, 2 gm.; potassium iodide, 1 gm.; water, 120 cc.; carbolic acid, 10 drops. In order to clean and disinfect the infiltrated mucous membrane in scarlet fever, Seibert irrigates the nasopharynx with a warm 1 to 5% solution of ichthyol, every 6 hours. A fountain syringe, suspended about 3 feet above the patient, is used in order to administer the douche, and about $\frac{1}{2}$ pint of the solution is allowed to flow through the nares and the nasopharynx. In some cases the obstruction caused by the swollen mucous membrane is so great that irrigation cannot be used. In such a case, the author makes a local application of a 50% solution of resorcin in alcohol. He has the baby held in the intubation position and the applicator, well saturated with the solution, is passed behind outside of the soft palate, while the tongue is held down by a teaspoon. As soon as the cotton is passed behind the palate, the muscles contract and squeeze the solution out of the cotton. The operation is repeated on the opposite side. No force was used and there is no swabbing employed in the 6 cases in which the method was used. All of the patients recovered promptly of their nasopharyngitis and not one suffered from middle ear disease.

[J. M. S.]

4.—Blumer and Shaw report the case of an infant, aged 7 weeks, who was suffering from general anasarca. The edema had begun, a week before admission, in the face and extremities. The abdominal walls were very thin and peristaltic movements of the intestines were plainly visible. There was no pain on abdominal manipulation and palpation. The only bowel movement that the child had while under observation contained blood, pus, mucus and undigested food. At autopsy it was found that acute gangrenous appendicitis with the formation of a localized abscess between the appendix and the sigmoid flexure was the cause of the symptoms. [J. M. S.]

5.—Eshner reports the case of a colored boy, aged 11 months, who had presented nodding of the head since contracting a cold 2 months previously. The movements were at times nodding and at other times rotary. When the head was at rest there was at times vertical and at other times lateral nystagmus. He also reports the case of a white girl, aged 8 months, who had presented nodding of the head for 5 months. The movements were usually to and fro, but occasionally rotary. They were aggravated by fatigue or sudden noise, but ceased during sleep. He referred to the case of an unmarried woman, aged 36 years, who presented a constant rotary movement of the head of 12 years' duration. The trouble had become worse following an attack of influenza, 5 years before Eshner saw her. The movement was aggravated by sewing, worry, excitement and periodically without obvious cause. It was sometimes worse at the menstrual period and also when the general vigor of the patient was impaired from any cause. At times, the violence of the movements became so great that it caused shaking of the body and limbs. There was no spinal tenderness and no acute pain. Both the children were rachitic. There was no history of rachitis in the adult. [J. M. S.]

6. Clinical Lecture. Pleural Effusion.

JAMES CARMICHAEL.

1.—See Philadelphia Medical Journal, vol. vii, No. 23, p. 1071.

2.—See Philadelphia Medical Journal, vol. vii, No. 23, p. 1071.

3.—There are two benign forms of rectal polypi met with in children, one composed of the elements of mucous membrane, soft and gelatinous in consistency, and the other, the mixed variety, supplemented by the cellular tissue beneath, the hard or fibrous polyp. Huber believes that these polypi are the local manifestations of the status lymphaticus in the intestines. In all cases of rectal polyp that have come under the author's personal inspection or which have been seen in the practice of his friends, the tonsillar ring of Waldeyer has been involved. The pathology, as far as the large intestine is concerned, is identical in status lymphaticus and in the case of polypi. [J. M. S.]

4.—Simpson reports an epidemic of infectious disease that occurred in the American School for the Deaf, at Hartford, Connecticut. There was much doubt as to the diagnosis, which lay between German measles and scarlet fever. Some of the patients, during convalescence, presented a lamellar desquamation that closely resembled the desquamation of scarlet fever. The disease was finally decided to be German measles for the following reasons: (1) the absence of albuminuria; (2) an incubation period of fifteen days or more; (3) previous occurrence of scarlet fever in 18 per cent. of the cases; (4) profuse development of rash in all cases with slight disturbance of the temperature; (5) absence of vomiting, strawberry tongue, angina and of complications, and (6) the morbilliform type of two-thirds of the cases. The author believes that the term, German measles, covers two distinct diseases, and that the "fourth disease" of Dukes was also represented by cases in the epidemic reported. The reasons for suspecting the existence of another disease than German measles are: (1) the appearance of a second rash in five patients; (2) the fact that four of the patients had already had German measles; (3) the previous occurrence of an epidemic of pink-eye, which Dukes claims may be the only symptom of German measles, and (4) the occurrence of the lamellar desquamation. [J. M. S.]

1.—Mayer and Dehler report an extraordinarily interesting case of esophageal diverticulum. The patient, a man of 39, who had frequently been obliged to eat rapidly, and who, on one occasion had had a fish bone in his throat for several days, suddenly discovered that he was unable to swallow large pieces of meat. This condition persisted and became somewhat more severe. He also noticed that after taking fluids there was a rumbling, gurgling sound in the throat. The esophageal bougie met with obstruction 18 cm. from the teeth, which could readily be overcome by pressure. The laryngoscope investigation was negative, nevertheless a diverticulum was suspected, and therefore an investigation made with Rosenheim's esophagoscope,

which showed an opening in the right posterior aspect of the esophagus, in the form of a narrow slit running transversely, 18 cm. from the teeth. Subsequent investigation showed that it was possible to enter the diverticulum with the bougie, and its length was found to be 3.5 cm. It could not be palpated externally. Subsequently it was found that it was possible to see this opening with the laryngoscope, and to observe food coming out from it when pressure was made upon the right side of the throat. Feeding with the stomach tube and electric treatment for the diverticulum were entirely without result; it was therefore determined to perform an operation, which was made from the right side of the neck, with careful blunt dissection down to the diverticulum, which was extripated, and the wall of the esophagus sewn together. As this was not likely to hold, the wound was packed with iodoform gauze and allowed to heal. For 5 days the patient received no food or liquid by the mouth; after this time milk and other liquids were permitted for 5 days, and then after 12 days, semi-solid food was given. After the 7th day the packing was removed from the wound, and no traces of esophageal contents were found. The diverticulum was 3 cm. long, had a diameter of 2 cm., and its opening easily permitted the entrance of a cherry. It was lined with squamous epithellum, which was much thicker than in the normal esophagus. There was a rich formation of papillae beneath this, then a broad sub-mucosa containing a few dilated glands, and a moderately thick layer of muscular fibres. At the fundus all the layers were much thinner, and at the extreme tip no muscular structure could be found. It appears that the diverticulum therefore was not congenital, but produced by injury, and from the thinness of the wall it is conceivable that perforation could readily have occurred. [J. S.]

2.—Gebbart reports the case of a man, 48 years of age, who had symptoms of tuberculosis of the apex of the lung. He developed a tumor in the region of the 7th rib on the left side, which was not painful, and grew rapidly after severe exertion. It contained only blood. The diagnosis of sarcoma of the ribs, was made, and an operation determined. This was performed, and showed that the tumor was merely a blood cyst, which was evacuated and packed with gauze. The patient for a time did very badly, had fever and evidence of rapid progress of the tuberculosis. He then recovered; the cyst granulated, although on 2 occasions there was a severe hemorrhage from the granulations. A second cyst developed, was excised, and found to be imbedded in scar tissue. The patient finally died of sepsis. The microscopic examination of the cystic area gave the picture of the multiple hematoma formation. This condition is most readily confused with cavernous angioma. [J. S.]

3.—See Editorial Philadelphia Medical Journal, October 19.

4.—Adler believes that all forms of morbid nervous phenomena may be explained by assuming an excess or deficiency in activity on the part of the ganglion cells. Thus, a moderate increase or diminution in the activity of the cells concerned in intelligence and emotion produce hyper- and hypaesthesia, increase or diminution of the reflex phenomena, paresis, etc. Epilepsy is due to excessive activity; myesthesia and melancholia to deficient activity; and mania to excessive activity, etc. [J. S.]

5.—Rahn has devised an ingenious apparatus which serves to insert or extract the tube in intubation of the larynx. This consists of a novel form of tube whose upper end flares like a funnel, and on whose inner side there is a small projection by which it is grasped during insertion or removal. This is grasped by an ordinary wire loop which passes through a tube moderately bent at the end. The handle by which the wire is regulated may be either in the form of an écraseur or a form resembling somewhat a pistol, which was devised by Rahn. The advantages are that the apparatus is simple, cheap, and that accidents of technique are very much less likely to occur. It is furnished in a small case to which are added a pair of grasping forceps, for the purpose of catching the thread should it be bitten off; a metal tongue-depressor; a pair of straight scissors, and the intubation apparatus with tubes of various sizes, thread and plaster. The whole occupies an exceedingly small space. [J. S.]

6.—Hornung has made some careful studies upon the hearts of laborers employed in caissons, and found that

there was a considerable increase in the size of the heart during work under pressure. The pulse varied considerably, sometimes increasing, sometimes decreasing in frequency. After prolonged work the size of the heart was sometimes diminished. After a few hours in the open air, that is, before returning to work after an interval of 16 hours, the hearts were entirely normal; due to a gradual diminution in size after returning from the caisson. Hornung at the time of the observation was suffering from perforation of the tympanum, and he observed that the symptoms in the diseased ear were very much less disagreeable than on the other side, and he therefore considers that the vertigo is not always due to pressure upon the internal ear, but to pressure upon the tympanic membrane. [J. S.]

7.—Kollman reports a case of membranous dysmenorrhea in a patient who, after four years of suffering, had a child, and was relieved for 2 years. The membranes then reappeared, proving that spontaneous cure is not possible. During the second attack the membrane was examined microscopically, and found to consist largely of round cells in the midst of which glands were imbedded, and tissue containing considerable extravasated blood. The subjective symptoms varied considerably. At times the patient suffered from severe pain, and at other times there was none at all. The degree of pain did not appear to depend upon the amount of membrane passed, in any way. Kollmann concludes, as a result of his study of this case, that membranous dysmenorrhea does not cause sterility, and is not the result of pregnancy or of abortion; and that the fibrinous membrane is not the product of the inflammatory process; the membranes are readily dysmenorrhelic products, but unless there is careful examination made of them they may be readily confused with blood coagula, or the products of croupous inflammation. He regards the true fibrinous membrane as the product of hemorrhage into the tissue followed by necrosis. The anatomical picture of the membrane is not characteristic. The pain is not due to the separation or extrusion of the membrane, and the latter is separated by a hemorrhage from the tissue beneath it. [J. S.]

8.—Reinach has made a series of experiments upon 2 children, one of 6, and one of 9 months, with Von Mering's preparation of chocolate, which is supposed to act as a substitute for fat in the nourishment of children. For one week the feces were carefully collected and estimated, and then the cacao butter given. He found that the fat was well absorbed, and that a very small proportion of it reappeared in the feces. In the second child practically the same results were obtained, and the child increased very rapidly in weight. The indications for the use of chocolate are those that seem to interfere with the use of the fat constituents of milk, and in cases where the nutrition of the children demands an excess of carbohydrates and fatty substances. Then it is useful in cases of acid dyspepsia, in cases of fat dyspepsia, in cases of chronic enteritis; in cases in which the bodily weight does not increase with normal rapidity upon the ordinary diet, and in rachitic and scrofulous children. He reports a number of cases showing how rapidly the weight increased. [J. S.]

9.—Paul and Sarwey continue their article upon the disinfection of the hands. Their technique was as follows: First, the number of bacteria upon the hands was estimated just before the disinfection and then disinfected by the method selected. The hands were then placed in an apparatus which they called their sterile chest, and in it all further manipulations were conducted. In this chest the hands were first washed in sterile water, then cultures were taken; then washed again for 10 minutes in warm sterile water, cultures again taken both from the water and from the hands; then rubbed with sand for 8 minutes, washed off with water, and cultures taken from the water, the sand and the hands. Then finally they were washed in a very dilute solution of sulphide of ammonia, and cultures taken for the last time. The cultures were taken from the hands by means of small wooden splinters or by silk threads. The former were employed only for the region under the nails. The wood and thread were then placed in tubes containing bouillon, thoroughly shaken, and cultures made from this. The tubes were kept cool in order that there might be no multiplication of the bacteria until the plates were made. The hands were washed in a basin with a cov-

er, not unlike a pewter dish. The results were as follows: In all cases numerous germs could be detected upon the hands before disinfection. After disinfection by the method of Furbringer, numerous germs could still be found. After the hands were washed for 5 minutes in water at the temperature of the body, numerous germs could be found in the water and obtained from the hands. After rubbing the hands in sand and washing them in sterile water at the temperature of the body, numerous germs could be found in the water and also obtained from the hands. After washing the hands in the diluted solutions of ammonium sulphide, numerous germs could still be obtained from the hands, the whole series of experiments indicating that Furbringer's method of sterilization is not sufficiently trustworthy to be used for surgical operations. The paper is still unfinished. [J. S.]

5. Mr. Carnegie's Gift. J. A. BERRY and D. D. BUCHAN.
6. British Medical Association: Sixty-Ninth Annual Meeting at Cheltenham.

2.—J. M. Cotterill states that the general practice is not to operate after the first attack of appendicitis. The author gives the following reasons why he does not approve of waiting: (1) A large percentage of all cases, estimated by various writers at from 25 to 40 per cent., have second attacks. In all but the mildest cases a second attack is the usual rule; (2) no one can predict that such a second attack will not be perforative nor prove fatal, in spite of treatment. Operative treatment during the acute attack is, of course, a much more serious undertaking than when done in an interval; (3) every attack adds to the extent and strength of the adhesions, and thus increases the difficulties and dangers of the operation, sometimes to a very great degree; (4) the mortality of the operation, when done in an interval, especially after a first attack when the adhesions are minimum, is comparatively trifling, say from 1 to 2 per cent. at the outside in the hands of competent surgeons. The writer lost but one case, but the patient had suffered during several years from an enormous number of attacks, and the operation was prolonged and difficult. [T. M. T.]

4.—J. W. Dowden, in his article on torsion of the spermatic cord with an account of three cases gives the treatment as follows: If the case be seen in the first few hours after the onset of symptoms, the cord should be untwisted. This is comparatively easy when the testicle has descended, but probably very difficult when undescended. The untwisting should be carried out at first in a direction from within outwards, and if this procedure increases pain, the opposite direction should be tried. As regards the after-treatment of these relieved cases, the probability is that in cases, in which a descended testicle is affected, an operation should be performed to fix the organ firmly in the scrotum. With this object the author suggests as a method to be carried out one in which a broad strip of visceral tunica vaginalis be removed from the upper attachment of the cord to the lowest point of the testicle and a corresponding portion of the parietal layer also removed, then the cut edges of the visceral and parietal layer are sewn together with catgut. Adhesions would form between the raw surfaces on the testicle and inner side of the scrotum, while the stitched edges of the visceral and parietal layers of the tunica vaginalis would hold the organ in position. In cases in which the testicle is undescended, after an acute attack has been early relieved by untwisting, the operation to be performed would be one of either bringing the testicle down into the scro-

tum, provided the vas deferens is of the looped variety and sufficiently long to allow this procedure, or what will much more probably be the case, removal of the organ. Cases in which the testicle has been affected for twelve or more hours, or in which there have been several attacks with atrophy resulting, the safest procedure is removal of the testicle, taking care in acute cases to make the section of the cord above the thrombosed area, lest it so happen that septic injection of the capillaries spreading to the veins has been a factor in the condition. [T. M. T.]

2. Skin-Grafting by the Wolfe-Krause Method: Report on Nine Cases. H. M. W. GRAY.
3. Wound of the External Iliac Artery treated by Ligature. J. HOGARTH PRINGLE.
4. A Case of Muscolo-Spiral Paralysis followed separation of the lower epiphysis of the humerus; recovery after operation. ROBERT PURVES.

1.—In the management of the third stage of labor, A. R. Simpson believes that the great value of the Credé method lay in doing away entirely with (1) traction on the cord, and (2) of introducing the fingers into the lacerated genital cavity. (1) In the first instance as regard the danger of pulling on the cord; he refers to the risk of the cord giving way. The strength of the cord varies greatly, resisting a strain from two pounds to over eighteen. In one-fourth of the cases tested with a weight, the average was four pounds; (2) with regard to the introduction of the hand or fingers to lay hold of the placenta, whilst every practitioner knows how to lessen the risk of septic inoculation through disinfection, he knows also that he can better secure the results of an aseptic accouchement if he can get the placenta extruded without touching even the vaginal mucosa. This is what Credé has taught him to do. [T. M. T.]

2.—H. M. Gray gives the technique he employed in skin grafting as follows: The part to which the grafts are to be applied, and the part from which they are taken are disinfected in the ordinary way. The process of disinfection should extend over three or four days, if possible, the length of time varying with the thickness of the epidermis on the parts. Where there is a granulating surface to be covered, the author thinks it best, as preliminary operation, if the surface is not already aseptic, to scrape away the granulations thoroughly and disinfect the vivified surface and parts around. The operation is preceded by a final disinfection of the parts. All antiseptics are washed away by normal salt solution. The diseased part, cicatrix, tumor, ulcer, or pathological condition, is excised if possible, care being taken where disease is present not to soil the vivified surface, either by allowing discharge to trickle over it, or by letting the scalpel come in contact with the diseased part. Both may be prevented by stitching a pad or mop over the diseased area. Bleeding is controlled by pressure with pads wrung out of warm normal saline solution, by pressure forceps, or even by touching the bleeding vessel with the finest point of a cautery. Ligature must on no account be used, except perhaps at the very edge of the vivified surface, where they may be so applied as not to interfere with the grafts. [T. M. T.]

ZEITSCHRIFT FUER ORTHOPAEDISCHE CHIRURGIE.

1901. (Volume 9, No. 2.)

6. The Operative Treatment of Congenital Luxation of the Hip. A. CODIVILLA.
7. A New Method of Reduction of Congenital Luxation of the Hip. ANGELO CACCIARI.
8. A New Method of Making Foot-prints. H. TIMMER.

9. Some New Orthopedic Apparatus. H. GRAFF.
10. Spondylitis Deformans. A. KUDRJASCHOFF.
11. The Static Relations of the Human Skeleton.
CESARE GHILLINI and SILVIO CANEVAZZI.
12. Mechanical Laws in the Formation of Scoliosis.
A. SCHANZ.

6.—Codivilla, after having operated upon 76 cases of **congenital luxation of the hip**, concludes that the bloodless operation is indicated in children from three to 12 years of age; in older children the bloody operation may be successful. In 53% of his cases the results were both good and permanent. In the others the dislocation recurred, but to a less degree than before. Plaster bandages and the Schede splint will keep the leg rotated inward; occasionally osteotomy of the femur is also necessary. If the lack of an acetabulum causes relaxation, a new acetabulum should be made by an extra-articular operation. Codivilla has devised a lever which is of use in replacing the head of the femur where it belongs, after the joint cavity has been incised. After the formation of a new acetabulum there is always danger of ankylosis. Codivilla considers that the best incision to reach the hip-joint is one made along the upper border of the tensor vaginae femoris muscle. Drainage should never be left in the wound, which should be immediately closed after operation. [M. O.]

7.—Caeiari shows that the methods of reducing **congenital dislocation of the hip** devised by Pacl in 1883, and by Lorenz in 1896, are nothing but the old method originated by Fabbri in 1840, with a few slight alterations. Ghillini does away with the different grades of deformity following the above operations by always fixing the head of the femur in the acetabulum. Plaster bandages are kept in place six months after operation. Ghillini has performed this operation upon children up to 13 years of age. In older children extension is kept up for two weeks before operation. Caeiari states that those operators are mistaken who claim to obtain recovery after operation for congenital dislocation of the hip, since recovery means a return to the perfectly normal condition. [M. O.]

8.—Timmer uses **plate glass** upon which **printers' ink** is spread in a thin layer. The patient steps upon this, then off upon a smooth piece of white paper. The **foot-prints** can be dried with talcum powder. Details show wonderfully well. The ink may be removed from the feet with soap, water, turpentine, or petroleum. This may also be used to secure thumb-prints. [M. O.]

9.—Graff describes three **new pieces of orthopedic apparatus**, giving excellent photographs of them to show their use. One huge contrivance is for flexion and extension at the hip-joint; another is for abduction and adduction at the hip-joint; and the other is an osteoclast for forcible reduction of deformities of the leg, ankle, or foot. [M. O.]

10.—Kudrjasehoff reports a case of **spondylitis deformans** in a man aged 42. Ten years ago he had rheumatism of the ankles and knees. Later the hips became affected, and now the gradually deforming process has gone from the sacrum up to the cervical vertebrae. His head is bent forward, his spine held rigid. The spinal column is curved backward and immovable. The upper cervical vertebrae are movable, causing marked crepitation. The lower cervical and the four upper dorsal vertebrae are turned to the left; the other dorsal vertebrae are turned to the right. The muscles of the back, shoulder, and neck have atrophied. No doubt remains that the case is one of spondylitis deformans, following the attack of rheumatism 10 years ago. The literature of the subject is fully cited. Photographs of numerous preparations of the spinal column show the deformity of the vertebrae. The condition has many causes and may be localized, generalized, or quite irregular and atypical. These facts account for the many names given to this disease. [M. O.]

12.—Ghillini and Canevazzi consider the question of the **static relations of the human skeleton** again. They believe that they have, in their previous works upon the subject,

shown how bony deformity occurs. They also think that they have explained the changes which produce genu valgum, a question which greatly interested the late Professor Albert. [M. O.]

12.—Schanz describes the **mechanics of scoliosis** illustrating his very technical article with diagrams. The vertebral column corresponds to an elastic upright pillar, bent by an overpowering force. Thus scoliosis, compensatory curves, and torsion of the vertebral column are explained. [M. O.]

WIENER KLINISCHE WOCHENSCHRIFT.

August 29, 1901. (XIV Jahrgang, No. 35).

1. The Sensory Neuroses of the Stomach. ALOIS PICK.
2. Eclampsia in a Young Girl of Sixteen.

KARL DORANTH.

3. Atypical Psoriasis. ALBRECHT BEYER.

1.—Will be abstracted when concluded.

2.—Doranth reports a case of **eclampsia** in a young girl of 16, who suddenly lost consciousness. Bromides were given, as the condition was believed to be epileptic. In her third year she had had her only previous convulsion, during teething. For two days preceding this attack she complained of headache, off and on. Five convulsions followed in quick succession, in one hour. These began with both eyes turning to the right, a twitching of the right side of the face, movements of the head, clonic and tonic spasms of the right arm, frothing at the mouth, etc. No albumin was present in the urine; its specific gravity was 1.044; and it contained 3% sugar. She was perfectly well in two days. Doranth believes this to have been a case, not of epilepsy, but of **true eclampsia in a virgin**. In all its characteristics, this case resembled the eclampsia of the pregnant woman. [M. O.]

3.—**Psoriasis** is often so atypical that it is with difficulty recognized; for another skin condition may exist upon the individual with psoriasis, such as eczema, scabies, syphilis, impetigo, etc. In fact, cases of psoriasis have been seen with all other skin diseases. The other skin condition may occur upon the site of the already existing psoriasis, as eczema, acne, furunculosis, etc.; or the psoriasis may appear over another skin disease, upon eczema, erysipelas, variola, etc. Truly atypical are those cases of psoriasis which simulate eczema, seborrhea, rupia, etc. Besides, the psoriasis eruption may be atypical in character, or in localization. After a review of the literature, Beyer quotes ten case-histories in full, to illustrate the atypical conditions to be found in psoriasis. [M. O.]

September 5, 1901. (XIV Jahrgang, No. 36).

1. The Pathology and Treatment of Hour-glass Contraction of the Stomach. KONRAD BUEDINGER.
2. Aneurysm of the Ascending Aorta with Rupture into the Superior Vena Cava. V. COMINOTTI.
3. The Sensory Neuroses of the Stomach. ALOIS PICK.

1.—Buedinger reports the case-history of a woman, aged 42, who had always had anemia and gastric symptoms. During the past two years these had become severe, and for some months prior to her admission to the hospital she could only take liquid diet on account of the pain. She was constipated, and **hour-glass contraction of the stomach** was palpable, with **gastroptosis**. Laparotomy was performed and the stomach resected. A T-shaped cicatrix was found to be the cause of the condition, with spasmodic contractions of the gastric muscle about it, forming a tumor. **Retro-colic gastroenterostomy** and **gastropepy** were performed, with excellent results. The contractions which were observed during the operation were exactly like those seen by Hofmeister and Schütz in their experiments upon dogs. The case-histories of two other cases of hour-glass contraction of the stomach follow. One recovered and one died. After a review of the literature of the stomach, Buedinger describes his **gastroplastic operation** to replace the cicatrix removed, with illustrations. This method is applicable in most cases in which gastro-anastomosis is done, if the communicating piece is not long; especially when the condition is congenital; and in cases in which, while

gastroenteroanastomosis is impossible, yet the cicatrix can be extirpated and the deepest point joined. [M. O.]

2.—Cominotti reports, with full details, the rupture into the superior vena cava of an aneurysm of the ascending aorta, in a woman of 48. A sketch of the specimen is given, with a table of 181 aneurysms which Cominotti has observed. The patient was a prostitute, had had no children or abortions, and had passed the menopause. She was perfectly well until seven months before death, when she noticed pain about the heart, radiating to the shoulder, more at night than in the day time. Dysphagia and dyspnea followed. She got better, then suddenly worse six weeks before death. Dulness was found anteriorly over the sternum and right side of the chest from the clavicle to the fourth rib. This region was very tender to pressure. Over the heart a loud, long murmur was heard during systole and diastole, most marked over the aortic area. A venous pulsation was visible over the right jugular vein. Before death the left inferior epigastric vein became markedly swollen. There was right-sided hydrothorax. The autopsy showed an aneurysm of the ascending aorta, which had compressed the superior vena cava and had eventually ruptured into it. The outlet of the thoracic duct was obstructed and dilated, as were the cisterna chyli and the mesenteric lymph-vessels. [M. O.]

3.—After reviewing the literature of the gastric neuroses, Pick divides the sensory neuroses of the stomach into two groups, the hyperesthetic, including gastralgia, and the hypesthetic. Hyperesthesia of the stomach may be due to thermal, mechanical, or chemical irritants. This condition frequently simulates gastric ulcer in its symptomatology, and the diagnosis may be extremely difficult. Its symptoms are described most completely. The condition may exist alone, or with other gastric affections. Great care must be taken in the regulation of the diet, while baths, lavage, alkalies, morphin, cocain, menthol, bismuth, etc., will help in the treatment. Gastralgia may be of four kinds, true neuralgia or that due to intoxications, pains with gastric diseases, pain due to affections of far off viscera, and pain from the disease of near by organs. The treatment of gastralgia consists of warm applications, electricity, or massage during the attack; bismuth, morphin, arsenic, quinine, silver nitrate, antipyrin, etc. may do good between attacks. Occasionally an empty stomach causes pain which disappears when food is ingested. Hypesthesia to all irritants is very hard to diagnose, also. Just as hyperesthesia is accompanied with hypersecretion, so hyposecretion occurs with hypesthesia. Bitters, electricity, gastric douches, etc. will be the treatment of this neurosis of the stomach. [M. O.]

September 12, 1901. (XIV Jahrgang, No. 37).

1. The Diagnosis of Concretio Pericardii and Tricuspid Disease. WILHELM TUERK.
2. The Method of Causing Ether Intoxication. FRIEDRICH TEWELES.
3. Ether Intoxication, an Experimental Intoxication Psychosis. OTTO LENZ.

1.—This will be abstracted when concluded.

2.—Teweles relates the results of the use of ether to produce intoxication during seven months, at the Rudolfinerhaus in Vienna. Both Gersuny and Moszkowicz operated, performing in all 157 operations, employing an inhaler similar to that in use in America. The ether was given simply long enough to produce intoxication, not enough to cause deep anesthesia. Asphyxia and other alarming symptoms were entirely absent. He concludes that the operator may begin almost as soon as the inhalation, since there is practically no stage of excitation; that but very little ether is needed; that the preparation of the patient for operation is purely psychical, his whole attention being concentrated upon the anesthesia; that its administration is very simple, and is especially applicable in private practice; that when deeper narcosis is wanted, the ether may be pushed, or chloroform, or a mixture may be substituted; and that, as no bad symptoms resulted from this method of administering ether, it is harmless. Its disadvantages are that

some sensitive patients cry out and weep; that some movements may occur upon the first incision; and that a few persons may remain unaffected by the ether. But these disadvantages are but few, compared to the advantages of this method. [M. O.]

3.—Ether, in the method of administration in use for operation at the Rudolfinerhaus in Vienna, was used by Humphry Davy in 1795 as an intoxicant. After reviewing the literature, as collected from the experiments of physiologists upon themselves and others, and from the observations of the patients after ether intoxication, Lenz reports two cases, describing the symptoms. The individual is insensible to pain though he may feel the knife; he may be maniacal or depressed; the depression may change to symptoms of poisoning; or furious delirium may occur. Besides, some people remain totally unaffected by even a large dose of ether. Lenz concludes that ether intoxication is an acute intoxication psychosis; that the result is the product of the individual reaction and the amount of the ether inhaled; that the nervous disturbance is only temporary; that the ideal ether intoxication is to have tactile sensibility kept, while sensibility to pain is benumbed; and that the use of ether to produce intoxication is contraindicated in individuals who drink freely or who are in any way neuropathic. [M. O.]

REVUE DE CHIRURGIE.

August, 1901. (21me. Année, No. 8.)

1. Radiography in Pulmonary Surgery. THEODORE TUFFIER.
2. The Pathogeny of Ranula. LEON IMBERT and EMILE JEANBRAU.
3. The Pathogeny of Flat-foot. de VLACCOS.
4. Vascular Tears in Fracture of the Clavicle. E. GALLOIS and P. PIOLLET.
5. Anuria in Uterine Cancer. PATEL.
6. Genital Tuberculosis in the Female. MARIE GOROWITZ.

1.—Tuffier believes that the diagnosis of surgical diseases of the lungs is very difficult. Out of 300 cases collected, there were 48 errors in the seat of the lesions. In nine of these the lungs were affected, yet the pleura, liver, and kidneys were diagnosed diseased. More frequent still are mistakes in the position of the lesion in the lungs. It is also difficult to determine the volume of a cavity and the number of disease foci. Exploratory puncture will help somewhat. Radiography helps even more. In 5 out of Tuffier's eight cases, radiography was positive. When radiography confirms percussion and auscultation, the lesion is surely localized. [M. O.]

2.—Imbert and Jeanbrau report a case of ranula in a woman of 23. This was successfully removed by suprahyoid operation, and examined histologically. They review the history of the subject in full, with many quotations from the literature. Ranulae containing vibratory cilia are very rare. Commonly there are no cilia. The wall of the common ranula consists of four layers: (1) cuboidal or polygonal epithellum, which may be absent; (2) embryonal tissue; (3) connective tissue, and (4) very little, deformed glandular tissue. When cilia are found, the epithelium arises from the anterior portion of the embryonal thyroglossal duct. After incision, cauterization, or excision, ranulae recur. Terrier advises ablation of the cyst and total extirpation of the submaxillary and sublingual glands whenever they are adherent. Imbert and Jeanbrau believe that the common ranula is congenital in origin, due to some unknown error of development, possibly connected with the branchial clefts. [M. O.]

3.—Flat-foot is generally accompanied by pain, whence comes its synonym, tarsalgia. de Vlaccos advances a new theory to explain the development of flat-foot. A straight line down the centre of the leg passes through very little of the os calcis and the astragalus, since they are both mainly external to such a line. The weight of the body

pressing upon the inner side of the foot will thus produce weakened and flattening of the plantar arch, and later outward rotation. This is normally prevented by the tendons of the tibialis posterior and the flexors of the toes. But under pressure the calcaneum assumes a condition of pronation, and slides to one side. The astragalus follows, ligaments give way, and flat-foot results. de Vlaceos thinks that this action is sometimes influenced by badly fitting shoes. [M. O.]

4.—Gallois and Piolet report a unique case of arterio-venous aneurism following simple, indirect fracture of the right clavicle, in a man of 25. The right subclavian artery and the right subclavian and internal jugular veins formed an irregular, hard, pulsating tumor. There was pain in the right arm upon motion. A distinct systolic murmur was audible over the tumor. Suppuration caused immediate operative interference. The tumor was laid open by resecting the clavicle. The hemorrhage was abundant, and the patient died four hours after operation. The autopsy showed that all the vessels had been ligated in the operation, and that there had been no bleeding afterward. 10 similar case-histories are quoted from the literature. The arteries were even more rarely injured than the veins. The cause of the vascular injuries in all these cases was the violence of the fracture. Experiments upon the cadaver showed the subclavian vein to be most often injured, the internal jugular vein coming next in frequency. The symptoms are the rapidly growing tumor, with the murmur, pulsation, etc. The prognosis is unfavorable. The best treatment will be freely laying open the sac, ligating the artery at a short distance below the aneurysm, and ligating all the veins when the aneurysm is opened. It will generally be necessary to resect the clavicle. [M. O.]

5.—Lesions of the kidneys and ureters are common with uterine cancer. A ureter may be compressed by the tumor itself, or by metastases in the broad ligament or lymph-glands. The ureter is then found sclerotic at the seat of the compression, dilated above it, with thinner walls. In the kidneys, cysts, sclerosis, degeneration, and atrophy are noted. Anuria results when both ureters are compressed. This may occur simultaneously, or upon one side some time after the other. Patel reports a case of uterine cancer in a woman of 75, with metastases in the broad ligament and vagina. Metrorrhagia occurred, with uremia. Total anuria preceded death. The autopsy showed compression of the right ureter, hydronephrosis of the right kidney, slight compression of the left ureter, and atrophy of the left kidney. Anuria may be the first sign of uterine cancer; it may occur suddenly with uterine cancer; or it may come on gradually. Patel believes the best treatment to be not ureterostomy, but **nephrostomy** in the lumbar region. The kidney is split in the median line, longitudinally, and the pieces are sutured to the abdominal wall, about the lumbar incision. If both kidneys are hydronephrotic, nephrostomy is to be done preferably on the right side. If one kidney is palpable, catheterization of the ureters may help to decide upon which kidney to operate. The operation is justified in all except very old, very weak patients. All symptoms improve after nephrostomy except the cachexia. The case-histories of two ureterostomies and six nephrostomies follow. [M. O.]

6.—Will be abstracted when concluded.

PRESSE MEDICALE.

August 14, 1901. (No. 65).

1. The Neuroglia in General Paralysis of the Insane. L. MARCHAND.
2. Hemorrhoids Treated by a New Forceps and Sutures. J. C. LIMA CASTRO.

1.—After relating the manifold views upon the subject of **general paralysis of the insane**, Marchand reports his own findings, histologically, in the cerebral cortex, cerebellum, medulla, and spinal column. In the latter both antero-

lateral and posterior tracts are affected. The neuroglia is found proliferated, especially in those parts of the nervous system which are normally rich in neuroglia. These regions are in contact with the cerebro-spinal fluid or the blood. It is this distribution of the neuroglial hyperplasia, early in the disease, that points to the existence of a toxin carried in the fluids of the organism, as its cause. Marchand believes that the nerve-cells are affected just as early as the neuroglia, but as we have as yet no means of staining the primitive fibrils of the nerve-cells, this cannot be shown.

2.—Lima Castro describes a **curved forceps** which has a dozen 5 mm. grooves along the upper part of its blades, permitting the passage of a needle through the tissues held by the forceps. These he employs in performing operations for hemorrhoids, by sutures. His technique is described in full, with excellent drawings. [M. O.]

August 17, 1901. (No. 66).

1. Occlusion of the Small Intestine in the New-born Infant. E. WEILL and M. PÉHU.
2. Cyto-diagnosis. XAVIER LEWKOWICZ.
3. Asepsis of the Hands in Surgery. L. LONGUET.

1.—Numerous cases of **congenital stenosis of the small intestine** in the new-born have been reported, due to an error in development. Weill and Péhu report such a case in a boy nine days old. His bowels had not moved since birth, and the abdomen was very large and tympanitic. Though he vomited constantly, the fluid vomited contained no fecal matter. The anus was well formed, but enemata brought away mucus only. There was albuminuria. Though an artificial anus was made by operative intervention, the child died. At the autopsy it was discovered that for about 15 cm. below the cecum the small intestine existed as a tiny cord only. The obliteration of the intestine was complete. The diagnosis is generally easy, the prognosis unfavorable. Though medical treatment should at first be attempted, it should very soon be abandoned in favor of laparotomy, with gastro-enterostomy when necessary. [M. O.]

2.—Lewkowicz calls attention to the fact that **cyto-diagnosis** was practiced before Widal originated the method in France in 1900. For Korszyrski and Wernicki proposed the examination of serous effusions for the cellular elements therein contained in 1896, for purposes of diagnosis. Winiarski also did some work upon the subject in the same year. Lewkowicz has found a few lymphocytes present in the cerebrospinal fluid of normal individuals. Lymphocytosis is the rule in tuberculosis. In 20% of his cases of tuberculous meningitis, polynuclear leukocytes predominated. These cases probably had an old caseous lesion which was in contact with the meninges. [M. O.]

3.—Longuet, who reviews the subject of **surgical asepsis of the hands**, concludes that care must be taken by the surgeon that he do not touch anything septic. If he must touch anything aseptic, he should put on gloves before so doing. The different gloves are described in full. For preliminary sterilization of the hands Ahlfeld's method with alcohol, Kelly's method with potassium permanganate, or the Haegler sublimate method may be used.

[M. O.]

August 21, 1901. (No. 67).

1. The Ambulatory Form of Bacterial Meningitis. A. SICARD.
2. The Treatment of Conjunctivitis. F. TERRIEN.

1.—Sicard calls acute **cerebro-spinal meningitis** which is neither tuberculous nor syphilitic, **bacterial**; for these cases may not be epidemic. Just as there are cases of "walking" typhoid fever, ambulatory cases of meningitis exist. These ambulatory cases may be fulminating in their severity; they may be simple and curable; or they may be subacute, ending eventually in death or recovery. Sicard has collected case-histories of four of the first, and three of the second and third groups, each. All these cases were reported by different observers before the Medical Society of the Paris Hospitals. These patients continued at work, in spite of their meningitis. Kernig's sign, while present in acute meningitis, is also found with meningis-

mus. But cyto-diagnosis now aids much in establishing the diagnosis. Lymphocytosis in the cerebro-spinal fluid means tuberculous, polynuclear leukocytosis, bacterial meningitis. Late in the disease the bacterial form also gives lymphocytosis. Finally bacteriological investigation confirms the diagnosis already made. [M. O.]

2.—Terrien divides conjunctivitis into the simple or non-specific, the specific, and the diphtheritic forms. Specific conjunctivitis may be catarrhal, which form is treated with boric acid, cyanide of mercury, zinc sulphide, and ammonium chloride. If severe, nitrate of silver or protargol solutions are used. In subacute conjunctivitis, due to the diplo-bacillus of Weeks, silver nitrate is best, as it is in gonorrheal conjunctivitis. Sometimes canthoplasty, ice and leeches are needed. Protargol or the biniodide of mercury are used on the eye-lids. For the non-specific varieties, due to streptococci, pneumococci, etc., the treatment is practically identical. [M. O.]

JOURNAL DES PRATICIENS.

August 10, 1901. (15me. Année, No. 32).

1. The Treatment of Phlebitis. EDGAR HIRTZ.
2. Tuberculous Rheumatism or Pseudo-Rheumatism of Biliary Origin. ANTONIN PONCET.
3. Electricity in the Treatment of Exophthalmic Goiter. DENIS COURTADE.

1.—At the beginning of a phlebitis, absolute rest is necessary for six weeks or longer. Cold moist applications should be made over the seat of the phlebitis. Later compression can be made by an elastic bandage. Later still, massage will be beneficial, with passive motion. During convalescence Hirtz advises salt baths, ichthyol ointment, etc. Constitutional treatment for gout, rheumatism, or syphilis, may do much good to the phlebitis. [M. O.]

2.—Just as there are attacks of pseudo-rheumatism due to gonorrhea, puerperal fever, scarlet fever, etc., there exists a form of rheumatism brought about by the tubercle bacillus. Poncet reports the histories of three such cases which he has observed. In the most typical case the autopsy confirmed the diagnosis. [M. O.]

3.—In exophthalmic goiter electricity is employed to act upon the cervical sympathetic nerves and the thyroid gland. Either faradic or galvanic electricity may be used, or both combined. This treatment is given for from 10 to 20 minutes daily. It should be kept up at least three months, while rest, baths, and sodium salicylate should be associated with the electricity. [M. O.]

1. Latent Heart Disease and Sudden Death in the Army. KELSCH.
2. A Clinic Upon Therapeutics. HENRI HUCHARD.
3. Paraldehyde. S. ROQUES.

1.—Will be abstracted when concluded.

2.—Huchard describes a case of hepatic colic which was pseudo-gastric in type. He advises morphin at first, and sodium benzoate and salicylate later. When large doses of digitalis are needed to prevent asystole, Huchard uses crystallized digitalin, a solution of 1 to 1000, 50 drops twice in one day. This is not given longer. As a simple heart sedative 10 drops daily may be prescribed. In the case of a man of 80, with simple arrhythmia, digitalis should not be given. Huchard ordered one or two grams of theobromin with success. Huchard also prefers sodium iodide to potassium iodide in all cases except those due to syphilis. He has ceased giving bitters for anorexia, now prescribing the alkalies instead. [M. O.]

3.—This is a detailed account of the physiology and therapeutics of paraldehyde. Paraldehyde is especially indicated in the insomnia of alcoholics, in delirium tremens, morphinomania, and as an antidote for strychnine, etc. The dose varies from one to two or three grams. It is contraindicated in those who are taking iodides. It causes a breath like that of a drunken man, which may, however, be counteracted by giving vanilla at the same time. [M. O.]

Special Article.

REPORT OF THE COMMISSION APPOINTED TO INVESTIGATE THE CASES OF TETANUS IN ST. LOUIS FOLLOWING THE ADMINISTRATION OF DIPHTHERIA ANTITOXIN.*

By B. Meade Bolton, M. D., C. Fisch, M. D., and E. C. Walden, M. D., St. Louis.

Our original plan was to have each of us carry out his investigations entirely independent of the others, and to combine our conclusions in a single report. It was impossible, however, for us to carry on the investigation in this way, on account of the small quantities of serum in some of the bottles, and as a consequence all serum has been tested by us conjointly, and also, insofar as it was possible, independently. All material obtained by us from autopsies has been studied by each of us, and the results in every instance have tallied.

The experiments have been directed to learn:

1. Whether pathologic lesions could be demonstrated revealing the characteristic picture of tetanus.
2. Whether tetanus could be produced from the pathologic material obtained at autopsies and during life.
3. Whether the serum dated August 24 was the cause of the outbreak.
4. Whether all serum dated August 24 had the same toxic properties.
5. Whether the disease was caused by an infection or an intoxication.
6. Whether any difference could be noticed between the serum dated August 24 and the serum dated September 30.
7. What the toxic strength of the serum was.

I.

It was fortunate that our appointment occurred at a time when an outbreak was at its height. We thus had an opportunity to see a number of patients, *intra vitam*, and so convince ourselves from the clinical observation, of the correctness of the diagnosis made. We saw, altogether, about ten patients, and, with one exception, could fully confirm the diagnosis. The exception was a case of Dr. Friedman, in which the only symptom pointing to tetanus was an incomplete trismus, evidently due to an enormous swelling of all the regional glands. The case, we hear, recovered.

An instructive series of three cases of tetanus was seen in the family of Mr. Goldstein, in which, according to the age and size of the patients, a gradual increase in the severity of the symptoms was observed. All of the three patients were, as we were informed, injected with the same amount of serum. All three cases are at present on the road to recovery. The incubation period in these cases, coming under our personal knowledge, varied from five to seven days, death ensuing in the fatal cases three to five days later, taking for granted that the infection or intoxication took its origin from the injections of the diphtheria antitoxin made in all of the cases. In no case were any wounds or other interruptions of the continuity of the epithelial surface of the body observed except those caused by the entrance of the canula, and these points were without inflammatory reaction in all of the cases.

Of the official autopsies made on a number of the patients that succumbed to the disease, we attended five (Jacob Centurio, Adele and Mamie Keenan, Emma Ernst and — Baker). These autopsies were made at a comparatively short time after death, so that no post-mortem changes could have interfered with the thorough examination. Only in the case of the Ernst child, embalming fluid had already been injected, and the investigation was, therefore, confined to the brain and the spinal cord alone. The reports of the findings are already in your hands. We emphasize here that only in two cases, Jacob

*From the St. Louis Medical Review.

Centurio and Mamie Keenan, changes other than of a tetanic nature were found. In the first case there was ample microscopic evidence of a simultaneous scarlatinal infection, characteristic desquamation, desquamative nephritis, fatty myocarditis, etc., while in the second case lesions of the kidney (fatty infiltration of the tubular epithelium) and of the liver (extensive fatty changes) were apparent, and most likely due to the action of the diphtheria toxin. With the exception of these two cases no microscopic pathologic changes could be found, aside from a very general and uniform engorgement of all the viscera, sometimes of the lungs, and always of the central nervous system. This engorgement was always pronounced in the venous system; in some cases extensive capillary injection and even the formation of petechial hemorrhages could be observed. In no instance was there any evidence of inflammatory processes in the meninges. A careful search for wounds revealed nothing but the sites of the injections, which, however, sometimes could only be detected with difficulty or not at all.

At each autopsy, pieces of the different organs (except in the Ernst case), were removed for microscopic examination, and in every case pieces of the hemispheres, basal ganglia, pons, medulla and cervical cord, were transferred immediately into alcohol or 10 per cent. formol. The microscopic examination has not revealed anything more than the macroscopic inspection. With the exception of the two cases mentioned above, where the macroscopically detected lesions due to other diseases were simply confirmed by the microscope, no anomalies but a very general and pronounced hyperemia of the organs were found. In one case the area of skin surrounding the site of injection was removed, and examined microscopically and bacteriologically; the microscope showed only intense hyperemia of all of the vessels of the skin, subcutaneous tissue and abdominal muscles, while the aerobic and anaerobic tubes inoculated with material from this specimen remained sterile. It must be mentioned, however, that the attending physician in this case had injected into the same place before death a solution of bichlorid of mercury.

The interest of the microscopic examination centered in the material taken from the cord and medulla. Numerous sections were made from the material of every case, and mainly stained after the Nissl method. Some were prepared according to the Weigert formula, but in the latter no changes could be seen. The Nissl specimens showed in all of the sections about the same condition in about the same degree of intensity. Numerous ganglion cells, and especially the large motor cells of the anterior horns, exhibited a beautiful picture of the so-called chromatolysis, swelling of the nucleolus, obliteration of the processes, etc. It seemed, however, that the changes did not have that degree of intensity that is the outcome of inoculation experiments in animals, or in the ordinary cases of human traumatic tetanus. Besides the pathologic nerve cell a greater number of normal cells were found. The pictures obtained otherwise corresponded perfectly to those published in Barker, "The Nervous System," pages 304 and 305. It is to be noted here that the changes described could not have been post-mortem alterations, because some of the autopsies were made too soon after death for such changes to have occurred.

If the whole of this is considered, it is seen that in all of the post-mortems made, nothing was discovered that could justify the assumption that the death of these patients was due to some other pathologic process. Even in Jacob Centurio and in Mamie Keenan, the scarlatinal and diphtheritic lesions were not such as to be looked upon as necessarily fatal. On the other hand, these investigations do not give any direct and incontrovertible evidence that the cause of the death was tetanus, although the clinical evidence alone was certainly sufficient to remove any doubt.

II.

To produce this direct proof we attempted to produce in animals the disease by means of incorporating into them material removed from the patients during life and after death. From the beginning the prognosis for a favorable result was bad, for two reasons. The human organism

belongs to that category of animal beings which absorb with great rapidity the tetanus toxin produced at the focus of infection or artificially introduced. In a short time after a given quantity of such a toxin is in some way introduced, it is completely combined with the susceptible cells, and it is the general experience that at the height of the tetanic process no free toxin is found in the human body. The second reason was, that most of the patients had received copious administrations of tetanus antitoxins before death, so that whatever quantity of the toxin was present in the fluids of the body of the patient must have been neutralized and made inaccessible to demonstration by this antitoxin.

That, in fact, a surplus of antitoxin was present was demonstrated in the case of Isaac Stein, from whom during life some cerebro-spinal fluid and blood were removed for therapeutic purposes. We injected some of this cerebro-spinal fluid, mixed with a fatal dose of the tetanus toxin, into a mouse, and found that the animal remained perfectly well, while another mouse injected only with the fatal dose of the toxic serum died within three days with typical symptoms of tetanus. Thus it was demonstrated that the patient died of tetanus in spite of the fact that his blood contained a large amount of antitoxin.

A number of animals were, nevertheless, injected with as large amounts of this material as was compatible with their size and weight. In no case have we obtained a positive result. Some of our animals died of secondary infection, or rather from infections with organisms introduced together with the pathologic material, as cultures made from the latter showed. In some cases, the presence of saprophytic bacteria having invaded it after death.

Especial attention may be called here to the experiments in which the site of injection was exposed and triturated. Here, too, no tetanus developed. It must, however, be mentioned, that this fact gives very little evidence against the presence of the tetanus-bacillus or spores, as it is well-known that these bacilli disappear very soon after the infection, unless they are accompanied by pus forming bacteria, which did not occur in our cases.

III.

The investigation of the third point, stated above, was pursued by experiments upon animals, chiefly by inoculation of mice and guinea pigs with the material placed in our hands by the coroner. In order to demonstrate whether we had to deal with a tetanus infection or intoxication, animals were inoculated with the suspected serum, and another series were inoculated with a mixture of the toxic serum and a protective dose of tetanus antitoxin. The animals receiving the tetanus antitoxin together with the toxic serum, recovered, while those receiving the toxic serum alone died with typical symptoms of tetanus. This point having been demonstrated, the samples of the serum delivered to us by the coroner were examined. Seventy-four animals have been used in this investigation.

It will be seen that seven animals inoculated with the serum dated August 24, died with the characteristic symptoms of tetanus. Nine animals were not affected, and three animals died of causes other than tetanus. In every instance the animals used were injected subcutaneously, with the observance of all necessary antiseptic precautions. Daily notes were taken of the condition of all the animals used.

IV.

It will also be seen from the appended tables,* that, while some of the serum dated August 24 was toxic, other samples labelled August 24 were found to be perfectly harmless.

V.

The result of our experiments has demonstrated unquestionably that none of the serum examined by us contained the organism of tetanus, either in the active or in the resting stage (spores.) On the other hand, our experiments have shown that those samples of serum which caused tetanus contained the tetanus toxin preformed.

*The tables in the original report are omitted here for lack of space. The conclusions, however, are plainly stated in the text of the report. [EDITOR, PHILADELPHIA MEDICAL JOURNAL.]

The following facts lead us to this conclusion:

1. Seventeen animals inoculated with different amounts of cerebro-spinal fluid, bloodserum, or suspensions made from the tissues at the point of inoculation, did not develop tetanus.

2. Culture tubes inoculated with thirty (30) different samples of the City Diphtheria Antitoxin dated August 24 and September 30, remained sterile. These tubes were subjected to aerobic as well as anaerobic conditions.

3. One cubic centimeter of the toxic serum heated to 50° centigrade for 45 minutes, was injected into a mouse without causing any toxic symptoms. One cubic centimeter of the same serum, unheated, killed a full-grown guinea pig within three days. As is well known, the spores of the tetanus bacillus resist a temperature of 80° for over one hour, while the toxin is destroyed when exposed to the temperature used in the experiment, for the time stated.

4. Suspensions from the tissues at the site of the injection in animals which had died of tetanus after injection of the toxic serum, failed to produce any symptoms of tetanus when injected into other animals.

5. In no case was there suppuration or inflammation at the point of inoculation, which tends to show that the serum contained no micro-organisms of any kind.

6. Small amounts of the toxic serum did not kill animals when injected, although these animals showed typical symptoms of the disease, and subsequently recovered.

VI.

As some of the serum dated August 24, and all of the serum dated September 30, tested, proved toxic to our animals, while other portions of the serum of August 24 proved nontoxic, it was our task to determine whether the three portions of the serum differed also in other respects. The result of our experiments in this direction proved that the toxic serum dated August 24 and the serum dated September 30, were identical, and that the non-toxic serum dated August 24 could easily be differentiated from it by other properties than its harmlessness. This conclusion was reached from the following experiment:

1. There was a distinct difference in the appearance of the toxic sera, on the one hand, and the non-toxic serum on the other. The toxic sera were more opaque than the non-toxic.

2. The absolute weight of the two toxic sera and the non-toxic serum differed. The toxic sera were found to be heavier than the non-toxic serum.

3. The same difference between the toxic sera, on the one hand, and the non-toxic serum on the other, was observed in the specific gravity; the toxic sera agreeing in this factor, and the non-toxic serum showing a difference.

4. The same difference between the non-toxic serum and the toxic sera was also apparent in the reaction. In order to determine the reaction of the three portions of serum, we have titrated a number of portions of all the samples with both litmus and phenolphthalein. All three sera reacted acid toward phenolphthalein, and alkaline toward litmus.

5. The amount of chlorine in the toxic sera was found to be greater than the amount present in the non-toxic serum.

6. The lutein band in the green portion of the spectrum in the non-toxic serum was more apparent than in the two toxic sera, the latter resembling each other very closely in this particular.

7. The lowering of the freezing point below the freezing point of distilled water (molecular concentration) was greater in the toxic sera than in the non-toxic.

8. The effect of the toxic serum of August 24 and the serum of September 30 upon animals was the same.

9. Tests of the antitoxic potency of the three samples of serum, the toxic and non-toxic serum of August 24, and the toxic serum of September 30, were made. The results of these experiments show that the toxic serum of September 10 and August 24 contain the same number of diphtheria antitoxin units, while the non-toxic serum of August 24 contains a smaller number of said units.

VII.

In order to determine the toxic strength of the serum which we had found contained the tetanus toxin, a num-

ber of animals were inoculated with varying quantities of this serum. Thus it was found that .1 of a cubic centimeter contained the minimal fatal dose for a guinea pig 300 gms. weight. From this very interesting deductions can be drawn as to the smallest amount of tetanus toxin fatal to a human being. If we consider 25 kilos the average weight of the children that died from tetanus, and that 10 c.c. of the serum proved fatal in all cases except in those in which tetanus antitoxin was administered early enough, an approximate computation can be made. That the dose of 10 c.c. of the serum contained not much more or less than the single fatal dose of tetanus toxin, is illustrated by the gradual increase in the severity of the symptoms in the three Goldstein cases. While the youngest child, 3½ years old, exhibited the typical picture of tetanus, the middle one, 11 years old, showed the symptoms less aggravated, and the oldest child, 14 years old, showed only incomplete trismus.

If, then, we reduce the amount of toxin necessary to kill a guinea pig, and on the other hand that necessary to prove fatal to a human being of 50 pounds weight, we find the relation of their susceptibility is 1 to 0.83, or if we take the horse, with double the susceptibility of the guinea pig, we obtain for the human being a susceptibility of about half that of the horse.

CONCLUSIONS.

As the result of our investigations we draw the following conclusions:

The diphtheria antitoxin prepared by the Health Department of the City of St. Louis, and dated September 30, and some of the serum dated August 24, was the cause of the recent deaths from tetanus in the cases where this tetanus was used.

This antitoxin was sterile, but contained the toxin of the tetanus bacillus in considerable amount.

There were two different sera issued under the date of August 24. One portion not containing the tetanus toxin and characterized by other properties, while the other contained the tetanus and was identical with the serum bearing the date of September 30.

The most important result we have arrived at is the positive demonstration that the toxic serum dated August 24 and that dated September 30 are identical. From this we conclude that the serum of September 30 was issued without having been tested by the proper methods, and that a part of it was filled into bottles bearing the date of August 24, and were furnished with labels having previously been stamped with this date. We are justified in drawing this conclusion from two observations. First, that the serum of September 30 was issued before there was time to have performed the simple tests necessary to determine the antitoxic potency of the serum. Second, in the same way, serum dated October 23 came into our possession on November 1. This serum had been issued to physicians by the Health Department, and by them returned to the coroner. It is obvious from this that no animal experiments could have been made with this antitoxin. As this was the case with the serum of October 23, it is the natural inference that the serum of September 30 was issued in the same way.

We must deny any possibility of latent tetanus having existed in the horse "Jim" from August 24 to September 30, as no well authenticated cases have been reported in which the incubation period extended over seven days. In experiments directed to test this point. The period of incubation cannot be determined from clinical observation, from the nature of the case.

It therefore follows from this that the serum drawn on August 24 was free from tetanus, but that the serum of September 30 was drawn during the period of incubation, and had it been tested upon animals it must necessarily have revealed its toxic properties.

From the foregoing facts we are forced to conclude that the diphtheria antitoxin prepared by the City Health Department has been issued before it was possible to have obtained results from the absolutely necessary tests. Had these tests been performed, the results upon animals would have been such that the serum would not have been dispensed, and the cases of tetanus forming the basis of this report could not have resulted.

SPLANCHNOPTOSIS.

Factors: A. Relaxed Abdominal Walls (including Pelvic and thoracic diaphragm);

B. With Consequent Distalward Moving of Viscera;

C. Gastro-Duodenal Dilatation, (with report of two operations for its relief and a rubber air pad as a supporter).

By BYRON ROBINSON, B. S., M. D.,

of Chicago.

The year 1885 was an eventful one in the pathology and treatment of relaxed abdominal walls, and consequent splanchnoptosis. This was the period in which Glenard's labors became known. But Glenard was not the only one working on the subject of splanchnoptosis. Czerney and Keher, of Heidelberg, were presenting cases of visceral ptosis in their clinics in 1884, and as a pupil I gained some views of the subject. However, during a whole year's study in Berlin, in 1885, with distinguished surgeons, the subject was not once discussed. Subsequently, in a year's course of study with noted German specialists, Professor Schröder showed

many subjects of splanchnoptosis. Dr. Landau, who wrote "Wander Niere" (wandering kidneys), and "Wander Leber" (wandering liver), gave extensive courses and discussed relaxed abdominal walls and consequent splanchnoptosis, with interest. In fact, among Germans the term "Hängebauch" (hanging belly) has been common for twenty-five years. Dr. August Martin presented instructive views on the subject in his excellent gynecologic course to physicians. During the past fifteen years I pursued the study of splanchnology among hundreds of gynecologic patients, both medical and surgical, and in the personal abdominal inspection of 500 adult autopsies. In this paper I will present essentials of the knowledge gained in that experience. The abdominal wall consists of oblique, perpendicular and transverse muscular layers woven in a powerful fascial band.

All abdominal muscles are fixed on bony parts, as the costal iliac and pubic crests, as well as the vertebral column, while the diaphragm is inserted into the ribs and vertebral column with its vault fixed by the pericardium. The abdominal wall is covered externally by skin and internally by peritoneum—both powerful and elastic membranes. Certain weak, yielding, muscular and fascial lines exist in the abdominal walls, viz.: (1) Musculi recti abdominales arise from the pubic crest and become inserted into the ribs and os sternum. The two recti muscles which lie parallel to each other are the ones which preserve the delicate visceral poise. Slight extra.intra-abdominal pressure produces diastasis of the muscles. In splanchnoptosis, the recti show (a) diastasis, (b) elongation, and (c) separation of the fibres, (d) extensive thinning and flattening, and (e) atrophy.

(2) The fascial lines which yield in splanchnoptosis are (a) the linea alba, which I have noted three inches wide, the fascial fibres are elongated and separated, making the abdominal wall very thin and lax in the median line, (b) the lineae semilunares which also become quite thin and lax, the fascial fibres elongate and separate, (c) the fibres of the linea transversae, inscriptiones tendinae or the abdominal ribs, which elongate and separate.

The physiologic action of the abdominal wall is a combined one, as the varied direction of its muscular fibres indicate. We may indicate its physiologic action in certain directions. 1. The abdominal wall acts as a circular band, to fix and support the abdominal viscera as the neuro-vascular visceral pedicles are not intended for mechanical visceral support. 2. The abdominal wall is a highly elastic apparatus. It distends and contracts fitting the abdominal contents. The skin and peritoneum are exceedingly elastic. Observe how the skin and peritoneum will return without a fold to the normal state after distention from gestation, ascites or tumors, etc. 3. The physical function of the abdominal wall is aided by its capacity of contraction and of extension in respiration, defecation, urination, expulsion of uterine contents; in laughing and coughing. In short it is the function of the abdominal wall to contract and dilate in the volume changes of the abdominal contents, as well as the volume changes in the thorax. 4. The physiological function of the abdominal wall is to keep up a vig-

FIG. 1.—The abdominal aorta and its branches. The vessels affected in splanchnoptosis are: 1, the splenic; 2, the renal; 3, the superior mesenteric (9); 4, the inferior mesenteric (11), and 5, the spiral segment (12 and 13) of the utero-ovarian artery (Author's circle); 6, the gastric; 7, the hepatic.

ilant guard, a vigorous but delicate elastic regulation of abdominal visceral contents. The elastic spanning of the abdominal walls maintains a delicate visceral poise.

Relaxed abdominal walls arise in various forms

FIG. 2.—A profile view to illustrate how the transverse segment of the duodenum is clamped by the superior mesenteric artery vein and nerve in splanchnoptosis. Note the excessive distalward movement of the collective loops of the enteron. The more the loops of enteron pass into the pelvis the more acute becomes the mesenterico aortic (vertebral) angle. This illustrates the 3rd factor in splanchnoptosis.

D—Duodenum. C—Colon.

in different subjects. Not all thin abdominal walls are relaxed, neither are all relaxed abdominal walls thin. The elements, the fascial, elastic and muscular fibres must be separated and elongated to constitute relaxed abdominal walls, which are best observed in the erect attitude. The causes of relaxed abdominal walls lie in the elements of the wall itself, viz.: fascia, muscle, peritoneum, skin and elastic fibres. The fine tonus of the wall, its delicate elasticity may be lost. Its fascia and muscular fibres are separated and elongated. It is flaccid and hangs too far distalward and the unsupported viscera follow it. There seems to be a limited life for the abdominal walls, as there is for the utero-ovarian vascular circle of the genitals. For the abdominal walls begin, as a widely applicable rule, to relax at about 35, and continue to relax or atrophy to the end of life. There can be no doubt that the elastic fibres

elongate and separate, perhaps also atrophy, for the abdominal wall is not only relaxed but is thinned out. It may be that at a time of malnutrition the abdominal walls become relaxed, never subsequently recovering their normal state. Relaxed abdominal walls frequently follow continuous fevers, gestation, ascites or any factor which increases intra-abdominal pressure. The most frequent supposed cause of relaxed abdominal wall is rapidly repeated gestation. In every gestation physiologic diastasis of the muscoli recti abdominales occurs. It is not infrequent to find the recti muscles three inches apart at the end of gestation. But relaxed abdominal walls are not confined to women, as the testimony of the 311 recorded autopsies of men proved, there being frequent splanchnoptosis in these cases.

The pelvic and abdominal viscera are liable to frequent dislocation. In 500 adult autopsies I found local peritoneal adhesions in over 80 per cent. In other words, more adult subjects have dislocated viscera from peritoneal adhesions than normally situated ones. The neuro-vascular visceral pedicle, the mesentery, becomes elongated and glides distalward on the dorsal abdominal wall. The distalward dislocation of the dorsal attachments of the mesentery allows (a) elongation of the mesentery, (b) an excessive range of visceral motion, (c) the abdominal and the pelvic organs pass distalward and crowd into the pelvis, (d) Splanchnoptosis compromises circulation and deranges secretion, (e) disorders of peristalsis, (f) traumatizes nerve periphery, (g) it impairs nourishment, (h) it produces especially indigestion, (i) it invites constipation. Splanchnoptosis accompanies a defective nervous system of congenital origin. As it increases every decade, after 35 years of age it is liable to cause stenosis or partial obstruction of the tractus intestinalis from traction of one part and elongation of the remaining parts of the mesenteries. It compromises canalization. The effects of splanchnoptosis (Glenard's disease of 1884), on individual abdominal organs, are varied and numerous.

The tractus intestinalis is affected chiefly by: (a) compromising of circulation, blood and lymph supply, i. e., congestion and decongestion, (b) trauma of nerve centers, strands and nerve periphery, (c) complication from loss of peristalsis and atony of bowel muscle, (d) gastro-intestinal catarrh and indigestion from excessive, deficient and disproportionate secretions. Also dragging on the abdominal brain, an independent nerve center producing nausea, neurosis, headache, reflexes, and deranges secretion and motion on other viscera. (c) Dilatation of the stomach and duodenum, caused by the superior mesenteric artery, vein and nerve, obstructing the duodenum at this point where they cross the transverse segment. The stomach is especially liable to dilatation from the above causes, where the prolapse of the enteron, enteroptosis is sufficiently advanced to allow the enteronic loops to pass distalward into the lesser pelvis and particularly when the subject lies on the back, for then the superior mesenteric artery, vein and nerve are put on a stretch and they constrict vigorously the transverse portion of the duodenum. (f) the enteronic loops

being dislocated (enteroptosis) into the pelvis, peristalsis, secretion, circulation and nerve periphery are compromised, followed by catarrh, constipation and indigestion. (g) the colon, especially the colon transversum, may lie in the lesser pelvis, producing similar compromising circumstances as in the enteron. (h) The appendages (liver, pancreas, and spleen) of the tractus intestinalis, in ptosis are compromised in circulation, secretion and nerve periphery.

FIG. 3 represents elongation of separation of the fascial and muscular fibres of the abdominal wall—the incipient factor in splanchnoptosis. This cut is taken from an elderly female subject. 4 and a, b, is the separated and elongated linea alba. 3 and 5 are the diastatic musculi recti abdominales. 2, 2, are the separated and elongated linea semilunares. 6, abdominal muscles.

In splanchnoptosis the *genital tract* suffers, especially in circulation and nerve periphery as well as secretion. Uteroptosis may arise to such an excessive degree of mobility that the uterus may be pushed above the umbilicus and in any portion of the great pelvis.

The *urinary tract* suffers in splanchnoptosis, chiefly from dislocation of the kidney (right) nephroptosis. From several hundred autopsic inspections and living abdominal sections, I can say that in many subjects the kidney (right) has motion and range of 4 inches, 2 inches proximalward and 2 inches distalward. Large numbers of subjects have a right kidney range of 3 inches, $1\frac{1}{2}$ inches proximal-

ward and $1\frac{1}{2}$ inches distalward. The mobility of the right kidney is of extreme importance in gynecology, as its symptoms mimic or simulate genital disturbances. In my practice 60 per cent. of multipara have a movable kidney, proved by examination in the horizontal and erect positions. The mobility of the right kidney is due to (a) the longer right renal artery, (b) the liver through the diaphragm forces the right kidney distalward, (c) muscular trauma of the diaphragm, quadratus lumborum and tight lacing, (d) absorption of pararenal fat, (e) the abdominal cavity of woman is funnel-shaped, with the large end of the funnel distalward, and hence the kidney receives less support below than it does in man, (f) subinvolution attacks the "Wolffian body." (g) The erect attitude. By continual relaxation of the abdominal walls its physiological and anatomic functions are impaired. The physiological regulation and chief anatomic support of the viscera are unbalanced, and the delicate visceral poise is lost. The abdominal viscera move distalward, become prolapsed following the relaxed abdominal walls. The condition of relaxed abdominal walls is followed by splanchnoptosis. Of the three great systems of the abdominal viscera, the tractus genitalis, tractus urinarius and the tractus intestinalis, the last suffers the most severely. Relaxed abdominal walls are followed by dislocated viscera. A viscus is dislocated when it is permanently out of position. In general a dislocated viscus suffers from trauma of its nerve periphery and its blood, and lymph vascular system is compromised. Also the nourishment of a dislocated viscus is defective, irregular. Dislocated or prolapsed viscera are the segments of vicious circles. Relaxed abdominal walls are followed by partial hernia, especially in the pouches of the most yielding parts, as the linea alba, supraumbilical and the lineae semilunares or the various defective rings.

In the following scheme are noted not only the three great factors in splanchnoptosis, but other detailed factors:

SPLANCHNOPTOSIS.	1. Relaxed abdominal walls	<ul style="list-style-type: none"> a, separation and elongation of fascial fibres. b, separation and elongation of muscle fibres. c, damaged elastic fibres. d, Diastasis of recti-abdominales. e, Defective pelvic floor. f, Defective diaphragm. 	
	2. Elongations of mesenteries with distal movement of viscera and mesenterial insertions.	<ul style="list-style-type: none"> a, Tractus intestinalis. b, Liver, spleen, and pancreas. c, Tractus urinarius. d, Tractus genitalis 	<ul style="list-style-type: none"> Gastrium Enteron Colon (appendages) Liver, spleen and pancreas. Kidney Ureter Bladder Urethra Uterus Oviducts Ovaries Vagina
	3. Gastro-duodena dilatation	Compression of the transverse segment of the duodenum by the superior mesenteric artery, vein and nerve.	

PROGRESSIVE FACTORS IN SPLANCHNOPTOSIS.	Vessels	Arteries Veins Lymphatics	Dislocated Lumen compressed. Dilatation. Contraction. Anemia. Congestion. Disordered circulation. Malnutrition.
	Glands		Excessive secretion Deficient secretion Disproportionate secretion.
	Respiration		Accelerated Slowed Irregular Disordered, deficient Oxygenation
	Visceral Function		Exacerbated Inhibited Irregular.
	Nerves		Traumatized (pain) Disordered motion Disordered sensation Muscular incoordination.

Results of Relaxed Abdominal Walls on the Tractus Intestinalis.

In splanchnoptosis the most damaging influence rests on the tractus intestinalis. The normal situation of the tractus intestinalis with its appendages (liver, pancreas, and spleen) is changed, disordered. The circular band apparatus of the abdominal wall

is relaxed. The long-neuro-vascular visceral pedicle allows the segments of the tractus intestinalis and its appendages to follow the relaxed abdominal wall, and hence move out of their normal range, compromising blood and lymph circulation and traumatizing nerve periphery. There is at once a disproportionate action between traumatized nerve periphery and separated, elongated fascial and muscular fibres of the abdominal wall. Muscular tone and nerve energy become deranged. Since the abdominal wall becomes relaxed, the segments of the tractus intestinalis become dislocated permanently from a normal position. Since the neuro-vascular visceral pedicles are not elastic, and not for the purpose of mechanical support, the viscera will pass distalward, i. e., in the direction of least resistance. The spacious abdominal cavity allows the viscera to shift and glide from weight according to the position of the patient. The mesenteries of course elongate when their essential support, the abdominal wall, yields. The visceral supports or visceral fixation apparatus are (a) the abdominal wall, (b) the pelvic diaphragm, and (c) the thoracic diaphragm. Any yielding of any one of these segments a, b, or c, increases the abdominal space and creates a disordered relation between viscera and supports. It may be a neurosis, malassimilation from disordered circulation (lymph and blood), or it may be disordered visceral motion (peristalsis) from the trauma and infection of the ganglia myenterica (Auerbach's ganglia) or disordered secretion from disordered action of the Billroth-Meissner plexuses, from trauma and infection. Constipation may occur. The form of the abdomen shows that the tractus intestinalis is dislocated distalward. In aged and spare persons the actual form of the bowel segments and the peristaltic movements may be observed through the thin abdominal wall. The tractus intestinalis in splanchnoptosis is manyfoldly dislocated. On account of the fact that while the subject of relaxed abdominal walls does not manifest the disease while lying on the back because the abdomen is flat, the autopsist does not observe the splanchnoptosis. It is the clinician who is impressed with the splanchnoptosis, when the subject is in the erect attitude manifesting the "hanging belly," but the clinician loses his usefulness because he scarcely ever sees the autopsy. It is the clinical and autopsic observation that brings out the required data. The great segments of the tractus intestinalis, gastrum, enteron, and colon, become disordered, deranged in relation, changed in situation. The flexures of the tractus intestinalis become more flexed, rigid supports become elongated, secondary supports are put on stretch and the lumen of the tractus intestinalis is stenosed and compromised in numerous places. Canalization is compromised. The rigid ligaments as the ligamentum hepato-duodenale, ligamentum costo-colicum will not yield as much as the adjacent slacker and weaker ligaments, hence the hepatic and splenic flexures become more and more flexed, stenosed. Food passes them with

FIG. 4 represents the surgical procedure which encloses the musculi recti abdominales in a single sheath. 1 and 2 represent the anterior sheaths of the recti partially united in the middle lines. 10 and 12 represent the posterior sheaths of the recti partially united in the middle line. 5, the linea alba. 8 and 9 the recti sheaths lifted up to show the recti muscles. This operation I have employed for 5 years.

FIG. 5 represents the appendix and cecum in its relation to the psoas muscle as a standard for position and peritoneal adhesions from trauma of the psoas muscle. In splanchnoptosis the fixation apparatus of the cecum and appendix is elongated and allows these organs to assume a potential position. Whence the appendix might rupture in dangerous area of the peritoneum as the enteric or diaphragmatic area. The appendix lying on the vertebral column is in the potential position.

difficulty. For example, there are 5 points to consider in regard to the fixation apparatus of the duodenum, viz.: 1. The duodenum is as a whole fixed. It has lost its peritoneal mesentery on both surfaces of the mesoduodenum and its middle mesenteric layer (*membrana mesenterii propria*) is fixed or coalesced to the dorsal wall. It is also fixed by the *musculus suspensorius duodeni*, and the strong ligamentous band from the left crus of the diaphragm. Also the head and body of the pancreas aids in fixing the duodenum.

2. The pylorus or proximal end of the duodenum is fixed to the vertebral column, to the liver, kidney and stomach.

3. The flexura duodeno jejunalis or distal end of the duodenum is especially fixed by *musculus suspensorius duodeni* and the strong fibrous and ligamentous band from the left crus of the diaphragm.

4. The duodenum being fixed, it can not move distalward, while all the other abdominal organs glide distalward during splanchnoptosis. Hence, the transverse segment of the duodenum becomes compressed by the superior mesenteric artery, vein and nerve, inducing gastro-duodenal dilatation. The

compression of the duodenum is due to the mesenterico-aortic (vertebral) angle becoming more and more acute as the splanchnoptosis progresses, and finally, when the enteron lies mainly in the pelvis,

FIG. 6.—Author's rubber air pad for visceral ptosis half distended. It is to be placed inside an abdominal supporter. 1. side of rubber pad; 2. the rubber tube through which the rubber pad can be distended with air. (This rubber air pad is manufactured by John Drake & Co., of Chicago.)

the mesenterico-vertebral angle is very acute, allowing only a small space for the duodenum. The passing distalward of the stomach stenoses the fixed pylorus, and the passing distalward of the enteron makes more and more acute the flexura duodeno-jejunalis, because the distal end of the duodenum especially is quite rigidly fixed. The ileo-cecal sphincter and angle are not so much stenosed, as both colon and distal ileum move distalward together, retaining the normal angle or relations. The duodenum may be deranged only the mobile right kidney through the *ligamentum duodeno-renale*. The dragging of the dislocated kidney aids to kink or stenose the duodenum, the retention of foods in the stomach, and thus enhances gastric fermentation, catarrh and dilatation.

The Flexura Coli Hepatica.

The flexura coli hepatica suffers in splanchnoptosis, because as the stomach passes distalward it forces the colon transversum before it and hence makes more and more acute the hepatic flexure. I have seen the transverse colon in the pelvis and 9 inches of it as an inguinal hernia. It would at first appear impossible for the food to pass such colonic angles, but it should be remembered the peristalsis is continued by means of the activity of local segments. However, since the hepatic flexure is generally an obtuse or right angle, its flexure is seldom drawn so tightly by the *ligamentum hepatocolicum* as to produce very vigorous stenosis. Besides, in splanchnoptosis the liver yields through its mesohepar and follows to some extent the distalward movements of the hepatic flexure, relieving its angle from acute bending.

The Flexura Coli Lienalis.

The flexura coli lienalis forms normally an acute angle. It is the remnant of the *ligamentum recto-lienalis* of the lower mammals and quadrumana. It is a distinct, direct apparatus fixing the colon to the costal wall. In splanchnoptosis the splenic flexure

is dragged on and its angle made more acute. The spleen also participates in the general splanchnoptosis passing distalward, gliding anterior to the colon, as shown in the autopsies, as far as the pelvic floor. This increases the acuteness of the colonic flexure, obstructing the fecal current. The stomach also forces the middle of the transverse colon distalward, which stenoses the hepatic and splenic colonic flexures in direct degree to the extent of the gastropptosis.

FIG. 7.—Profile view to illustrate the pressure of the rubber air pad on the abdomen. 1, distended rubber pad; 2, wall of abdominal supporter over rubber pad.

Also the colon transversum in extensive distalward movements is often forced into a V-shaped condition, with acute bends becoming adherent by plastic peritoneal adhesions, due to bacteria or their products passing through the colonic mucosa, myocolon to the serosa, resulting in peritoneal exudates and organized peritoneal adhesions. All dislocation of the viscera compromises them, especially if it be by a peritoneal adhesion. All dislocation of viscera compromises peristalsis, fecal blood and lymph circulation and traumatizes nerve periphery. Besides, splanchnoptosis is a general term. The tractus intestinalis and its appendages, the tractus urinarius and the tractus genitalis, all share in the distalward movement due to relaxed walls, so that splanchnoptosis of the tractus intestinalis is made worse by the nephroptosis (especially on the right side), hepatoptosis, splenoptosis and genital ptosis. The enteroptosis is especially responsible for the gastro-duodenal dilatation, because the duodenum cannot pass distalward from a definite fixation apparatus, and the superior mesenteric artery, vein and nerve—the constricting arm—compresses the transverse duodenum tighter the more the enteronic loops pass distalward into the pelvis. Again, the distalward dislocation of the colon favors fecal accumulation, which favors migration of germs or their products through mucosa muscularis into the peritoneum, inducing plastic peritoneal exudates

and organized peritoneal adhesions. The peritoneal adhesions compromise all anatomy and function of the segments of the tractus intestinalis. Again, a tractus intestinalis made defective by dislocation and fecal accumulation becomes an easy prey to *muscular trauma*. Muscular trauma of the psoas, for example, makes over 70 per cent. of the peritoneal adhesions on the right side (adjacent to the appendix, cecum, and distal ilium), and over 80 per cent. on the left side (in the mesosigmoid). Other abdominal muscles produce equal damage by trauma of their segments of the tractus intestinalis, according to the power of the muscle. Now, the less drained and more defective, the more damage arises in the tractus intestinalis from muscular trauma.

The fecal accumulations are most damaging when collected in the most dependent colonic segments, as the cecum, middle or transverse colon and sigmoid; besides it favors hernia, invagination and volvulus. Doubtless it is the stenosed and superior flexed splenic flexures of the colon which produces the dull pain and fecal accumulation with dullness or percussion. The multiple stenosing of various segments of the tractus intestinalis (and perhaps the ductus hepaticus) in splanchnoptosis, is of a temporary character, because on change of the erect to the horizontal position the stenosis of the tractus intestinalis is damaging from the point of circulation, nourishment and assimilation.

It induces trauma on secretory, sensory and motor nerves, it produces irregular congestion and decongestion, its muscularis is impaired by irregular local contraction and dislocation. Dislocation of the tractus intestinalis indicates absorption of deleterious products. The relaxed abdominal walls having lost their power of contraction, the fecal current is defectively driven distalward. From loss of tone in the diaphragm, abdominal wall and pelvic floor, through overstretching, defecation is difficult and hence fecal and gas accumulations are distressing. Discomfort almost always attends the patient with any considerable degree of splanchnoptosis from traumatized nerves, or from distension with gas or food, from incapacity of the abdominal walls to hold the viscera in the normal position. If a subject with distinct relaxed abdominal walls be examined per vaginam or per rectum, stagnated fecal accumulation will be found in the sigmoid and if the cecum assume the pelvic position (female 20 per cent., males 10 per cent.), it may also be found filled with feces. The abdominal wall (thoracic and pelvic diaphragm) having lost their tone, defecation is not only difficult but defective. Besides, long retained feces in the colon induce catarrh of the colonic mucosa, resulting in the absorption of toxic substances. *Meteorism* arises in splanchnoptosis from excessive, deficient or disproportionate secretion and consequent fermentation, from stenosing of the tractus intestinalis, from loss of power in the abdominal walls, from catarrh due to constipation, from expansion of gas due to rise of the temperature after toxic absorption. Such subjects have a foul-smelling breath from the gases being absorbed by the veins in the tractus intestinalis and becoming exhaled through the lungs. Meteorism induces pain and discomfort from pres-

sure and dislocated viscera. The results of splachnoptosis are constipation, catarrh of the different segments of the tractus intestinalis, icterus through pressure, and stenosing of the ductus hepaticus. Also the nephroptosis induces stenosing of the duodenum and ureter by kinking and rotation.

FIG. 8.—The rubber air pad is fitted to the abdomen inside the abdominal supporter. 2, 3 are rubber tubes to fix the abdominal supporter.

Patients subject to splachnoptosis suffer frequently from discolored skin and irregular kidney secretion, also from nausea, vomiting, irregular and obscure pains, with continual weakness.

The Circulation in Splachnoptosis (compromised).

In operating on the deep glands of the neck, where the large veins are isolated, it is very plain that respiration governs to a certain extent the venous circulation. Now, the diaphragm, pelvic and thoracic, as well as the anterior abdominal walls, when in proper tone normally influence the circulation in the abdominal veins. If the abdominal walls are relaxed, it becomes evident in difficult defecation and in the same manner the venous circulation of the abdomen suffers from lack of pressure. With relaxed abdominal walls the abdominal veins (and the entire system) are congested and stenosis results. As a sample of the evil effects of relaxed abdominal walls and consequent splachnoptosis, in repeated pregnancy there is heart weakness, because the veins of the abdomen are too constantly overfilled with excessive blood, robbing the heart of its required amount. Since receiving instruction from Prof. Schröder, some fifteen years ago, I continued the study and investigation of this subject. In relaxed abdominal walls one sees the distended veins of the extremities, the extensive and prominent veins of the vulva, as well as the large hemorrhoidal nodes. Besides the frequent and free uterine hemorrhages occur. In post mortems I

have carefully noted that subjects with splachnoptosis possess a plexus pampiniformis with straightened-out irregularly dilated veins. Spiral and uniform calibered veins are normal. In advanced splachnoptosis the pelvic veins, especially of the genitals and rectum, are widely and irregularly dilated, holding enormous quantities of blood. This causes hyperemia, congestion and stasis of the pelvic organs, resulting in hemorrhage, malnutrition, and pathologic changes in the genitals. The liver suffers likewise from congestion, hyperemia and blood stasis, for it drains the tractus intestinalis (spleen and pancreas) and the liver, by its dislocated position, compromises the blood current, especially in the portal and hepatic veins, besides, the dislocated liver drags or compresses the inferior vena cava, stenosing it. If the liver be dislocated to any considerable extent, which is frequent in gynecologic patients, the definite relations of the portal vein are disturbed, the liver veins and the inferior vena cava are dislocated or compromised, as the vena cava lies on the rigid dorsal wall. Venous circulation is of more physiologic and complex delicate nature than arterial, which is more mechanical, and is easily compromised by relaxed abdominal walls, by position, by disturbed respiration, by stenosing of venous lumen and by splachnoptosis. The veins of the abdominal wall are dilated and compromised as is noted by the enlargement, conspicuously observed in the inferior and superior epigastric veins. Continuous hyperemia, congestion and stenosis in the dislocated viscera produces pathologic changes in the organs themselves, impairing sensation, motion, secretion and nutrition. We thus have a vicious circle which might be called the visceral disease. Relaxed abdominal walls and consequent splachnoptosis disturbs a wide area of complicated functions. They distort an extensive and delicate mechanism, resulting in impaired respiration, circulation, sensation, motion and secretion and in the end result in malnutrition and neurosis.

FIG. 9 represents a normal transverse segment of the abdominal wall. About the umbilicus. 1, rectus; 2, skin; 3, fascia; 4, fascia; 5, external oblique; 6, transversalis; 7, peritoneum; 8, linea semilunaris; 9, linea alba; 10, spinal muscles; 11, quadratus lumborum; 12, psoas muscle; 13, vena cava, and 16, aorta.

The Respiration in Splachnoptosis (irregular).

The prominent symptoms of the respiration in splachnoptosis are shortness of breath, irregular long respiration, difficult breathing and asthmatic breathing with cardiac palpitation. The relaxed ab-

dominal muscles, the respiration muscles, have lost their power and perfect muscular relaxation is not possible. Complete respiration is muscular relaxation and contraction. In the erect attitude the dislocated liver drags on the diaphragm through its coronary ligaments, and through the vena cava. Besides, the liver is in turn dragged on by the tractus intestinalis through its two ligaments attached to the liver, viz., ligamentum hepato-colicum and ligamentum hepato-cavo-duodenale, resulting in disturbance of a respiratory organ—the diaphragm. The irregular respiration—a frequent symptom of relaxed abdominal walls and consequent splanchnoptosis—is another link in the vicious circle, because it imperfectly and irregularly oxidizes the blood, disturbing nutrition.

(To be Continued.)

A CASE OF PISTOL SHOT WOUND OF THE STOMACH, LIVER, AND TRANSVERSE COLON, IN A PREGNANT WOMAN. RECOVERY AND DELIVERY AT TERM.

By ANDREW B. GLONINGER, M. D.,
of Lebanon, Pa.

Surgeon to the Good Samaritan Hospital.

Whilst I do not wish to pose as an authority on gun shot wounds, my experience with this class of cases has been considerable, and I have been so impressed with the value of drainage in wounds of this character that I have become a firm believer in that mode of procedure.

Apropos of the articles recently published in *The Philadelphia Medical Journal* by Dr. John B. Roberts and Dr. G. W. Penn, the following case should prove interesting:

On September 30th, 1895, I was called to see Kate F., who had been shot by her husband at close range with a 38 calibre revolver. The woman was young and robust, of the phlegmatic type, characteristic of the Pennsylvania German, and consequently showed slight evidence of shock, her respiration and pulse being only slightly above the normal. The physician in attendance was industriously employed in probing the wound and had succeeded in forcing a passage between the abdominal muscles and the fascia. After considerable parlying he desisted from his efforts and agreed to have the patient removed to the Good Samaritan Hospital of this city.

Pistol Shot Wound.

I found the wound to be about one inch to the left of the median line, and two inches below the ensiform cartilage. I made an incision in the median line and found that the missile had passed through the lower portion of the stomach (allowing a considerable quantity of partly digested food to escape into the abdominal cavity,) transverse colon and lower lobe of the liver. A thorough search of the abdominal cavity failed to discover its further passage or whereabouts. The edges of the six orifices made by the bullet were trimmed back to a distance of a quarter of an inch so as to remove all bruised and devitalized tissue, the edges brought together with Lembert sutures using fine catgut, torn vessels were ligated with gut, the abdominal cavity thoroughly flushed, a large drainage tube introduced, and the incision closed in the usual manner.

The patient's temperature an hour after the operation was 98.3°, pulse 84. She vomited a considerable quantity of clotted blood shortly after the operation, and complained of much pain which was controlled by hypodermics of morphia. A high enema was given on the following day. She voided a normal quantity of urine during the first twenty-four hours, slept fairly well, and was given nutritive enemata every four hours. The abdominal cavity was flushed out at frequent intervals.

On the third day she was allowed to take a little cracked ice, later on a little brandy, the nutritive enemata being continued. On the fourth day she was given two ounces of peptonized milk and had a normal bowel movement. On the fifth day she was given three ounces of malted milk and the drainage tube becoming clogged, a little extra pressure by elevating the water bag caused the expulsion of a quantity of broken down tissue through the drainage tube. On the seventh day the sutures were removed and the liquid coming clear from the abdominal cavity, the drainage tube was removed. The bowels were kept open by the use of small doses of calomel and an occasional high enema. The temperature rose on the twelfth day to 102.4°, due to a suture abscess which was opened and drained. A light diet was continued up to the fourteenth day, when the temperature reached the normal point. From this time the patient made an uninterrupted recovery.

About four months subsequent to the receipt of the injury the patient was delivered of a healthy female child. The successful termination of this operation was particularly gratifying from the fact that it saved three lives, the patient, the child, and the husband, who instead of being sent to the penitentiary for twelve years would doubtless have been hanged.

In November, 1899, I located the bullet with the use of the X-Ray in the left innominate bone.

My assistants at the operation were Dr. John Beattie, of this city, and Dr. Charles Schmehl, at present resident physician at the Warren Insane Asylum.

THE PRESENT STATUS OF THE BOITINI OPERATION AS A METHOD OF TREATMENT IN OBSTRUCTIVE HYPERTROPHY OF THE PROSTATE GLAND, DERIVED FROM A SUMMARY OF EIGHT HUNDRED AND EIGHTY-EIGHT OPERATIONS BY FORTY-EIGHT OPERATORS.

By ORVILLE HORWITZ, B. S., M. D.,

of Philadelphia.

Clinical Professor of Genito-Urinary Diseases, Jefferson Medical College; Surgeon to the Philadelphia Hospital, Jefferson Medical College Hospital and State Hospital for the Insane.

(Continued from 918).

I am indebted to Mr. M. R. Dinkelspiel, of the Jefferson Medical College, for the great amount of work so ably performed in compiling and tabulating the cases in the following table:

No.	Author and Operator.	Reference.	No. of opera- tions.	Deaths	Un- improved.	Im- proved.	Cured	Remarks
						Improved and cured (See remarks.)

49	Bangs.	N. Y. Med. Journal.	42	3	20%	20%	60%	Five of these operations were performed by Dr. Bang's assistants Dr. Pedersen and Dr. Squier.
50	Horwitz.	l. c.	3			1	2	

An analysis of these statistics gives the following results: Of 888 operations death resulted in 51 cases, making a mortality of 5.7 per cent. In 88 cases no benefit was derived from the operation, so that ten per cent. of the cases were unimproved, making 84.3 per cent. either cured or improved by the operation.

On examining the table it will be found that 435 of the cases, which were operated upon either by Bottini or his assistants, are classified under the heading "Cured and Improved," the surgeons who reported the results of the operations having failed to make any special distinction between the two results. If, then, we reject from the statistics, when considering the percentage of cures, the 435 cases referred to as not sufficiently explicit, as to cure and improvement, there will remain 453 cases of which we have definite information concerning the actual number of cures that resulted from the operation. Out of this number 214 cases of cures are recorded, giving a percentage of 47.2 per cent.

The results obtained in 888 operations may be summarized as follows:

Improved and cured, 84.3 %.

Unimproved, 10 %.

Deaths, 5.7 %.

Of 453 cases of which we have accurate information, the percentage of cures was 47.2 per cent.

It is fair to assume that the 888 individuals who submitted to the Bottini operation did so because they had arrived at that period when surgical interference was the only thing that offered any hope of relief. They were not selected as specially suited for the method of treatment employed. All were operated upon without discrimination. Every known condition, configuration, and kind of prostatic hypertrophy, frequently associated with one or more of the numerous complications and pathological changes which follow a prostatic hypertrophy, made up the number. The ages of the individuals varied from those who were entering upon the decline of life up to those who were far advanced in years.

When these cases were under the surveillance of the respective surgeons in attendance, the Bottini method was yet on trial, and its employment was still in abeyance, being largely experimental. But the results of these operations have been to place this process upon a firm basis, its advocates claiming that it is reliable and most satisfactory as well as the safest in the hands of the skilled surgeon, for the relief of senile hypertrophy of the prostate gland.

The fact that out of 888 unselected cases 715 of the number were either cured or improved, the mortality being only 5.7 per cent., confirms this statement. The value of the methods of treatment is brought more forcibly to our attention when we compare the mortality of the Bottini operation with that of other radical measures in vogue for the relief of hypertrophy of the prostate. The mortality of partial, perineal or suprapubic prostatectomy is given as 14.3 per cent. Unfortunately, the employment of this operation is limited to only special forms of prostatic overgrowths. The mortality of the

complete removal of the gland by means of either the perineal or suprapubic route is variously estimated to be between 18 and 25 per cent, whilst that of the Bottini ranges from 4.5 to 7.3 per cent., varying in the hands of different operators, giving an average of about 5 per cent. From the results obtained from the list of cases tabulated, I think we are justified in drawing the conclusions that follow:

1. There is less fear on the part of the patient to submit to the operation than there is to any other surgical procedure so far suggested for the relief of prostatic hypertrophy.

2. The principal advantages to be derived from the method of treatment are: A short time only is required to perform the operation, which is attended with little shock and usually slight loss of blood, convalescence is rapid, and the mortality is lower than that by any other radical measure.

3. Cures result in the large majority of cases, especially if the operation is undertaken early. Marked improvement may be looked for in a vast number of cases, where otherwise individuals would be condemned to suffer, as the danger attending any of the other radical methods of treatment would be too great to warrant their employment.

4. Failures occur in but a comparatively small percentage of cases, want of success being due to the pathological changes and complications which have taken place. Especially is this true in those instances where an incurable cystitis exists.

5. The operation is contraindicated when a valve-like formation exists, or where there is a greatly increased overgrowth of the three lobes, associated with tumor formation, giving rise to a pouch, above and below the neck of the bladder.

6. It may be employed with benefit, and safety, as a palliative measure in cases of prostatic hypertrophy of long standing, associated with cystitis, when the general health will be improved and constipation, which is usually associated with this condition, relieved, mitigating the prostatic spasm of the urethra, and rendering the insertion of the catheter easy and painless.

7. Pyelitis, when present, adds greatly to the danger of the operation, but is not always a contraindication to its employment.

8. The character of the growth has but little bearing on the result of the operation.

9. The operation may be employed as a safe and satisfactory means of causing a suprapubic fistula to close, which so frequently follows a suprapubic cystotomy when the prostate gland is hypertrophied.

10. In suitable cases it is not only the best radical measure thus far devised for the relief of prostatic hypertrophy, but is attended by the smallest mortality.

11. The operation is especially indicated in the beginning of obstructive symptoms due to hypertrophy of the prostate gland and may be regarded as a prophylactic method of treatment.

12. The operation is capable of producing a symptomatic cure in a great number of cases of various conditions and configurations of the prostate gland due to hypertrophy, as is shown by the disappearance of prostatic spasm, the restoration

of the function of the bladder to its normal condition, and the improvement of general health.

13. When operating early, before the prostate has become much enlarged, the safest method to pursue is to perform a preliminary perineal cystotomy, introducing the "perineal galvano-cautery incisor" of Chetwood, so as to make the incision in the prostate.

14. In some instances a prolonged preparatory treatment is necessary before the operation can be safely undertaken.

15. In cases of prostatic obstruction, which have existed for a lengthened period, where there is chronic cystitis, the physical condition of the patient being below par, both local and constitutional treatment must be persisted in for months after the operation before the great benefit derived from the procedure can be insured, which treatment would be ineffectual unless the obstruction had first been removed.

THE EARLY RECOGNITION AND MANAGEMENT OF ARTERIAL DEGENERATION.*

By LOUIS FAUGERES BISHOP, A. M., M. D.,

of New York.

The conditions that most occupy the attention of those practitioners, who take care of the health of a class of patients to whom they act in the capacity of family physician are not always diseases to which definite names are given, nor which can figure in the health reports of a community.

Such a condition is arterial degeneration, which in its latter development is often known as Bright's disease, heart disease, paralysis, gout, senility, and by many other names according to the processes that develop alongside of it, or are caused by it. In its last development arterial degeneration can go on to extraordinary deformity of the blood vessels and I have brought with me the specimens of such a case because in its last stages it presented some symptoms that are often premonitory.

A popular belief is that the chief danger of arterial degeneration is rupture of a blood vessel. The term apoplexy though originally, of course, meaning to fall suddenly, has been so far diverted from its original significance that a hemorrhage into the lungs is often spoken of as apoplexy of the lungs. The fact is that the rupture of a blood vessel is comparatively one of the least common evils of arterial degeneration. It rarely does serious damage in any part of the body except the brain, and in the brain it forms a small minority of the accidents that lead to paralysis. Far greater is the danger of the establishment of secondary disease of the heart and kidneys or the interference with the circulation in the brain even to the extent of thrombosis. If apoplexy were the only danger to be feared from chronic intoxication or over-work and worry the chances might often be worth taking. The same thing is true of aneurism, the cause of which is probably nearly always specific and very frequently associated with the history of physical toil. The form of arterial degeneration of most interest to the general practitioner, who has the care of the health of indi-

viduals over long periods of time, is that which affects the smaller arteries. It is these arteries which first give the signs of disordered function by offering an unhealthy resistance to the circulation of the blood and causing tension. The early recognition of this tension and its treatment by appropriate methods is well worth careful study. It is this tension that inevitably leads to organic changes of these smaller arteries and finally to cardiac and nephritic disease. There is, however, a stage preceding even the development of tension when under certain circumstances from an irregular action of the vaso-constrictors a tendency to tension may be detected. This irregular action of the blood vessels is most evident when involving circulation of the brain. It is shown by temporary loss of consciousness, attacks of dizziness, temporary affections of the motor areas causing clumsiness of an arm or a leg or slight evanescent aphasic symptoms. In this early stage there may be disordered action of the coronary arteries of the heart leading to temporary irregularities of action or of mild attacks of the nature of angina. In fact all the symptoms that are so familiar in cases of advanced arterial sclerosis may be imitated in a shadowy manner by the functional degenerations of the arteries that forebode organic disease. All clinical workers are perfectly familiar with these cases in the advanced stage and with the difficulty of obtaining permanent improvement. For that reason it is profitable to study the early recognition of the tendency to this condition and the management of the individual to prevent its further development. It is a disease that belongs to the most useful and successful members of the community. The slothful, colorless individual, who never accomplishes anything good or bad is in no danger of this form of arterial degeneration early in life. The most typical cases for the early recognition of this disease are seen in young men,—generally successful men, who are laboring under great mental tension and who combine their work with a certain amount of dissipation.

This study is purely a clinical one, and in practice it is extremely difficult to say when degeneration has become sufficiently advanced for gross or even microscopical demonstration. Degeneration frequently first manifests itself as a tendency, and this tendency is known by disordered function. Degeneration at first is fatty, later connective tissue is formed, and finally calcification occurs. In practice calcification, when advanced, is easily detected in the moderate sized superficial arteries. In considering the causes of degeneration of the blood vessels heredity must be acknowledged to be a powerful factor. Arterial degeneration is the natural accompaniment of advancing age, and its onset is attended with a certain amount of regularity in families. This, however, is not inevitable and the life of the blood vessels will depend for most upon the use that is made of them. Men may not all be agreed as to the wisest conduct of life. Most serious are those conditions which are well described as the chronic intoxications, that is, in which they are the poisonous or products of disease prevailing the system for a long time. Among those alcoholic poisoning, gout, syphilis, the retention products of Bright's disease

* Read before the New York Academy of Medicine, June 6th, 1901.

and chronic blood poisoning can be classed. The second series of causes are those that have to do with function, and it is upon these causes of arterial degeneration that we wish particularly to dwell. It is among men who live under a constant strain in which tension of the brain and nerves leads to tension in the arterial system and finally to functional disorders of the circulation that we may look for premature degeneration apart from the causes which have been classed as the chronic intoxications.

Fothergill, writing many years ago, in "The Heart and its Diseases," has the following very suggestive paragraph concerning tension:

"This condition is slowly developed, and up to this point the individual is often the type of health and vigor to look at. The high blood pressure gives vigor and activity to the body generally; the brain, perched at the top of the organism, is well supplied with blood, and its action is energetic and sustained. The complexion is often ruddy, showing a full vascular system; the walk is firm, showing that the muscles are well fed; the appetite and digestive processes are excellent; indeed, the individual presents the appearance of a well-nourished, active, energetic being, who never has to consult a doctor. The hard brain-workers of society, are commonly men who are in this first stage of lithiasis, and who in time will furnish the cardio-vascular changes which are the associates of the gouty heart. It does not follow, however, that there are not other persons than the stalwart and ruddy who are in this first stage, and who possess a high arterial tension. Slightly built individuals, of the nervous diathesis, may be rather pallid even, and yet have a sustained high blood pressure in their arteries, and be characterized by energy. The contrast betwixt the ruddy-complexioned persons of the gouty diathesis, and the pallid persons of the nervous diathesis, each being in the early stage of the gouty heart, is considerable; yet comparison soon brings out the points which they present in common."

The management of arterial degeneration where the tendency is distinctly recognized must consist more in hygienic measures than in the administration of drugs. If the cause be one of the chronic intoxications it is plainly necessary to make an attempt to remove the cause. Syphilis will be the cause more often than even those who are alert will believe at the time. For that reason, and from the fact that the iodides are particularly beneficial wherever there is a tendency to high arterial tension, they will find a place in the treatment of all these cases. Alcohol must by all means be limited in amount. Unfortunately there are but few individuals who having once become habituated to the use of alcohol will on the advice of a physician abandon its use. It is better therefore to lay down certain rules that are within the reach of attainment. Limit the alcohol to meal times, and reduce its quantity as much as possible. There are two drugs that are distinctly contra-indicated in early cases of arterial degeneration, and these are iron and digitalis. Digitalis is a prince among drugs when failure of circulation threatens a drowning out of life by pathologic effusions. Iron remains supreme in the treatment of the anemias and debilitating diseases

of youth. However in the early stages of arterial degeneration digitalis will hasten the development of high arterial tension and an excess of iron will act on the blood vessels as an astringent. The persistent use of alkalies to smooth the irritated blood vessels, the abundant use of water, the use of bitter tonics in small doses about complete the list of drugs that need to be considered as having a direct bearing upon arterial degeneration. The rest is the management of the physical and mental condition that predispose to arterial disease.

An interesting type of individual who comes under the care of the physician, particularly in large cities, is the man between youth and middle age, who by native ability and strenuous exertion has become successful in business and is carrying a weight of responsibility disproportionate to his antecedent training. Such a person is apt to fall into a condition of neurasthenia with disturbances of circulation strongly suggesting early arterial degeneration. One cannot say there is arterial tension, but the palpation of the pulse gives the impression of an unstable pressure showing that the arterial tone is unstable. The patient complains of momentary loss of power to fix the attention so that he suddenly for a few seconds seems to lose his grasp of things. He has a sense of pressure at the back of the head, and is decidedly apprehensive about himself. He presents the appearance of health, and indeed his color may be particularly good. In such a case the use of the bromides is of the greatest value. Bromides have the power of controlling this condition that has happily been described as chorea of the blood vessels. It is seen most strikingly in women at the menopause, but is also an early symptom of a tendency to arterial degeneration. In older people this tendency is shown by irregularity of the circulation of the brain as manifested by slight hemiplegic symptoms as described above. The use of the iodide of soda in small but persistent doses and the administration of nitro-glycerine for part of the time are of the greatest value in this type.

I received a note the other day from a patient who had these symptoms in a marked degree over a year ago. She has taken a tooth of a grain of nitro-glycerine three times a day for one week out of each month. She has been free from symptoms so that I have not had occasion to see her. It is particularly important that persons in whom the tendency to arterial degeneration is recognized readjust their lives to avoid heavy responsibility. If the individual is carrying unnecessary burdens in the way of assumed responsibilities they should be abandoned. If a business man has attained a reasonable degree of fortune he should adjust his affairs so that half of his time should be devoted to country life and the pursuit of pleasure. Every man cannot become a devotee of sport, but any one can become interested in a country place or some other out-of-door hobby.

Sansom points out the mental symptoms of commencing arterial sclerosis after middle life. He says that such a patient becomes fanciful, interspersive, low spirited, and moody, but shows no obvious signs of disease other than those of dyspepsia.

The effect of arterial degeneration upon the organs of special sense is sometimes striking. The

rupture of a small blood vessel in the eye in an individual who is past middle life, and who is suffering from the strain of over-work, that is work out of proportion to his strength, is a sign the significance of which should not be neglected. The oculists tell us that these small conjunctival hemorrhages are not important or dangerous. It is true that they often precede more serious manifestations of arterial disease by a long time, but nevertheless I have in mind an instance in which sudden death attributable to a large cerebral hemorrhage followed this occurrence. People of the temperament to be the subject to arterial degeneration are not easy to frighten or to arouse to a sense of their danger. They are generally of a sanguine type, not given to introspection or care of their health. A superficial hemorrhage being apparent will more often arouse such people to the sense of their danger, and for that reason it should not be made too light of by a physician. In the same person a really serious disorder of circulation of the brain leading to temporary loss of power or attacks of dizziness might not excite nearly so much apprehension. In dealing with degeneration of the arteries we are dealing with a condition that is essentially chronic, and for that reason one that should interest exceedingly a large class of those who care for the sick. The cry of the nurse, the medical student, and the hospital intern is for acute disease, so-called interesting cases and rare conditions. It is hard to arouse their interest in the phenomena of old age or earlier degeneration, but to the physician whose practice consists in caring for families,—both young and old—these phenomena will ever be of such importance that they cannot fail to be interesting. The problem that in the long run Ad The early Recognition and Managements etc. — is propounded to the family physician is how to attain a long life and a healthy one, and the answer is bound up in the regulation of those conditions that tend to hasten or delay arterial degeneration.

As in suspected myocarditis it is difficult to decide between cases in which the heart is functionally disordered and in which there is organic change, so with disease of the blood vessels functional degeneration will often resemble closely structural degenerative changes.

The analogy between degenerative disease of the vessels and degenerative disease of the heart is emphasized when the evolution of the circulatory system is remembered, and the fact that the heart is only a differentiation of a portion of the circulatory tube. Thus, as in myocarditis attention is directed to the coronary vessels, so in arterial disease the office of the vasa-vasorum must be remembered. Probably when the vessels of the vessels are involved the process goes on with much greater rapidity than when the disease takes another form, and it is perfectly philosophic to explain irregularities in the action of the muscles of the vessels by deficiencies in blood supply.

This problem of the early recognition of arterial degeneration is one well worthy of the exercise of the most careful judgment. Particularly

must a hasty conclusion be avoided from a single symptom.

There are not a few cases where arterial degeneration has undoubtedly started, and yet a change in the mode of life and proper treatment has brought about an arrest of the condition. Such instances are sometimes seen in young medical men, who over a period of time work under great strain and anxiety, but afterwards attain to a sounder philosophy of life and more easy circumstances. This would account for the albuminurias of over-worked young men. The relation between neurasthenia which is undoubtedly a condition of mal-nutrition of the nervous system and arterial degeneration which in its beginning is mal-nutrition of the arteries, there are several points of analogy. The first is a giving out of the nervous system and the other of the circulatory system. No doubt many a man is saved from arterial degeneration by the development of a neurasthenia that checks his tendency to over-work or limits his capacity for dissipation. Arterial degeneration is the penalty of chronic intoxication whether the intoxication is of over-work, the intoxication of alcohol, the intoxication of a too rich diet, the intoxication of syphilis. Its early recognition by the physician at a time when it can be checked and the circulation preserved and its proper management is well worthy of the attention of medical practitioners.

A CASE OF POISONING WITH OIL OF CEDAR.

By J. T. CLEGG, M. D.,

of Siloam Springs, Ark.

A. M., age 34, married, mother of two children, the youngest living a year old, never miscarried. Now pregnant in the fourth month of gestation. Was found in convulsions at 8.45 P. M., May 8th, 1901. I saw her thirty minutes later. She was comatose and having violent epileptiform convulsions recurring about every ten minutes. Pulse during the intervals between the convulsions was full and slow. Respiration was hurried and irregular, face was flushed and extremities cold, pupils slightly dilated, not reacting to light. Abdomen tympanitic. There was an odor of an essential oil on her breath. A glass was shown me that smelt strongly of oil of cedar. I gave at once 1/10 grain apomorphia hydrochlorate hypodermically, emesis occurring ten minutes later, the contents of the stomach exhaling the same odor. The stomach was then washed out as quickly and thoroughly as possible. A quart or over of a solution of bicarbonate of soda was left in the stomach thirty minutes when apomorphia was again administered, resulting in ejecting the soda solution that still smelt of the oil. After this, however, the convulsions ceased to recur. At one o'clock A. M. she was resting quietly. Although there had been involuntary discharge of urine during the convulsions, a large quantity of limpid urine was drawn from the bladder. At 8 A. M. she was restless and uneasy, but showed some indications of returning consciousness. Pulse and temperature normal, respiration remaining irregular. There were frequent, but voluntary discharges of large quantities of limpid urine. The bowels had moved once during the night, the feces having the odor of the oil. At 6 P. M., May 9th, she was still very restless but sufficiently conscious to complain of a general muscular soreness, doubtless the result of the muscular spasms of the night before. She is taking egg albumin, but no other food. 8 A. M., May 10th, she has almost regained consciousness, pulse, respiration and temperature normal, kidneys are not acting so copiously, abdominal tympany has disappeared, but she has passed a restless night and is suffering from a general muscular soreness and an indefinable uneasiness. She is taking egg

albumin in cold water. May 11th, 8 A. M. has had a comfortable night and feels fairly well, takes milk in small quantities. From this time on recovery was uninterrupted except by a tenderness over the stomach with complete anorexia and other symptoms that led me to think perhaps there might be an abrasion or even an ulcer of the stomach. About a teaspoonful of the cedar oil was taken, doubtless for the purpose of causing an abortion. Abortion did not occur and so far as I was able to observe there was no direct influence on the uterus in any way. The oil of cedar is the volatile oil of the leaves or spines of the *Juniperus Virginiana*, *Virginia* or *Red Cedar*. It is not official and is mentioned briefly in the last edition of the United States Dispensatory as having properties similar to those of the oil of savin and of having been used for the purpose of producing abortion and as having been known to cause death. It is sold as a popular ingredient of many domestic liniments, and as an insecticide. It is often sold to the public; many persons use it for the purpose of driving away flees, gnats, mosquitoes, etc. This case proves it to be a very active and dangerous poison, for not over 90 minims could have been swallowed not longer than thirty minutes before violent convulsions set in, which doubtless would have proven fatal, but for prompt interference. Moreover it was taken just after a full meal and much of it must have become diluted with the contents of the stomach, and this facilitated its evacuation by vomiting. Yet in spite of this fact alarming symptoms continued several hours, and the patient made a very slow convalescence. So far as I am informed but few cases of poisoning from this substance are recorded. But poisoning by oil of savin, which it resembles, shows gastro-intestinal inflammation with ulceration of the mucous lining of stomach and bowels. The indications for treatment of these cases are of course obvious; speedy evacuation of the stomach by emesis and the stomach pump, in addition to which I washed out the stomach with the sodium salt, hoping that the alkali would combine with the oil and thus facilitate its complete removal. I chose a bicarbonate, thinking that by setting free, by normal acid combination and reaction, a quantity of carbolic acid gas in the stomach, the stomach could be distended so that its surface could be more effectually freed from oil, some of which no doubt would have lodged in the mucous folds of the stomach.

ARCHIVES DE MEDECINE DES ENFANTS.

September, 1901. (Volume IV. No. 9.)

1. The Peritoneal Complications of Vulvo-vaginitis. JULES COMBY.
2. The Causes of Deaf-Mutism. A. CASTEX.
3. Maxillary Sinusitis in the New-born. A. CASTEX.
4. The Treatment of Croup. PECHADRE.

1.—Comby gives the case-histories of eight girls between the ages of 4 and 12, in whom peritonitis occurred as a complication of vulvo-vaginitis. In two cases the peritonitis occurred after scarlet fever, in one case after typhoid, and in one case after pleurisy. But in all case the peritonitis followed a vulvo-vaginitis, and gonococci were generally found in the discharges. Comby believes that the ordinary microbes of suppuration do not tend to cause peritonitis as a complication of vulvo-vaginitis. Peritonitis occurs suddenly, with vomiting, pain, tympany, constipation, pollakiuria, fever, cyanosis of the extremities, etc., lasting from two to eight days. Relapse is unusual. Most cases are generalized, though rarely localized or pelvic peritonitis may develop. As a rule the prognosis is favorable. Appendicitis and tuberculous peritonitis must be distinguished from gonococcal peritonitis. The treatment is primarily local, ice, morphin, normal salt injections and stimulants when necessary. For the vulvo-vaginitis Comby uses hydrogen peroxide, 1 to 12, or potassium permanganate, 1 to 1000. [M. O.]

2.—Castex, in an interesting article, gives details upon the study of the deaf and dumb. A minute history of each child is taken, a thorough physical and functional examination made, and the peculiarities of each individual are noted.

After a review of their characteristics, complicating conditions, measurements, etc., Castex discusses the causes of deaf-mutism. He concludes that this condition is as often found congenitally as it is acquired. The causes of congenital deaf-mutism are consanguinity of the parents, tuberculosis, syphilis, alcoholism, lead poisoning, or accidents occurring during pregnancy. Deaf-mutes rarely have deaf and dumb children. The causes of acquired deaf-mutism are meningitis, convulsions, brain fever, etc. Autopsy shows the majority of the cases to have labyrinthine, cerebral, or bulbar lesions. In the treatment of deaf and dumb children, gymnastics, bathing, and thyroid extract will aid the work of the instructors. The acoustic examination shows how much each child can hear, which is of value in his special instruction. The instruction of the deaf and dumb in asylums should be made obligatory. [M. O.]

3.—Castex reports a case of severe maxillary sinusitis in an infant five weeks old, upon which he operated. There was a purulent discharge from the right nostril, with abscess of the right lower eye-lid, and that side of the arch of the palate seemed somewhat raised. Pressure increased the amount of pus exuding through the right nostril. An external incision was made, the maxillary sinus evacuated, irrigated, and drainage left in. Bacteriological examination gave a pure culture of staphylococci. The child recovered rapidly. Not only was there maxillary sinusitis, but peristitis of the bones surrounding the sinus also. [M. O.]

4.—Péchadre reports two cases of diphtheria in which he performed paracentesis of the trachea, introducing oxygen through the trocar afterward. One case died and one recovered. Alcohol and antitoxin were administered in both cases. Péchadre hopes that more cases, treated in this manner, will be successful. [M. O.]

A Case of Congenital Ophthalmoplegia.—Felix Lagrange reports the case of a child of three, with double congenital ophthalmoplegia. She squinted at birth, and showed facial paralyses. The strabismus has been stationary since. There is double facial paralysis, more marked on the left side, and the eye-lids fail to close. The facial paralyses have improved as the child has grown. Refraction is normal. There is slight congestion of the optic papillae. On the right side there is complete paralysis of the right externus muscle, with paralysis of the superior facial nerve; on the left, are complete paralysis of the right externus muscle, almost complete paralysis of the superior facial, and paresis of the inferior facial nerves. There is diminished contractibility to the faradic current, but no degeneration. The origin of the facial paralyses is certainly central. Therefore it seems most probable that the cause of the paralyses of the right external muscles is also central. There is one common lesion, probably. The double origin of the facial nerve is clearly shown by this case. (*Bulletin Medical*, June 12, 1901, No. 46). [M. O.]

Experimental Data on Tubercular Toxins and Antitoxins.

—L. Ia. Frenkel and O. I. Bronstein (*Meditsinskoje Obozrenie*, May, 1901) experimented with the various derivatives of the tubercle bacillus, following largely the methods of Maragliano. Their conclusions are as follows: By means of simple mechanical processes there may be obtained from cultures of the tubercle bacilli, besides Koch's glycerin tuberculin, derivatives, such as tubercular toxins, fluid and solid; watery tuberculin and its sediment; fat-free bacilli, and a few others. (2) Many of these products possess a marked toxicity and may be subjected to accurate dosage. (3) All these substances when injected into animals in sufficiently large doses cause death, accompanied by typical phenomena. (4) By the gradual introduction of these derivatives, beginning with small doses up to the maximum dose, active immunity may be produced in animals. (5) The serum of immunized animals possesses marked anti-toxic properties, bearing a specific relation to each of the derivatives. [A. R.]

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended November 22, 1901.

SMALLPOX—United States.

Cerebellar Tumors.—At a recent meeting of the Medical Society of the Paris Hospitals, (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 20, 1901, No. 21), Henri Huchard and P. Bergougnan report the case of a patient, aged 22, in whom cerebellar tubercles were found. Hemiplegia occurred suddenly two months ago. Occipital headache, vertigo and vomiting have persisted since. She feels "drawn" over to the right. There is no paralysis, sensibility is increased, and the left patellar reflex is exaggerated. Titubation was marked. Her sight was unaffected. General convulsions occurred, with divergent strabismus and death. At the autopsy, tubercles were found in the right lobe of the cerebellum and in both occipital

lobes of the brain. There was slight meningitis. Pierre Merklen reports a case of cerebellar tubercle in a man of 18. The first symptom was intermittent, severe occipital headache; with effort this became intense. So severe was the headache that he groaned aloud, and the muscles of his neck, contracted tensely, remained immobile during the paroxysm. In five months titubation was noted. Nothing relieved the pain. Trephining was done, but ventricular dropsy followed, with hernia of the lateral ventricle through the trephine opening. Lumbar puncture was repeatedly performed, 500 to 1000 g. of fluid being withdrawn at a time. Death occurred four months after operation. The autopsy revealed a solitary tubercle of the left lobe of the cerebellum. Merklen considers this severe occipital headache, either provoked or increased by effort, with stiffening of the muscles of the neck, an excellent sign of cerebellar tumor. In another case it decided him to suggest operation, which was followed by recovery after evacuation of a cerebellar cyst. Triboulet lays most stress upon the eye symptoms in tumors of the cerebellum. Early optic neuritis occurs from pressure. Comby believes that this severe headache only accompanies large tumors of the cerebellum. [M. O.]

The Etiology of Appendicitis.—Lilpaevski (*St. Petersburg Dissertation, Vrach*, vol. xxii, No. 22) performed a number of experiments on rabbits to determine the possible causes of appendicitis. In the first series (eight experiments) he introduced mechanical and chemical irritants into the appendix. The result was a slight inflammation, somewhat intensified when the irritant was very strong. The inflammation never spread beyond the appendix. In the second series (twenty-two experiments) cultures of streptococcus and coll communis were injected into the appendicular artery and also introduced into the lumen of the appendix. The first mode of inoculation was followed by no visible changes, but when the streptococcus was introduced into the lumen of the appendix a violent inflammation set in, the entire thickness of the appendix became infiltrated with the offending organism, and peritonitis followed. When the lumen was narrowed or closed by a ligature gangrene was the result. The introduction of the colon bacillus was followed by inflammation and the formation of granulation tissue in the serous coat of the appendix. These changes were greatly intensified, resulting even in death from peritonitis, if in addition a mechanical or chemical irritant was used. The opinion is expressed that in man appendicitis depends, not on a single factor, but on a combination of several. [A. R.]

Orthostatic Albuminuria.—At a meeting of the Medical Society of the Paris Hospitals (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 20, 1901, No. 21), Méry and Touchard report two cases of orthostatic albuminuria in young girls. Regular examinations of the urine for albumen was made, as well as several cryoscopic examinations. The albumen varied from 2 to 8 g. to the liter of urine excreted. This only occurred when the patients stood up. As long as they remained in bed, there was no albumen in the urine. In one case the night urine was always more than that passed by day. Albumen was no longer found in the urine passed 40 minutes after lying down. The most albumen was found at 11 A. M., before lunch. They believe that true renal albuminuria may become orthostatic. Achard and Loeper report another similar case. Her sister and mother also have albuminuria. They believe that albuminuria may be orthostatic before becoming or after having been permanent. [M. O.]

A Case of Trichosis Lumbalis with Concealed Spina Bifida.—In the *Centralblatt fuer Chirurgie*, (June 1, 1901, No. 22), Dr. Kellner, of the Eppendorf Hospital in Hamburg, reports the third case of trichosis lumbalis, an idiot boy of 14, who was brought to the Hamburg Asylum at Alsterdorf. Over the fourth and fifth lumbar vertebrae and upper part of the sacrum was a thick growth of hair, 45 cm. in circumference, 13 cm. in diameter. The hairs were 30 cm. long, blond and thin. They were noticed at birth, and grew with the hair on the child's head. They were often cut short. A Röntgen photograph showed a cleft in the fifth lumbar vertebra, proving the existence of spina bifida. Photographs show the condition off well. [M. O.]

Two Ways of Transmitting Yellow Fever.—We are indebted to Dr. Charles J. Finlay, of Havana, for the discovery of the transmission of yellow fever through the inoculations of contaminated mosquitoes, and more recently (*Journal of the American Medical Association*, Nov. 23, 1901) this author has directed our attention to two different ways in which yellow fever may be conveyed by these insects. Finlay's first observation of mosquito transmission, which was made in 1881, was subsequently confirmed by the Yellow Fever Commission, presided over by Dr. Reed, in August and November of 1900.

Dr. Reed and his colleagues demonstrated that mosquitoes of a distinct species—*stegomyia taeniatata*—infected with the blood of yellow fever patients in whom the disease had not existed for more than three days, were capable of transmitting this disease after a lapse of twelve, sixteen or more days, in a large majority of the cases, while bites from these insects, five, six, eight, and ten days after their contamination were unsuccessful in the production of yellow fever in non-immunes. This method of propagating yellow fever, as pointed out by Dr. Reed and his colleagues, seems analogous to that of malaria, in which disease the parasite undergoes a series of transformations in the mosquito and is finally present in its salivary secretions, the medium through which infection occurs. Yellow fever, as malaria, may also be transmitted by direct injection of infected blood into a susceptible individual. Finlay states that he has been informed of "a recent experiment by Dr. Carroll, of Camp Columbia, showing that the blood of a mild experimental case of yellow fever, kept over night and a part of the next day (some fourteen hours) and injected into a non-immune, has produced a mild but characteristic attack of the disease." Finlay, after most careful clinical study, leads us to infer that the specific germs may be conveyed from the sick to the healthy in two ways. (1) During the first few days after the insect has bitten the patient, the germs contained in the blood remain attached to the parts constituting the sucking apparatus and may induce direct infection; (2) after a lapse of a longer period the germs are introduced through

the agency of the saliva in which they are contained.

We quote from Finlay's most interesting article what appears to be a valuable suggestion from the standpoint of prophylaxis, and one which is indeed worthy of early and more extended investigation: "The direct infection through the bite of recently contaminated mosquitoes, as far as I can judge from personal experience, produces much milder pathogenic effects, the fever is much less prone to develop albuminuria and the period of incubation is often prolonged. I believe that after this mode of infection has been duly verified, and with certain improvements, including the employment of home-bred insects and the proper adjustment of the number of these necessary to secure visible pathogenic effects, it will be found to constitute the only method which may be safely used, upon a large scale, for the purpose of conferring immunity."

Our Foreign-born Insane.—We print elsewhere a clipping from the *Boston Herald* that gives food for thought both to physicians and to statesmen. According to that newspaper the number of alien insane, at present confined in asylums in this country, is far in excess of the proportion which the foreign-born population of the United States bears to the native-born. In the country at large (by the census of 1890) the proportion of native-born to foreign-born citizens was 84 to 16, while the proportion of native-born insane to foreign-born was 65 to 35. In other words, the alien insane in our asylums are more than twice as numerous as they apparently should be.

The *Boston Herald* very properly calls attention to the immense expense which these alien insane impose upon the taxpayers of this country. It is estimated that this excess of foreign-born lunatics entails an expense of not less than \$10,000,000 a year. In New York State alone the item is \$1,000,000, and the necessary buildings have cost \$3,000,000. This feature of the case is not to be ignored, but it is really not so important as some other disadvantages which will readily suggest themselves to the medical mind.

First in importance among these is the great risk

involved in engrafting a deteriorated population upon our native stock. The American people are often accused of being "nervous" or "neurotic"—disposed to nervous diseases, such as neurasthenia and insanity. But the above figures tell a different tale. They show that our native-born population is twice as good as the foreign-born races which we are admitting to mingle with it. This is a most significant fact—one that has its encouraging features at the same time that it clearly indicates a danger.

This danger is that by our lax immigration laws we are admitting too many of the degenerate classes whose descendants in the future will be a charge upon and a source of responsibility to the State.

Congress already has under consideration a law extending the time within which an emigrant may be returned to his native country if he develops insanity. This time, which is now one year, is to be extended to two. This is none too short. It is proposed also to institute a more searching inquiry into the personal and family history of immigrants in order to exclude the degenerate and insane. Certainly it is but just and fair that a country which gives a free entrance to all, should at least protect itself as far as practicable from an invasion by the invalid and degenerate classes.

Humanity Versus Statistics.—In discussing such a subject, however, as that of the preceding comment, it is well to reflect that there are other considerations than those supplied merely by figures. These latter may not lie, but they are woefully lacking in sentiment; and to be lacking in sentiment is sometimes equivalent to viewing things in a false light. From an economic standpoint it is well to reflect that this country has drawn largely from the lower classes of other countries, and it has done this for its own advantage. These people have come here to do their share in developing resources and making wealth. If they have contributed to our insane and invalid classes, they have also added to our brawn and our prosperity. To separate the strong from the weak is not always possible in a free country—the problem is one that is not concerned with the importation of live-stock or slaves, but with the introduction of men, women, and children in family units. The query arises whether on the whole we have not gained a greater advantage than we have lost. The laboring classes naturally contribute a large proportion of the indigent insane in any country. The problem of hereditary insanity is not so easy that it can be solved offhand in our immigration laws. Some harm may be done as well as good in the attempt. The indefinable thread of degeneracy is inextricably interwoven with the warp and woof of social and industrial life.

Tetanus in Camden.—The Board of Health in Camden has investigated the cases of lockjaw following vaccination in that city, and reports that samples of the vaccine virus under suspicion have been tested by the State bacteriologist. These samples were found pure and free from the germs of tetanus. The Board attributes the disease to infection by the patients themselves through carelessness in handling the sores. It points out that tetanus has recently occurred in Camden in cases of wounds other than those of vaccination, and believes that the atmospheric conditions, characterized by prolonged drought and dust, are responsible for so much tetanus in the city. The samples were tested on animals, and in no instance caused tetanus. The facts that different kinds of virus were used for vaccinating, and that the same kinds were extensively used in Philadelphia without causing lockjaw, point very clearly to the conclusion that the vaccination virus was not the cause of the trouble. The epidemic—for it deserves to be called by that name—has been a most unusual one. We do not recall ever to have heard of such an extensive complication anywhere else in the history of vaccination. It is true, however, that epidemics of tetanus in other circumstances have been observed both in man and in animals, showing that the germs of the disease are sometimes exceedingly virulent in certain localities. Some years ago Mr. Jonathan Hutchinson reported such an epidemic in a flock of ewes after lambing; and in the human subject military surgeons have noted an epidemic influence. In India the disease is sometimes rife in obstetrical practice.

The conclusions of the Camden Board of Health seem to be justified. Local conditions must be largely at fault. This sad experience does not in any way militate against the practice of vaccination, but merely indicates with utmost emphasis the necessity of strict antisepsis in the care of vaccination wounds just as of any other seemingly trifling injuries.

Concretio Pericardii.—It is a pleasure to come upon an article so interesting and instructive as the one written by Wilhelm Türk, one of Neusser's assistants, upon the clinical resemblance between adherent pericardium and tricuspid disease, which recently appeared in the *Wiener klinische Wochenschrift* (XIV. Jahrgang, Nos. 37, 39 and 40). He gives the history of a man of 54, with orthopnea, cyanosis, edema, precordial pain, venous pulse, a systolic murmur loudest along the left sternal border, the absence of any pause between the heart sounds, pulsating liver, etc., in whom the diagnosis rested between mitral disease, myocarditis, and ad-

herent pericardium. After a profound study of the case, Türk decided that the condition was probably mitral disease. The autopsy showed concretio pericardii. This led him to look up his cases of adherent pericardium, six of which he reports in detail. The text-books mention many so-called signs of adherent pericardium, a systolic inraction of the precordial region, failure of the boundary between the heart and lungs to change with respiration, immobility of the apex with change of position, pulsus paradoxus, the metallic character of the heart sounds, a constant reduplication of the second sound at the apex, and a systolic wave in the cervical veins with rapid collapse during diastole. Some inraction in the precordial region is noted in normal individuals, but when the lower sternum, the precordial and apiceal regions, including the costal cartilages, are all drawn in with the heart beat, not only is the pericardium adherent to the epicardium, but to the sternum also, a result both of internal and external pericarditis. This condition is rarely seen, and even then the inraction is not marked. The reduplicated apiceal second sound and the systolic impulse in the cervical veins are the result of inraction of the thorax wall, from any cause whatever. Nor are the other so-called signs of adherent pericardium only found with pericardial adhesions. In forming his diagnosis, Türk lays most stress upon the general clinical symptoms. For experience has shown that adherent pericardium commonly occurs in patients who have had a general *serositis*, formerly called *perivisceritis* by Bamberger, a condition accompanied by widespread portal congestion. The symptoms only become severe and striking after the pericardium has been obliterated, when the muscle of the right heart becomes insufficient. Of the six cases reported, all but one occurred in young subjects, ranging in age from 11 to 28 years, four of them being tubercular. In all cases there was marked cardiac insufficiency, with some valvular condition and congestion, but without any cause to explain a degenerative myocarditis. The right heart was in every case found much dilated and hypertrophied, and the muscle showed degeneration. In fact all the symptoms pointed to tricuspid disease. The liver was always most congested, while many signs of a general *serositis* were found, such as adhesions, effusions, etc., in the serous cavities of the body. Hydrothorax and ascites may occur, but generally appear late in the disease, while adhesions may already have existed in the pleura or peritoneum. Late in the illness, when cyanosis, congestion, etc., are marked, and all the other serous cavities contain fluid, the main symptom of concretio pericardii is the absence of hydropericardium. At that

time the purely local cardiac symptoms aid in forming the diagnosis. When adhesions exist upon the under surface of the diaphragm, with or without perihepatitis, they are noted upon forced inspiration. Türk has seen more cases of tricuspid disease than of adherent pericardium. In either case, the cause of the congestion is the same, primary weakness of the wall of the right heart. Should there be no marked venous pulse, the case of adherent pericardium may resemble a simple case of mitral stenosis. From Türk's long and valuable article, the fact remains plainly before the reader, that the differential diagnosis between organic disease of the tricuspid valve and adherent pericardium is exceedingly difficult, even for the specialist in heart conditions.

Comfort from the Sins of Others.—Americans who have studied in Europe are prone to lament the lack of government supervision of medicine in this country, and the opportunity thus given for all sects to practice their nefarious methods adding to the woes of the sick, and filling our graveyards with the earthly remains of those who have died all too young. Occasionally, however, something leaks out that serves to remind us that, even in much educated Germany, the common people love to have the attendance of those who through ignorance and assurance promise cure where cure is impossible, or exalt the importance of their own instinctive knowledge by deriding the ability of the educated medical profession.

An interesting example of this is given by Zaggl in a recent number of the *Münchener medicinische Wochenschrift*. A boy had his foot crushed under the wheel of a wagon laden with sand. The wound was extensively lacerated, the bones were comminuted and a considerable amount of earth was ground into the tissues. When called to the case, Zaggl, in view of his knowledge of the course of wounds contaminated with dirt in that region, believed that tetanus was almost unavoidable, and strongly urged amputation. To this the parents refused to accede and called in a local wound quack, a man of 77, and so ignorant that he was unable to read or write, even in Germany. This man made extensive promises, treated the case with various balsams and oils, which he admitted he obtained from the local apothecary, and, finally, when tetanus had fully developed and the outcome was inevitable, abandoned the case in order that a regularly educated physician might have all the odium attached to the death. In spite of all this the courts, with their usual lucidity in medical matters, decided that as the quack had not caused the tetanus, he could not be punished for his bad treatment, although it was altogether likely that had a regular

physician been accused of the same conduct he would have been severely punished. The absurdity of the whole matter was, that the court contended that because Dr. Zaggl, when first called, had suggested the strong possibility of tetanus, therefore, its subsequent development showed that the dirt in the wound, and not the quack was to blame. We think it would be difficult, even in this country, to persuade any physician to testify that tetanus could be produced otherwise than by inoculation with the tetanus bacillus, or its occurrence in a wound, and that the fault in the quack was not so much the result of his active intervention, although this apparently produced suppuration and local gangrene, as it was in his neglecting reasonable precautions to prevent the occurrence of the disease, such as amputation or inoculation with antitetanic serum, both measures so well recognized by this time that their neglect is criminal. After all, the case shows that perhaps we are not much worse off than our older cousins on the other side of the Atlantic, if this is any satisfaction.

Dr. Hollopeter's valuable and suggestive paper on "Hypodermoclysis in Children," published in this number of the *Journal*, opens up a new and interesting line of investigation and a useful means of treatment. The therapeutics of infancy and childhood have generally been more or less shrouded in mystery, and to many physicians the treatment of children has been a veritable *bête noir*. The suggestions made by the author are timely and worthy of widespread application. We would add that to those who lack the courage or facilities for performing hypodermoclysis in these young patients, the use of saline injections *per rectum* in the management of the conditions mentioned is often of the utmost advantage.

The cry in California now is "Burn Chinatown!" This celestial abode is the center of pestilence, crime and vice, and the people in their wrath cry out to raze it to the ground. The Californians should reflect that their present troubles are not confined to Chinatown. As long as they have a Governor and a State Board of Health that hoodwink public vision and mislead public opinion in the matter of the plague, they will burn down their infected cities in vain. These would soon rise again from their ashes. It is their present State Government that the Californians need to eradicate—a government which has deliberately closed its eyes, ostrich-like, to the dangers at hand. A great State cannot

fight disease by burning down the houses of its citizens—modern science prescribes other methods.

With the passing of the football season the nerves of some estimable people will regain their equilibrium. The casualties reported from the whole country for this season have been many and grave, and even the best friends of the game hereabouts may rejoice that a rather unpropitious season is ended. We are not among those who believe that sport (in the Anglo-American sense of that term) can ever be entirely divested of physical danger, but we often wish sincerely that some one had invented or would invent a somewhat less strenuous kind of football.

Current Comment.

THE ALIEN INSANE.

A matter that is receiving more and more attention from those who are acquainted with the conditions prevailing in institutions for the insane, for idiots and epileptics, is the disproportion of the alien-born to the native-born who are imposed upon the charitable care of the government. The statistics of the last census bearing on this subject are not yet available, but those of the census of 1890 revealed a state of things that suggested the need of some defensive measures. They showed that, while the proportion of native-born citizens to foreign-born in the whole population was 84 to 16, the proportion of the insane of the two classes cared for in public institutions was, respectively, 65 to 35. That is to say, the proportion of foreign-born insane in our public institutions was more than double what it should be in consideration of the proportion of the foreign-born to the whole population. In the State of New York a similar disproportion is noted. While the foreign-born population of the state is but 25 per cent. of the whole, the number of the foreign-born insane in the state institutions is 50 per cent. of all. Here in Massachusetts, according to the census of 1895, the proportion of the native-born to the foreign-born population is 69.41 to 30.59, while the proportion of native-born insane in the state institutions to the foreign-born insane is 60.40 to 39.60. It appears, therefore, that, while the foreign-born population here supply much more than their proper share of such wards of the state, the disproportion is not so great as in New York, or as in the country as a whole.—*The Boston Herald*.

DESTROY CHINATOWN.

The Annual Report of the San Francisco Board of Health contains the following paragraph: "Chinatown, as it is at present, can not be rendered sanitary except by total obliteration. It should be depopulated, its buildings leveled by fire and its tunnels and cellars laid bare. Its occupants should be colonized on some distant portion of the peninsula, where every building should be constructed under strict municipal regulation, and where every violation of the sanitary laws could be at once detected. The day has passed when a progressive city like San Francisco should feel compelled to tolerate in its midst a foreign community, perpetuated in filth, for the curiosity of tourists, the cupidty of lawyers and adoration of artists." The Board of Health of San Francisco has made an honorable record in its fight against the plague and the unprincipled commercial interests backed by the state government. That it has had to make this fight is due to the existence of Chinatown which perpetuates a state of heathen barbarism in the central business section of an American city. It is a wonder that it has been tolerated so long; as it exists it is a pestilent nuisance endangering the health not only of the

city but of the State of California and the whole United States. Its abolition ought not to be expensive; its proprietors obtain their present income by maintaining it as a nuisance, and with it redeemed and put to decent business uses they ought to be well repaid for any loss by an enhanced value of their real estate. So long as they permit it to be continued in its present condition, it would be only decent justice to mulct them by heavy fines for keeping up a disease-breeding nuisance.

—*Journal of the American Medical Association.*

AS OTHERS SEE US.

The eccentric playwright, George Bernard Shaw, has been indulging in medical controversy. In a characteristic letter to the *British Medical Journal* he thus pays his respects to the profession: "Unfortunately medical practice has as yet been so lightly touched by the scientific spirit that the average doctor is still, not only in his patient's view but in his own, a dealer in cures and preventive charms. But that is an additional reason for bringing to bear on it the criticism of an independent branch of science. A great deal of what is called scientific opinion to-day is nothing but medical opinion; and a great deal of medical opinion is simply energetic trade-unionism, and very superstitious trade-unionism at that."

—*The Literary Digest.*

A DIET OF GROUND ROCK!

The report of the Connecticut Experiment Station just issued contains (page 165) a somewhat startling arraignment of the alum baking powders with which the country is flooded. Of the fifteen brands analyzed, about every imaginable adulteration was discovered, varying from sulphuric acid (22 per cent.) to ground rock! The latter form of adulteration is characterized by the report as "a particularly reprehensible adulteration, because very likely to prove injurious to health," which may well be believed, considering that it was found in one sample to so large an extent as over 25 per cent. Of this baking powder the report says:

"This preparation contains more than 25 per cent. of a ground rock, insoluble in strong acids and consisting chiefly of silicates of magnesia. Prof. S. L. Penfield, of Yale University, kindly examined this material and found it to be a mixture of pulverized talc and tremolite, a species of hornblende, which is extensively mined in northern New York, perhaps elsewhere, and is much used as a filler in the paper manufacture. The tremolite appears under the microscope in sharp needle-like splinters, which makes it a dangerous admixture in food."

Correspondence.

THE THEORY OF RELATIVE LEUKOCYTOSIS.

By ROBERT N. WILLSON, M. D., of Philadelphia.

To the Editor of the *Philadelphia Medical Journal*:

I have noticed in your columns in an article by Drs. Deaver and Moore (Nov. 23, 1901) a statement crediting to me the theory of "relative leukocytosis" as determined by the differential count. I feel warranted in assuming as much owing to the fact that I laid stress upon this method of diagnosis recently (*American Medicine*, 9, 17-21, 1901), in a reply to a previous article by Dr. Deaver (*Philadelphia Medical Journal*, 6, 1, 1901) which I have reason to know came to his attention. My only object in writing now is to place the credit where it belongs and to correct the statement that it has not yet been verified. Clinical and experimental verification of this most valuable advance in the study of the blood can be found in so many articles by

eminent students that it seems almost ridiculous to name them. Among such, however, may be suggested:

Rüder, *Beiträge zur Kenntniss der Leukocyten*, 1892.

Cabot, *Clinical Blood Examination* (Chapter on Leukocytosis).

Sahlb, *Lehrbuch der Untersuchungs-Methoden*, 1899, p. 646.

Chantemisse and Ray, *Presse Medicale*, July 1, 1899.

Musser, *Medical Diagnosis*, 1900, p. 409.

Stassano, *La Semaine Medicale*, July 17, 1901.

Stengel, *Textbook of Pathology*, p. 324.

v. Goetschl, *Vergleichende Analyse des Blutes gesund. u. septisch-infectierter Schafe*, etc. Dissertation, Dorpat, 1883.

Grätz, *Klinisch-exper. Blutuntersuchungen. Zeitschr. für klin. Med.*, 1893, B. 22.

Kanthak, *Acute Leukocytosis pro. by Bact. Products. British Medical Journal*, 1892.

Krebs, *Beitrag zur entzündlich. Leukocytose. Dissertation, Berlin*, 1893.

Roscher, *Blutuntersuch. bei septischem Fieber. Dissertation, Berlin*, 1899.

Wilkinson, *British Medical Journal*, Sep. 25, 1896, p. 836, and many others.

It is possible that the statement with regard to the increase in the relative number of the polymorphonuclear cells in the absence of an increase in the total number of leukocytes is original with me, although I had not previously considered this true. Nor do I yet feel convinced in regard to the matter. But this renders the statement none the less accurate, and I would again recommend, on the ground of personal experience and advantage derived therefrom, the employment of the differential count in all cases in which a condition of the acute or chronic type is suspected of being caused by pus producing organisms. As previously stated "there will seldom be found (even) a chronic suppuration without a relative increase of the polymorphonuclear leukocytes."

I shall take the opportunity at an early day of publishing a series of cases that will demonstrate the value and accuracy of this principle, which has long since shed the name of theory.

Cabot evidently was also thinking along this line when he defined leukocytosis, as long ago as 1897, as "An increase in the number of leukocytes in the peripheral blood over the number normal in the individual case, this increase never involving a diminution in the polymorphonuclear varieties, but generally a marked absolute and relative gain over the number previously present." (*Clinical Examination of the Blood*). He evidently had not reached the point where he felt convinced of the invariability of the change in the relative number of polymorphonuclear cells in the absence of a general leukocytosis. I do not believe that he had not noticed its occurrence.

I may say here that I have held this theory for a number of years, and had proved it by clinical blood study prior to the appearance of an article on the subject. The credit of its publication, however, I have never claimed and it may not belong to me.

As time passes by, more and more will be learned through the recognition of the special roles, played by the different forms of leukocytes. At present, however, our understanding of these conditions and functions is far from complete. One thing seems certain, that the polymorphonuclear cells are vitally interested in the resistance of systemic infections of all sorts, and I believe that this principle will be found beneath and behind much of the fuller understanding that is yet to be developed.

ABOUT THE PURITY OF VACCINE MATERIAL.

By CHARLES W. DULLES, M. D., of Philadelphia.

To the Editor of the *Philadelphia Medical Journal*:

In the series of articles published in the *Philadelphia Medical Journal* of November 23 in regard to smallpox and vaccination I have not observed any mention of a matter

which has seemed to me of great importance for the information of medical men and for honest dealing with those who trust their health and lives to them. I mean the actual testing in a bacteriological way of the materials furnished by the manufacturers. My own experience with vaccination during the last few months has furnished no illustration of what I would call a bad arm; that is, I have seen no extensive inflammations nor any patient that had a large ulcer or diffuse cellulitis. But I have seen some quite angry looking local lesions, and by no means all of my primary vaccinations have presented the course which I used to see in former days when the demand for vaccination material was only what is ordinary. A short time ago, because I did not know that anybody else had taken this step, I determined to make a bacteriological investigation of the form of virus which I had been using and expected to use in the future. For this purpose I went to the office of a purveyor of glycerinated lymph and purchased a case of capillary tubes. This I took at once to the Philadelphia Clinical Laboratory for examination. Of this examination I received the following report, dated November 25.

Examination of Vaccine Virus.

Tube 1.—Sterilized with formaldehyde gas, and handled with sterile forceps. The contents of this tube was put in 5 c. c. of bouillon. From this inoculated bouillon, plates and other cultures were made as follows:

1. A set of Petri plates, consisting of three, were made upon agar-agar. The first tube was inoculated with three wire loops of the bouillon containing the virus; the second tube was inoculated in the same manner from the first tube, and the third from the second. These plates were incubated over night.
2. A similar set of plates was made and grown at room temperature.
3. Anaerobic cultures were made in gelatine, and the oxygen of the air was excluded by Buchner's method. One set of these cultures was incubated; the other was grown at room temperature.

Result. The first set of plates, after incubation for twenty four hours:

Plate 1. 71 colonies.
" 2. 21 "
" 3. 15 "

After 48 hours:

Plate 1. 120 colonies.
" 2. 21 "
" 3. 15 "

The second set of plates grown at room temperature:

After 24 hours no colonies visible.

After 48 hours or more each of these three plates contained from 50 to 100 colonies.

Anaerobic cultures. Both those incubated and grown at room temperature were quite negative and remained so from Nov. 19 to Nov. 25.

Character of growth on plates. The greater number of the colonies were arborescent in form and suggested the ordinary saprophytes found in air. There were, however, on most of the plates very tiny colonies which may belong to the cocci. These were few in number.

I am now engaged in a further investigation—which requires considerable time—in regard to the specific character of the micro-organisms to be found in vaccine material which I have heretofore used under the impression that it was germ free.

As I have reason to believe that the mode of preparing glycerinated virus, is not known to all medical men, I would say that it consists in scraping with a blunt scalpel the vaccine lesions upon the udders of previously inoculated heifers, carrying away epiderm and contents of the lesions and anything that is attached to them, and rubbing this mixed material up into a pulp to which glycerine is added, the mixture being set away and examined bacteriologically

from day to day until it is regarded as proper for employment. So far as I have been able to learn, this point is supposed by most medical men to be a point at which a bacteriological investigation discloses the presence of no micro-organism: it being believed that prolonged contact with glycerine is fatal to the life of micro-organisms and that these disappear progressively from the glycerinated mixture, as taught by Dr. Copeman, of London, who devised the method of "glycerinizing" vaccine virus. The most exact recent expression of opinion on this subject that I have, is contained in a letter from a distinguished bacteriologist of this city, who, after a conversation had with me, wrote that the routine method at present is to test the material, "every two or three weeks until its bacteriological condition justifies its use upon human beings. Presumably no firm puts on the market glycerinated lymph until that point is reached, but you must understand that this is an assumption. It is my impression from what I have seen of the action of glycerinated lymph that the majority of it is when sold free from danger."

It would be hard to understand how any person with a proper sense of responsibility could furnish vaccination material that had not been subjected to tests sufficient to indicate its absolute freedom from dangerous ingredients; but, when it is known that the process of glycerinization requires fully four weeks before it accomplishes the destruction of the micro-organisms gathered up in the pulp derived from the heifer, and when the demand for vaccine material is enormously increased in a short time, it is conceivable that some purveyors of lymph might find a way to justify to themselves the distribution of virus which had not been subjected to the long continued action of glycerine which is indispensable to entire safety.

This thought led me to make the investigation here reported; and I think its result ought to be made public at once. I cannot but think that some of the curious lesions I have seen, in spite of the most exact and scrupulous method of asepsis which I have observed in doing the operation and in the subsequent management of each case, may have been due to the fact that I have at times used material which was not pure. Furthermore I cannot avoid the thought that something in the preparation of vaccine material may account for the fact that in my most recent operations the percentage of "takes" has fallen decidedly below what I secured two months ago.

It seems to me that it will be a great pity if the medical profession fails to learn a great deal from its experiences and observations in the last few months and the coming months of this winter; and I therefore make this contribution to the facts from which our opinion must be formed.

The Agglutination of the Colon Bacillus by Typhoid Serum.—E. Sacquépée (*Presse Medicale*, June 8, 1901) reports the results obtained by experiments with colon bacilli and the blood serum of typhoid fever patients. The agglutination test was tried when colon bacilli and serum came from one individual, in ten cases. It was not constant, and varied in intensity. The agglutination was never so marked as with the typhoid bacilli. When the colon bacilli and the typhoid serum come from one individual, but at different times of the disease, agglutination occurs again, if it did occur in the former test; and does not occur if it did not appear formerly. Upon colon bacilli from other individuals, the action of typhoid serum is also variable. Whence Sacquépée concludes that agglutination of the colon bacilli by the serum of the typhoid individual from whom they come is frequent; that all the colonies of colon bacilli secured at different periods of the disease do not react alike to the serum; that colon bacilli from other typhoid individuals may be agglutinated by the serum; and that the agglutination of the colon bacilli in typhoid fever seems to show an added infection or intoxication, due to the colon bacilli. [M. O.]

American News and Notes.

PHILADELPHIA, PENNSYLVANIA, ETC.

Resolutions Passed by the Board of Managers of the Hospital of the University of Pennsylvania, Wednesday, November 27, 1901.—Whereas, the Board of Managers of the Hospital of the University of Pennsylvania has been bereft by death of its distinguished president, William Fisher Norris, M. D. Resolved: That the Board has lost a colleague who, as one of the founders of our splendid hospital, gave of his knowledge, experience, time and private means in the erection of the building, and when the structure was an accomplished fact, continued as a member of its Board of Managers his earnest and unceasing efforts in assuring its equipment, maintenance, extension and improvement. Resolved: That as President of the Board for the last nine years, his successful administration, beset with difficulties, has been marked by foresight, patience, and a conscientious attention to duty. Resolved: That we mourn a friend who, while he excited our admiration by his wisdom and energy, endeared himself to us by his gentleness and courtesy. Resolved: That a copy of these resolutions be sent to his bereaved family with the expression of our respectful and affectionate sympathy.

Society Meetings Next Week.—The following societies will hold meetings next week at the College of Physicians, Philadelphia, at 8.15 P. M.: Monday evening, December 9, Section on Medicine, College of Physicians; Tuesday evening, December 10, Pediatric Society; Wednesday evening, December 11, County Medical Society; and Thursday evening, December 12, Pathological Society.

Municipal Hospital.—City Solicitor Kinsey has decided that the city has the right to remove the present Municipal Hospital to another site within the city limits, in what would be deemed not to be a built-up portion of the city, but not in a built-up portion thereof.

Charitable Bequests.—Bequests aggregating over \$100,000 to charitable institutions, contained in the will of Thomas Elkinton, who died in September, are now operative through the death of the widow, Rebecca E. Elkinton. From this the Jefferson, Orthopedic, Polyclinic, University, and Pennsylvania Hospitals are each bequeathed \$5000.

Smallpox in Philadelphia.—During the seven days ending November 30, there were reported 116 new cases and fourteen deaths. The nearest approach to this record is sixty-nine cases three weeks ago, and it is surpassed only by the statistics of the smallpox epidemic of 1876. Since January 1 there have been 768 cases of smallpox in the city and 111 deaths. Of the 657 persons who survived, 259 are still ill and 398 have recovered entirely. The cases reported during the week were confined to the northwestern and northeastern parts of the city. Down-town is almost free of the disease and West Philadelphia has only two cases. The Philadelphia Almshouse has been closed to visitors.

New Castle County Medical Society.—A medical society has been formed by the physicians in New Castle County, Pa.

Two Men Dead from Anthrax.—As a result of the death of Miles Jenkins, a teamster in the employ of the Union Tanning Company, at Hills Grove, Pa., all teamsters employed by the company have quit work. Jenkins' death was due to anthrax, the disease first appearing on his neck in the form of a small pimple. It spread rapidly and he died in agony. This is the second death from the disease among the teamsters, and the others have concluded to find work elsewhere rather than run the risk of contracting the disease.

New Vaccine Company.—A charter has been secured in Lancaster by the Pennsylvania Vaccine Company, with a capital of \$10,000.

Harrisburg Academy of Medicine.—Dr. William Osler, of Johns Hopkins University, delivered the address at the sixth anniversary of the Harrisburg Academy of Medicine, November 22. Dr. Osler complimented the Harrisburg medical profession upon the organization of their academy and its library. Eighty members of the profession were

present, including some from Carlisle, Mechanicsburg, Northumberland, Ashland, Middletown, Millersburg, Sunbury and other places.

Smallpox in the State.—On November 29th two nurses in the State Hospital for the Insane, at Norristown, were removed to the Municipal Hospital with smallpox. For the last three weeks visitors have not been allowed to enter the hospital, and the employees who resided there were not allowed to leave the institution. There are 2500 patients and about 500 attendants and workmen in the asylum. The disease still exists in Plymouth and Tunkhannock, and new cases are continually being found in Manayunk. Signs have been posted outside of Pittston, warning peddlers that a rigid smallpox quarantine has been established, and cars passing through the suburbs of Wilkes-Barre are fumigated and disinfected before entering the city.

University of Pennsylvania.—The professorship of ophthalmology in the Department of Medicine is vacant. Individuals desiring to be considered candidates for the position may send notice to the Rev. Jesse Y. Burk, Secretary of the Board of Trustees, University of Pennsylvania, 400 Chestnut street, Philadelphia, before December 28, 1901.

Pennsylvania State Board of Health.—The following resolutions were adopted at the meeting held at Harrisburg, November 21, 1901: Resolved, That in view of the very natural public apprehension in regard to the possibility of tetanus following vaccination, this Board desires to state its conviction, founded upon a careful study of the history of vaccination, that it has yet to be demonstrated that vaccine virus ever contains or becomes contaminated with the germ of tetanus. When such occurrences take place, it is because, owing to carelessness, usually on the part of the person vaccinated, the germs of tetanus gain access to the wound on the arm as they may to any other wound, abrasion or scratch upon the surface. Resolved, That there is no reason for dreading, or abstaining from vaccination, because of recent cases. This is demonstrated by the fact that more than half a million persons have been vaccinated in the city of Philadelphia within the past few months without the occurrence of a single case of tetanus. Resolved, That, inasmuch as new cases of smallpox are being reported to the Board daily from all parts of the State, the present would be a most unfortunate time to interrupt general vaccination. Resolved, that this Board condemns, in the strongest possible terms, the use of any material or medicament administered by the mouth as a substitute for vaccination, and that any physician furnishing a certificate of successful vaccination based upon the administration of any such substance or remedy, lays himself open to prosecution for violation of a State law. Resolved, That this Board reaffirms its previous declaration of confidence in the value of vaccination as a preventive or modifier of the severity of smallpox, and its belief that the possibilities of serious results following its performance must be looked upon as infinitesimal in comparison with the inestimable advantages derived.

NEW YORK AND NEW JERSEY.

The Official Report of the Camden Board of Health, concerning the cases of tetanus which occurred in patients who had been vaccinated, states that samples of the different vaccines employed have been tested for tetanus germs by the State Bacteriologist and have been found entirely free from tetanus germs; that the history of each case shows vaccination was practiced in a correct and cleanly manner in every instance, infection resulting from neglect on the part of the patients; that one case of tetanus occurred from gunshot wound, during the same period, in a boy who had not been vaccinated; that indisputable evidence that the tetanus germs were not introduced at the time of vaccination is that acute tetanus occurs in from 5 to 9 days after the introduction of the germs, whereas in every case tetanus occurred in from three to four weeks after vaccination; that further proof of the purity of the virus exists in the reports of the physicians in Cooper Hospital, who tested on animals samples of all vaccines employed in Camden, no animal developing tetanus; that during the past five weeks, there have been vaccinated in Philadelphia a very large number of people with the same virus without a case of tetanus; that the tetanus cases in Camden are explained by the atmospheric and telluric con-

ditions which have prevailed in Camden during the past six weeks, a long period of dry weather with high winds, so that tetanus germs have been distributed in the atmosphere. It is noticeable in all cases that the wound had been exposed by the scab being knocked off or removed, or else the arm had been injured and infection resulted; frequently children scratched the vaccinated area with dirty fingers and nails and infected the wound; that vaccination should be regarded as a surgical operation, should be performed in an aseptic manner, and in every instance the physician should be consulted for advice if any unusual inflammation develops; and that it is the unanimous opinion of the Board of Health, as well as of their committee of experts, that, inasmuch as vaccination is harmless, it should be insisted upon by physicians as an absolutely necessary procedure for the prevention of smallpox. Tetanus, or any other infection, can never occur if the vaccination is properly protected from contact with the atmosphere or with soiled clothing, bandages, etc.

Smallpox in New Jersey.—Four cases have been found in Hoboken, and 16 are in the Hospital for Contagious Diseases in Jersey City. Scattered cases have also been reported in the country near New York, with one case in Gloucester.

German Hospital, New York.—On Saturday, December 7, the new buildings of the German Hospital, at Seventy-seventh street and Lexington avenue, were formally opened to the public. These buildings contain well equipped wards and rooms for private patients, with electric lighting, bells, and telephone connections in every room. An ice manufacturing plant is also included in the building.

WESTERN STATES.

Drug Adulteration and Substitution.—Attention is called to the fact that not only have phenacetin, sulfonal, trional, and aristol been found adulterated with acetanilid, caustic soda, etc., but, in some cases, acetanilid has even been substituted for these preparations. Such adulterated drugs have been bought in the drug stores of Detroit, and the medical profession is warned that these counterfeit preparations are on sale.

The Arizona Board of Medical Examiners announces that its next meeting will be held at Phoenix, January 6, 1902. Applicants must present diplomas from a recognized medical college. These examinations are written and require two days. Communications should be addressed to William Duffield, acting secretary, Phoenix, A. T.

Smallpox in Wisconsin.—A severe epidemic of smallpox has developed in and near Potter, a small village ten miles east of Hayton. Twelve cases have been reported so far. Two schoolhouses and Freund's cheese factory have been closed and many families are under quarantine. The disease is supposed to have been spread at a dance held some time ago at Potter. Some of those present were recovering from the contagion at the time. There are hundreds of cases of smallpox in Calumet county, and there is grave danger of the disease spreading further.

Parents of Antitoxin Victims Sue St. Louis.—Seven families, whose children died of tetanus following the administration of diphtheria antitoxin issued by the city, and four whose children were stricken with tetanus and recovered, have announced their intention of suing the city. The verdict of Coroner Funkhauser, in which the deaths were charged to negligence on the part of the Health Department, is made the basis of the proposed suits.

CANADA.

(From our Special Correspondent).

New Immigration Board.—The United States Government has appointed an Immigration Board at Montreal for the inspection of immigrants destined for that country. Dr. James Barclay has also been appointed medical officer, and after immigrants have been inspected by the Board they will be examined medically by Dr. Barclay. Aliens arriving at Canadian ports who are judged inadmissible will be returned to their native countries at the expense of the steamship company transporting them. The jurisdiction of this board extends from the city of Quebec to Niagara Falls; it will convene daily, and will watch especially for cases of trachoma, as many such patients reach the United States through Canada.

Montreal Maternity Hospital.—The Directresses of the

Montreal Maternity Hospital decided to rebuild, at the annual meeting of the Board held a few weeks ago. The site has already been purchased, 16,000 square feet of land, for which the sum of \$10,000 has been paid. The building will be constructed on the most approved plan, to accommodate forty-five patients, and will be erected at from \$30,000 to \$40,000, exclusive of equipment. The reports presented were of a very satisfactory character, showing that the institution is prosperous. The number of patients treated, the great majority being married women, was practically the same as for the previous year. The site for the new building is larger than that of the Sloan Maternity in New York City. During the year there had been 229 confinements.

Montreal General Hospital.—Dr. von Eberts, who read the medical report of the Montreal General Hospital at the regular quarterly meeting last week, showed that during the quarter 720 patients were treated in the public wards, 64 died, 32 within three days of admission. This makes the mortality 4.65%. In the dispensary there were 7638 visits, a decrease of 3405 as compared with the corresponding quarter of last year. During the early part of the quarter the number of typhoid fever cases filled the wards. At present there are twenty-four patients with this disease in the hospital.

Resignation of the Dean of McGill University Medical School.—Dr. Robert Craik, who has been Dean of the Medical Faculty and professor of hygiene and public health since 1889, has resigned. Dr. Craik has been connected with McGill during his whole professional life, and has seen the Medical School develop from thirty to over five hundred students. He matriculated in 1850 and was graduated M. D., C. M., in 1854. Two years later he received an appointment in the Anatomical Department, and has been associated with the teaching of medicine ever since. The honorary degree of LL.D. was conferred upon him in 1895. Synchronous with his resignation comes the announcement of his appointment as Governor of the University, a compliment rare in the history of McGill, only conferred upon one member of the teaching faculty. Dr. Girdwood, professor of chemistry, senior professor, is likely to be appointed Dean, although the name of Dr. T. G. Roddick, M. P., is also mentioned.

An Unusual Suit Against a Doctor is at present being tried in Montreal, a patient claiming damages against Dr. J. P. Gadbois for illegal detention. Dr. Gadbois, who has paid particular attention to the treatment of dipsomaniacs, states that the man was brought to him by a Sister of Charity who told him that he had been drinking very heavily. He alleges that he only employed methods recognized and used in these cases, but the appellant claims abusive treatment and illegal detention.

Smallpox in Canada.—Smallpox continues to increase in several sections of the Dominion. There have been over 50 cases at St. John, N. B.; Ottawa has had 80 odd cases, and the City Council of that city has rescinded the order for compulsory vaccination, although new cases are appearing daily. There are several centers in the province of Quebec, and the provincial Board of Health has had to issue special orders with regard to the outbreaks. Montreal has eleven cases in its Civil Hospital, and large corporations are complying with the order of the Board of Health compelling general vaccination of their employees. Several centers exist throughout the province of Ontario, and the Medical Health Officer of Toronto is watching for cases, none at present existing there. Manitoba has had a number of cases, as has Winnipeg. In British Columbia, fear is entertained on account of several outbreaks just below the boundary line, and special quarantine officers are guarding the frontier. Two cases of tetanus are reported from Impure lymph, one in Quebec and Nova Scotia. The Quebec Board of Health recommends glycerinated vaccine only.

The National Sanitarium Association wants to control the consumption sanitarium business in Ontario. A short time ago the Medical Health Officer of Toronto recommended to the local Board of Health that the time was opportune to recommend to Council that a by-law be submitted to the people, at the coming municipal elections in January, to raise \$50,000 to purchase a site not more than forty miles from Toronto, comprising at least fifty acres of land. Now the National Association comes forward again,

stating that they are going to build this institution for Toronto's consumption population. A conference is to be held between the Medical Health Officer, Dr. Sheard, and the officers of the Association, and as this class of patients is now debarred from all the city hospitals, it is to be hoped that a consumption sanitarium will soon be established.

Royal Victoria Hospital.—Dr. C. B. Kean, who was surgeon to the Strathcona Horse in South Africa, has been appointed surgical pathologist to the Royal Victoria Hospital, Montreal, and will have charge of the surgical dispensary. Dr. Kean resigned as senior house surgeon of this institution when he went to South Africa.

Vancouver City Hospital.—The growth of Vancouver has been so great in the last few years that it has outgrown its hospital accommodation, and the present institution is entirely inadequate to accommodate the population. The City Council is seriously considering the question of erecting a new, up-to-date hospital. The great difficulty hitherto has been to secure a proper site, but the offer by the C. P. R., of five acres of land in a good situation, has been accepted and early in 1902 the building of the hospital will begin. It will cost in the neighborhood of \$100,000.

Child Insurance.—The Montreal Board of Health has taken a most decided stand against child insurance, and will recommend that in the future no insurance be allowed on a child's life until it is 10 years of age. They came to this decision from the rapid increase in infant mortality in Montreal. It was shown that many infants were insured, and in some cases these were neglected when ill, in order that the parents might collect on their policies. It hardly seems possible that parents could do such a thing, but the same charge has often been made in England. It is reported that the Montreal statistics are so conclusive that it is probable the Canadian Parliament will forbid child insurance entirely.

MISCELLANY.

Bubonic Plague.—From Honolulu comes the news of an outbreak of bubonic plague. According to information received, Honolulu will be quarantined against the world before the end of another week. Twenty-three cases of plague are known to exist, that number of patients being at the Kalihi retention camp. It is reported on good authority, that two Japanese died and were cremated midnight, November 24. Every effort has been made to suppress news of the alarming state of affairs. Fourteen of the known cases are Japanese and nine are Chinese. The utmost precautions have failed to prevent the spread of the plague, and Honolulu is threatened by such another epidemic as that of 1898, which cost 112 lives and \$7,000,000.—The British steamer Monmouth, which arrived at Norfolk, Va., November 20, direct from Cape Town, South Africa, reports the existence of over 800 cases of bubonic plague in the vicinity of Cape Town. Up to the time she sailed over 380 deaths from the plague had occurred.—Cases are also reported in Asuncion, Paraguay, and Rio de Janeiro, Brazil.

Obituary.—Dr. J. C. Scarborough, at Prescott, Ariz., November 22—Dr. M. P. Roach, at Rozellville, Wis., November 25, aged 36 years—Dr. Robert E. Edes, at Boston, Mass., November 27, aged 32 years—Dr. James F. Alexander, at Atlanta, Ga., November 14, aged 77 years—Dr. Levi L. Todd, at Indianapolis, Ind., November 16, aged 71 years—Dr. Zachary Taylor Harvey, at Council Grove, Kan., November 15, aged 49 years—Dr. Richard M. Phillips, at Topeka, Kan., November 15, aged 74 years—Dr. Charles R. Stephens, at Victor, Cal., November 14—Dr. Wilford J. Bates, at Sibley's Corners, Mich., November 16—Dr. D. H. Parker, at Medon, Tenn., November 14, aged 60 years—Dr. Mortimer Bainbridge Ruggles, at Long Island, N. Y., November 15, aged 22 years—Dr. Alexander N. Simpson, at Creede, Colo., November 16—Dr. Charles L. Hormanson, at Onancock, Va., November 16, aged 43 years—Dr. Guy Coulter, at Columbus, Ohio, aged 40 years—Dr. L. A. Schaefer, at Schuyler, Neb., November 15—Dr. Andrew J. Stoner, at Decatur, Ill., November 13, aged 76 years—Dr. John G. C. Swaving, at Pottsville, Pa., November 26, aged 80 years—Dr. Magruder Muncaster, at Rockville, Md., November 28, aged 42 years—Dr. Robert McLearn, at Fredericton, N. B., November 29, aged 47 years—Dr. Charles J. Essig, at Wallingford, Pa., December 2, aged 74 years.

GREAT BRITAIN, ETC.

Smallpox Epidemic in London.—At a meeting of the London Metropolitan Asylums' Board last Saturday, the chairman stated that London was probably in for a heavy epidemic of smallpox. Since August 10 there have been 864 cases notified and 141 deaths from the disease. During the past fortnight 262 fresh cases have been reported. Statistics already published show that since the present outbreak of smallpox 116 persons have died of the disease, while there were fifty-seven doubtful cases, 233 have recovered and there are 420 cases under treatment. Sixty per cent. of persons who had not been vaccinated died and 20 per cent. of those who had been inoculated. The first case was reported on May 20.

Cancer Hospital, Brompton.—A window in memory of the late Dr. William Marsden, founder of the Cancer Hospital, was unveiled in the chapel of the hospital on November 16th by the Bishop of London. This charity was founded fifty years ago.

Sunlight an Old Remedy.—Professor Finsen, of Copenhagen, has received much praise for cures effected by sunlight; but an English scientist points out that this method of curing diseases was known and practiced in England centuries ago. John Gaddesden, who wrote the famous medical treatise, "Rosa Medicinæ," who died in 1361, treated the son of King Edward I. for smallpox by wrapping him in scarlet cloth and placing him in a bed and room with scarlet hangings, and the patient recovered, never showing any trace of smallpox. There is also evidence that other physicians believed in the virtues of phototherapy and adopted it to cure certain forms of skin disease.

Charing Cross Hospital.—It has been decided to add an ophthalmic department to the Charing Cross Hospital.

Noma.—From London comes the report of Dr. W. H. Allebin, in which the statement occurs that, out of 1300 patients admitted to the Hospital for Sick Children in Great Ormond street, but six cases of noma have been seen during the past 13 years.

20,798 Free Meals are provided daily for underfed school children in London.

A Bequest.—Mrs. George Field donated \$5000 to the North London Hospital for Consumption, in memory of her late husband.

Dr. Lazarus Barlow, of the Westminster Hospital, London, who has been seriously ill with blood poisoning following a recent post-mortem examination, is now reported to be gradually improving.

Norfolk holds the record for the lowest marriage-rate, and **Sussex** for the lowest birth-rate in England.

Obituary.—On September 28 in Adelaide, South Australia, Dr. Edward Wills Way died, aged 55 years. He was a graduate of the University of Edinburgh, formerly demonstrator of anatomy in the University of Edinburgh, but for many years past lecturer on obstetrics and diseases of women and children in the University of Adelaide.—W. G. M. Manley, retired Surgeon General of the Army Medical Department, died in Cheltenham, November 16, in his 70th year.—At Ventnor, Isle of Wight, Dr. J. M. Williamson died November 12, aged 52 years. He was a graduate of Edinburgh University.—John Palmer Way, former assistant surgeon of the Royal Navy, a graduate of St. Thomas' Hospital and surgeon to the Royal Portsmouth Hospital, died November 16, in his 63rd year.—On November 19, Dr. Henry Sutherland died, who was for many years lecturer on insanity at the Westminster Hospital.—Colonel G. H. Fetherston, late principal medical officer of the Victorian Military Forces, recently died in Melbourne, Australia, aged 72 years.

CONTINENTAL EUROPE.

PARIS LETTER.

(From Our Special Correspondent, Dr. Edmund L. Gros).

At the meeting of the French Academy of Medicine, October 22, Prof. Poncet related the history of a patient of 49 years, with enlarged ganglia and repeated colds, who entered the hospital with what was diagnosed acute articular rheumatism. Salicylic acid gave no relief. After a few months he left and for a year felt well, his knee remaining swollen, though painless. At that time severe articular

pains reappeared. Dr. Poncet withdrew some of the synovial fluid and injected it into a guinea-pig. This inoculation revealed tubercle bacilli. The sero-diagnosis performed by Dr. Courmont was also positive. Unmistakable signs of pulmonary tuberculosis developed later.

Prof. Dieulafoy reported a most interesting case, which weakens the doctrine of cerebral localization and touches the question of surgical intervention in intra-cranial lesions. The patient was a man of 40. He was brought to the hospital comatose, temperature 40°C., with ten successive attacks of partial epilepsy. The attacks began in the right arm, spread to the right leg, and the mouth and face, were drawn to the right. A history of syphilis 10 years before indicated the nature of the lesion and the epilepsy seemed to indicate the motor region affected. The diagnosis of *gumma* of the lower two-thirds of the motor centers was made, and mercuric biniiodide injected in large doses. In spite of this and potassium iodide the attacks recurred over 50 times in 24 hours, and the man died. The autopsy showed that the motor regions were absolutely intact. A *gumma* the size of a small egg was discovered in the external part of the frontal lobe. Prof. Dieulafoy considers that this case shakes the doctrine of cerebral localization. Prof. Pitres, of Bordeaux, expressed surprise that Prof. Dieulafoy should incriminate the theory of cerebral localization on account of this case, since it is generally admitted that exact localization can only be made from a distinct monoplegia or hemiplegia, and not from Jacksonian epilepsy. In the case cited by Prof. Dieulafoy the frontal lesion was near the motor regions. Dr. Lucas-Championnière agreed with Prof. Pitres. In operating, he insists upon a large cranial opening, for this should be mainly exploratory; often the lesion will be found some distance from the point apparently indicated.

In discussing rachicocainization, Dr. Chaput states that he injects $3\frac{1}{2}$ to 4 centigrams of cocaine, directs the stream upwards and thus obtains an anesthesia which includes the arm, thorax, chin and ear. Before the operation 25 drops of Tr. digitalis and one centigram of morphine are administered and a loose elastic ligature is placed around the neck. The patient is placed in the Sim's position. A 1% solution is injected rapidly, and immediately following this 500 grams of a normal salt solution are injected into the leg. His report includes a series of 120 cases. He concludes that to obtain anesthesia of the upper extremities, four centigrams are sufficient; that the face and head are not sufficiently anesthetized for operating; that isotonic solutions appear less diffusible and less active than aqueous solutions; and that anesthesia is not accompanied by frequent or grave complications. Dr. Guinard always draws off a little of the cerebrospinal fluid to make the cocaine solution. He places a concentrated solution of cocaine in the syringe, inserts the needle into the spinal canal and draws off enough spinal fluid to fill the syringe, thus making a 1% solution. This is then re-injected. He reports 70 cases without any complications. To this series of successful cases must be added two cases of immediate death reported by Dr. Leguen. Both cases were most unfavorable, one being an emphysematous, congested individual with a cardiac lesion, who had recently had an apoplectic stroke. Less than two centigrams was injected. The other was a man of 60, who was infected for strangulated hernia. The general condition of the patient was deplorable. Six minutes after the injection breathing became labored, and death quickly ensued. The autopsy revealed kidney lesions not in themselves sufficient to cause death. Dr. Leguen thinks that in both cases death was due to direct action on the medulla.

At the meeting of the "Société Médicale des Hôpitaux," November 8th, Dr. Chantemesse reported 100 cases of typhoid fever treated with injections of anti-typhoid serum. In all cases in which it was used before the tenth day he obtained a sudden and permanent drop in the temperature, with recovery. In other cases the fever rose in a few days if the serum was not again employed. Of these 100 cases six died, all injected after the tenth day. The injections, 10 to 14 c.c. at a time, are neither painful nor irritating and are given in the forearm to facilitate quick absorption.

Medical Plays on the French Stage.—Among the novelties recently produced in Paris were two plays upon the influence of heredity, *Les Rernants* by Ibsen, and

L'Erasion by Bréux. *En Pair* dealt with the French lunacy law and *Les Remplacantes* discussed the subject of wet-nursing. In *Le Baillon* occurs the question of professional secrecy, while *Les Ararics* shows the dangers of the marriage of syphilitics. The last-named piece was prohibited by the censor.

Fiftieth Anniversary of the Ophthalmoscope.—On November 13th, 1851, Helmholtz first demonstrated the ophthalmoscope before the Königsberg Medical Society. The fiftieth anniversary of the invention of the ophthalmoscope was celebrated in Berlin November 13th, 1901, under the leadership of Professor Greeff. 120 ophthalmoscopes were exhibited in historical order, among them instruments from various countries. The meeting of the Charité Hospital Society, held the next day, was devoted to ophthalmoscopy.

Austrian Medical Students.—The number of medical students in the Austrian Universities has been gradually decreasing during the past ten years. While there were 5,275 medical students in 1891, there were but 2,555 in 1900-1901, yet the number of degrees of "M. D." conferred has only fallen from 721 in 1891 to 603 in June, 1901.

The Schools of Vienna are to have medical attention. The Board of Education is considering the appointment of a staff of medical school inspectors. It is proposed that the duties of these officials shall include periodical inspection of the schools, more frequent during contagious epidemics.

Vaccination Abroad.—Vaccination and revaccination of all children of school age has been compulsory in Germany since 1874, and in 1899, when this law had been in operation for 25 years, the total deaths from smallpox in 285 German towns, with a population of nearly 16,000,000, were only four. In France, where vaccination is far less universal, in 116 towns, with a population of 8,500,000, the deaths from smallpox in the year 1899 were 600. This seems precisely the kind of parallel which is calculated to strike popular imagination. In Germany, out of 16,000,000 of people, four died of smallpox in a year. In France, out of 8,500,000 of people, 600 died of smallpox in the same year.

The Famine in Russia is worse than the government seems to have anticipated. From the local government boards of many provinces come daily reports of deep and increasing distress and an appalling scarcity of grain and provender. Simbirsk asks for 180,000 pounds of grain, 200,000 roubles with which to buy grain, 35,000 roubles for medical relief and 10,000 roubles for public works. From Tomsk, Western Siberia, are reported crop failures and the flight of peasants back to Russia. The assignment of money and grain is declared to be insufficient, and hungry peasants have been driven to robbery and even murder. Epidemics of scurvy and typhoid are making steady progress in many governments. Between October 1 and 23 373 cases of scurvy were reported in eleven villages of the district of Khvalinsk, and both diseases have reappeared in Kherson. It is also reported that there has been an alarming spread of the plague in Southern Russia. According to despatches from Lemberg, hundreds of fatal cases have occurred in Moscow, Odessa, Kieff, Kherson, and other towns.

The Population of Sweden.—According to recently reported statistics, Sweden in 1900 contained 5,136,441 inhabitants, of whom 2,506,436 were males, and 2,630,005 females, an increase of 351,460 over the census of 1890. While 4,032,284 people inhabit the country, the cities contain 1,103,957 inhabitants, 300,724 in Stockholm, 130,619 in Gothenburg, and 60,857 in Malmö, the three largest cities.

St. Petersburg has the highest death-rate of any European capital, 51 per 1000.

Obituary.—At Marseilles, Dr. Auguste Villard, professor of medicine in the Marseilles Medical School, corresponding member of the French Academy of Medicine, died, aged 65 years.—At Ulm, Germany, Dr. Gustav Veesenmeyer, a graduate of Heidelberg, died, at the age of 86. Since 1863 he has been professor in the Ulm High School, and was later appointed librarian to the public library of that city.—In Rome, November 15, Dr. Luigi de Rossi died, a graduate of the University of Genoa, professor of otology, rhinology and laryngology in the University of Rome, aged 57 years.—Dr. J. Magaz y Jaime, former professor of physiology in the University of Madrid, has recently died.

1.—Swain reports a case of a female aged 26 years, who had complained of dysphagia, dyspnea, and vomiting for over two years. Just before the onset of the symptoms she had fallen down a flight of stairs. A tube could be easily passed into the stomach and after withdrawing it 8 or 10 inches, undigested food, alkaline in reaction, could be washed from the esophagus. A bullet-shaped metallic body after being swallowed was found by the X-rays to be lodged at the level of the 6th dorsal vertebra. The swallowing sound was absent. Both the Rumpel and the Einhorn tests showed that all the fluid flowed into the stomach, i. e., that the dilatation of the esophagus was spindle-shaped. The Rumpel test is as follows: A tube with numerous perforations in its lower third is passed into the stomach and a second tube passed into the esophagus. A measured quantity of fluid is poured into the first tube and if a diverticulum exists only a portion of the fluid will be recovered from the stomach; the rest which occupies the diverticulum may be withdrawn by the second tube which is in the esophagus. Einhorn has the patient drink a cup of clear water after a cup of coffee has been passed into the stomach. A tube introduced into the esophagus will bring away clear water of alkaline reaction and when pushed on into the stomach will withdraw coffee of an acid reaction. Swain's patient is comparatively comfortable when soft foods only are ingested and when the esophagus is systematically washed out. [F. T. S.]

2.—Heuston's successful operation for typhoidal perforation was done about 4½ hours after the onset of the symptoms. The patient was a woman, aged 32 years, who had passed through an uncomplicated attack of enteric fever. Four days after the temperature had become normal she was seized with violent abdominal pain; the temperature rose to 104° and the hepatic dulness was displaced by tympany. Although the abdomen swelled, the tension was but little increased. The perforation, about the size of a pin-head, was found 8 inches above the cecum; the whole ulcerated area was inverted by Lambert sutures of silk. The thin fecal material which had invaded the peritoneal cavity was removed by copious washings of salt solution.

[F. T. S.]

3.—Maylard publishes two cases of post-operative thrombosis of the mesenteric veins. The first patient, a woman

aged 26 years, died 4 days after a gastro-jejunostomy for pyloric obstruction; the second patient, a woman, aged 28 years, perished 3 days subsequent to an excision of the left half of the thyroid gland for exophthalmic goitre. In both a ventricular systolic murmur and a rapid pulse was noted before operation. The heart of the first was not examined after death and that of the second presented no valvular lesions. Both patients were excessively restless on the second and third days following operation; both complained of severe pain in the lower portion of the abdomen; and in both the operative wounds were healthy. The pyloric case passed flatus, the goitre case had diarrhea and passed blood; in the pyloric case 3 feet of the ileum immediately above the cecum were dark purple in color, collapsed and contained no blood; in the goitre case the whole ileum was ecchymosed, distended, sloughing in places, and contained fluid blood. Maylard has searched the literature of the subject and has been unable to find any case following or dependent upon operation. The following symptoms occurring shortly after an operation should suggest thrombosis of the mesenteric vessels especially if the operation was not one involving the intestinal canal: abdominal pain; diarrhea with or without blood; vomiting which is not of the obstructive character; rapid pulse; extreme and inexplicable restlessness and excitability; and symptoms of cardiac or vascular disease.

[F. T. S.]

4.—Excision of extensive portions of intestine when not immediately fatal is followed by an enormous appetite, diarrhea, and a fatal marasmus. As a result of experiments on animals Senn concluded that the resection of more than one third of the intestinal canal was productive of a fatal marasmus. Trzebielky maintains that one half of the intestinal tract may be resected without a fatal issue. Monari has removed seven-eighths of the intestine of the dog without seriously interfering with metabolism. Blaney studies the subject from a clinical standpoint. Including the case reported in the present communication he has collected 33 instances in which more than one metre of intestine has been removed. Nine died soon after operation and three after 4 months. In the 21 surviving, the part resected consisted of colon in 2, of ileum and jejunum in 1, and of a portion of the ileum in the remaining cases. In the 7 cases which showed digestive disturbances subsequent to operation, the length of intestine removed, with 2 exceptions, was over 200 cm. (6 ft. 6½ in.). The 14 which showed no untoward symptoms lost less than 200 cm., with one exception in which 205 cm. were removed. From these statistics the author concludes that 200 cm., or less than one third of the total length of the intestine is the danger limit. Children stand extensive resections better than adults; and the loss of intestine is more serious the nearer one approaches the stomach. This study will be of little value to the surgeon at the time of operation, for if the bowel be gangrenous he must remove all of it no matter how far it extends. [F. T. S.]

5.—Stead reports a successful operation for intussusception in a woman aged 72. A mass of bowel 8 inches long and 8 inches in circumference protruded from the anus. Even after the abdomen had been opened, reduction could not be effected, until the sphincter ani had been divided. A slow but interrupted convalescence followed. [F. T. S.]

6.—Gilford discusses the after-treatment of cases of gastrorrhaphy for perforated gastric ulcers. Water may be given 4 hours after operation. After 24 hours grape sugar in the form of raisin tea or a decoction of malt may be administered in small doses. Milk contains proteids which undergo digestion in the stomach and should be avoided; beef tea and the various beef extracts stimulate the secretion of gastric juice and are not to be employed. After from one to three days cream and water (1 part of the former to 12 parts of the latter) may be added to the grape sugar. At the end of a week solid food may be commenced, but for 2 weeks longer it is better to select food

which is digested mainly in the intestine. The patient should lie on the right side with the shoulders slightly raised in order to facilitate the egress of fluids from the stomach; if the ulcer be low down on the anterior wall of the stomach, the supine position is the best attitude. The bowels should be moved by the use of enemata if possible; calomel and salts being withheld unless ileus is threatened and rectal injections have proven ineffectual. [F. T. S.]

7.—Buck believes incisional hernia may be prevented by having the breach in the abdominal wall supported by muscle whose nerve supply has not been injured and whose fibres are not constricted by sutures. He proposes slitting the anterior sheath of the rectus abdominis about one inch from its inner edge, retracting the muscle outward, and opening the peritoneal cavity in the same vertical plane as the primary incision; after the intra-abdominal manipulations have been completed, the posterior sheath of the rectus together with the peritoneum is sutured with fine silk, the rectus allowed to slide in place, and the anterior sheath and the skin united. [F. T. S.]

8.—Shriaw's patient was a child 9 weeks old whose abdomen had been swollen from birth. A kidney-shaped tumor occupied the left side of the belly. The hydronephrosis was drained through an incision just below and parallel to the last rib. [F. T. S.]

9.—The bilocular hydrocele recorded by Firth occurred in a laborer aged 20, who had a swelling in the left scrotum since infancy. This swelling could be reduced, was translucent, and transmitted a wave of fluctuation when struck to a hand on the abdomen as high as 5 inches above the pubis. At operation a large extraperitoneal sac was found communicating with the scrotal hydrocele; the intrapelvic portion of the hydrocele was enucleated. [F. T. S.]

10.—Hodgson publishes the notes of a case that he believes was a primary tubercular inflammation of the seminal vesicles. The patient was 32 years of age. The symptoms were frequency of micturition, dysuria, pain in the perineum, and occasionally hematuria. Tubercle bacilli were found in the urine. By rectal examination the right seminal vesicle could be felt enlarged and nodular. Both vesicles were enucleated through a transverse perineal incision. Three months after the operation the right epididymis began to enlarge. [F. T. S.]

11.—Young proposes to substitute for the ordinary rubber bag which is used with the Clover inhaler, a bag made of fine linen. A freshly washed and starched bag is used for each patient. Cyanosis is usually absent but more ether and more time are consumed in the anesthetization. [F. T. S.]

12.—Ball sterilizes catgut by winding it on a glass spool, placing it in a 5% solution of formalin for 24 hours, boiling it in water for 5 to 10 minutes according to the size of the gut, and finally keeping it in a solution of corrosive sublimate 1 part, glycerine 250 parts, and methylated spirit 1,000 parts. The glycerine and spirit dehydrate the gut, the former renders it pliable, and the mercury hardens it. [F. T. S.]

7. Rotation of the Forearm. RICHARD J. ANDERSON.

8. On a New Method of Preserving Museum Specimens. HUGH GALT.

1.—Buckstone Browne presents to the Harvelan Society his personal experience of twenty-five years' in genito-urinary surgery. He speaks of his long association with Sir Henry Thompson and details the various advances made in genito-urinary work during this period. In speaking of the operations of litholapaxy and lithotripsy he suggests the propriety of not employing these methods in cases in which the urine is purulent and alkaline, the prostate large, and the stone large and phosphatic. In such cases suprapubic cystotomy is indicated. [J. H. G.]

2.—Richard W. Lloyd in a post-graduate lecture on the administration of anesthetics in operations about the mouth, nose and throat discusses the various means of employing anesthesia in these operations. Interference with respiration and the loss of blood necessarily associated with the operations prolong the state of anesthesia and render a small quantity of the anesthetic effectual. The patient should never be profoundly anesthetized or else the pharyngeal and laryngeal reflexes will be abolished and blood is apt to make its way into the trachea. The application of cocaine as a preliminary to the administration of the general anesthetic is sometimes useful. Where chloroform however is to be employed, the cocaine should be used very sparingly. In operations about the mouth and face ether or ether and gas may be first employed and the anesthesia kept up by the administration of chloroform. Lloyd prefers the patient to occupy a position on his side with the pillow removed and the face turned toward the table as this facilitates the flow of blood away from the air passages. He does not approve of the position with the head hanging over the end of the table. No hard and fast rules can be laid down as to the particular anesthetic to be employed in these cases. [J. H. G.]

3.—W. M. Banks presents at some length his impressions about chloroform and ether. He does not consider the experimental work which has been done upon animals of much value. Chloroform is undoubtedly much more dangerous than ether and he thinks that the latter anesthetic might be employed more frequently in Great Britain. Since the surgeon is held responsible for deaths occurring during anesthesia, he should always maintain control and direction over the anesthetist. Stress is laid upon the fact that in nearly every instance there are danger symptoms which present themselves before the patient goes into collapse and that these should be carefully watched for by the anesthetist. Imperfect breathing is greatly counteracted by withdrawing the tongue and Banks is a strong advocate of the tongue forceps. Since the period of greatest danger in chloroform anesthesia is while the patient is struggling, the greatest care should be taken to avoid this. It is a mistake to restrain the patient when he begins to struggle, as this only excites him. The dangers of chloroform lie: (1) in absolute over-dosing of the patient up to the poisoning point when there is no necessity for it as regards the operation; (2) an omission to allow the patient to be constantly and freely getting abundance of air into his lungs; and (3) violent repression during the stage of excitement combined with continued dosing with chloroform. The danger is greatest between six and ten minutes after the anesthetic is commenced and great watchfulness is required at this time. Nausea is more frequent after ether but is apt to be more prolonged after chloroform. The patient is best resuscitated by elevating the feet and the employment of Silvester's method of artificial respiration. Subcutaneous injections of ether and strychnia are of advantage. Banks has found friction

of the nose and lips with a dry towel of advantage in preventing and overcoming minor forms of collapse which take place during anesthetization. Large doses of brandy with a small amount of water given just before the anesthetic is begun is highly recommended. In commencing the anesthetic Banks instructs the patient to count and is very careful to see that everything in the room is perfectly quiet. In old people and those suffering from bronchitic or asthmatic conditions chloroform is to be preferred. The safest position for the administration of an anesthetic is the recumbent one with the patient on the left side.

[J. H. G.]

4.—C. H. Keetley reports four cases of ulceration of the esophagus and stomach due to swallowing strong hydrochloric acid. The first case was one of enormous dilatation of the stomach after accidental poisoning by strong hydrochloric acid eight months previously. Complete relief was obtained in this case by the performance of Loreta's operation. The second case was a man 25 years of age, who a number of weeks previously had swallowed a large amount of strong hydrochloric acid with suicidal intent. When the abdomen in this case was opened, the patient became collapsed and the stomach was not opened. The mere attempt at operation was followed by improvement for ten days. Death, however, occurred and the patient was found to have a pneumonia and contraction of the pylorus. Case No. 3 was a woman, 46 years of age, who had swallowed strong hydrochloric acid with suicidal intent. Operation was performed six weeks later and marked stricture and progressive ulceration of the esophagus as well as of the pyloric end of the stomach was found. Immediate relief and continued improvement for nearly six weeks followed gastro-enterostomy with a Murphy button. Death occurred from bronchitis and pneumonia. The Murphy button was found in the stomach and the ulceration of the esophagus was unhealed. It is Keetley's opinion that ulceration of the esophagus and pharynx leads to infection of the air passages. This infection may take place through the lymphatics or through the trachea. In the future it is proposed to carry out the following treatment:

"1. The patient should receive no food (either liquid or solid) by the mouth for several weeks—i. e., he should not be fed by the mouth as soon as he can swallow with little or no pain, but oral feeding should be postponed until there is good reason to believe that the injuries have completely healed.

"2. When the injuries are serious (and they generally are so) an operation should be performed within a few days of the date of the poisoning—the sooner the better." It is impossible to say definitely that the ulceration of the stomach or esophagus is healed since only the mouth and pharynx are visible. The pyloric portion of the stomach is the part most seriously injured. In these cases Keetley strongly recommends that a gastro-enterostomy be performed and that two tubes be introduced through the abdominal wound, one entering the intestine through the new opening and the other remaining in the stomach; through one the patient can be fed and through the other the stomach can be irrigated. The after-treatment is of the greatest importance. [J. H. G.]

5.—Geo. H. Rodman reports a case of severe and long-standing (twenty years) lupus occurring in a woman 33 years of age. Various local measures had been employed together with curettage. The patient was subjected to the X-rays for periods varying from five to twenty minutes for about three months, at the end of which time complete healing had taken place, as is shown by the accompanying illustrations. At the early stages the length of the exposure should be shorter and the distance of the tube from the disease greater than that employed later on in the treatment. In this way the patient's tolerance can be ascertained. The healthy portions of the face should be

covered by a paper pulp mask, the outer surface of which is covered by a layer of thick lead foil. [J. H. G.]

6.—T. Coke Squance reports a case of *lupus vulgaris* of two years' duration in a seventeen-year-old girl, in which a cure was obtained by the employment of the X-ray. [J. H. G.]

7.—Richard J. Anderson shows that in rotation of the forearm not only the radius revolves but that the ulnar also takes part. [J. H. G.]

8.—Galt devises a new method for preserving museum specimens which possesses many advantages over the methods now in use. The formula for this fluid is as follows: common salt, five ounces; potassium nitrate, one ounce; chloral hydrate, one ounce; water, 100 ounces. After washing the specimen in water and allowing it to remain in 80% alcohol for from one to four days, it is placed in the solution just indicated. He states that the cost of the preliminary treatment of this method is much less than the preliminary Kaiserling's solution. Shrinking of the specimen is distinctly less than with Kaiserling's method and far less than with the old formalin and alcohol methods and finally he remarks that the color of the specimen is retained to a very high degree. [F. J. K.]

MEDICAL RECORD.

November 30, 1901.

1. Vaginal Cancer. W. ROGER WILLIAMS.
2. Various Methods of Infant Feeding. LOUIS FISCHER.
3. On the Presence of Typhoid Bacilli in the Blood of Typhoid Fever Patients. ALBION WALTER HEWLETT.
4. A Device for Irrigating the Male Bladder. U. S. BIRD.

1.—Williams, in speaking of cancer of the vagina, remarks that of the organs evolved from the different segments of the Müllerian ducts only the uterus manifests great proclivity to tumor-formation; the vagina and Fallopian tubes are seldom affected. From this it may be inferred that the biological peculiarities which determine a given part to tumor-formation depend more upon functional than upon genetic consideration. He further remarks that notwithstanding its rarity, cancer of the vagina is by far the commonest form of primary vaginal neoplasm. It may be said that less than one per cent. of all cancers in women are of vaginal origin. This is contrary to the belief that irritation is the chief determining factor in cancer-causation, for few parts of the body are more prone to all kinds of irritation than the vagina. A controversy is still maintained concerning the question of glandular structures in the vaginal members. Most observers have failed to find structures of this kind. Preuschen and others have, however, asserted their existence. Williams gives a description of the clinical characteristics of the various forms of vaginal cancer. Posteriorly evolving cancers tend to spread backward and forward, involving the rectum and resulting in recto-vaginal fistulae. Anteriorly evolving cancers are apt to invade the base of the bladder and the periurethral region. Cancers of the lower part of the vagina nearly always invade the vulva. Pelvic peritonitis is a common complication of vaginal cancer. Dissemination of the disease in the adjacent lymph-glands generally takes place sooner or later, but it is usually of somewhat tardy development. [W. A. N. D.]

2.—Louis Fischer presents an article upon the various methods of infant feeding, including breast feeding and bottle feeding. The article deals with familiar observations upon the subject, and includes the study of some personal cases which were benefited by the methods of treatment outlined. [T. L. C.]

3.—A. W. Hewlett presents a paper on the presence of typhoid bacilli in the blood of typhoid fever patients. The great certainty of such a means of diagnosis led to a systematic test of its value in a series of cases at the New York Hospital. There was a total of twenty positive cases out of the twenty-four, or eighty-three per cent. of the number investigated. Of sixteen consecutive cases from the male and children's wards, typhoid bacilli were ob-

tained from the blood of fifteen, showing that the above percentage was not raised by a selection of patients. He employs Cole's method in making the blood cultures. His series of cases leads to the view that in the great majority of cases of typhoid fever there is an invasion of the blood with bacilli in the various stages of the disease. It is not, however, properly a septilemia, for the number of bacilli present is ordinarily very small. During the third week of the disease, or about the time the temperature begins to fall, bacilli are no longer to be obtained in blood cultures. With the onset of a relapse, the bacilli reappear in the blood, only again to disappear as the relapse subsides.

[T. L. C.]

4.—U. S. Bird presents a device for irrigating the male bladder. The reservoir containing the irrigating fluid is raised to a convenient height; the nozzle is introduced into the meatus, and pressure sufficient to prevent escape of liquid is made with the thumb and forefinger on the glans and urethra around the nozzle, and the bulb is compressed. The use of gentle, slowly increased, and regulated pressure will cause the liquid to enter the bladder, and the rest is easy. The bladder is emptied naturally and the operation repeated as indicated. He uses the bulb and discharge tube or a bulb syringe connected to the tube of a fountain syringe, and a hard nozzle guarded by a soft-rubber tip displaces the one originally used. He believes that the advantages of the device are: That there is greater safety from infection than when instruments are passed into the bladder; that the possible pain and nervous reaction are more tolerable than when either intravesical instrumentation or gravity alone, as a motive power, is used; and, that it is more certain than gravity alone, as a motive power.

[T. L. C.]

THE NEW YORK MEDICAL JOURNAL.

5. Cholecystectomy for Gallstones. C. L. GIBSON.
6. Fifty Years of Medicine; A Retrospect of Progress During the Past Half Century. T. GALLARD THOMAS.

1.—S. A. Knopf, in his article, gives the following experiences of authorities as to bacilliary transmissions: (1) Lartigan reports four cases, and even in these it was possible that there was hereditary predisposition with subsequent bacterial infection. Benda thinks spermatozooids incapable of transporting immotile bacilli; (2) Walter examined microscopically 230 different preparations from the testicles and 63 from the prostate glands, coming from 21 patients who had died from pulmonary tuberculosis, and could not find a single bacillus in any one of them; (3) Straus, who has made extensive experiments in this direction, repeatedly transplanted portions of the various organs of a fetus from a mother in the last stages of consumption into guinea pigs, and never succeeded in producing tuberculosis in these animals; (4) von Leyden failed likewise in his experiments to inoculate tuberculosis by means of organs taken from a child which had died a few minutes after birth and which had a consumptive mother; (5) Noceard, who only experimented with animals, took the organs of 32 fetuses from four tuberculous rabbits and eight tuberculous guinea-pigs, and inoculated 32 guinea-pigs, all with negative results. From these data the author assumes two cardinal points: (1) That tuberculous infection, contracted in whatever way, during infancy or childhood comes from without and not from within; (2) That there may, however, exist a hereditary predisposition to tuberculosis. As to the frequency of tuberculosis in childhood, Bollinger, in 500 autopsies of children of all ages up to the fifteenth year, found lesions of tuberculosis in 218 cases. In 150 of these the lesions were active, and 68 latent. The maximum death-rate from tuberculous lesions in childhood is reached between the second and fourth years. [T. M. T.]

2.—G. U. Light gives the three characteristic factors in

the blood of infants and childhood: (1) The blood of an infant tends constantly to resume embryonal characteristics when the clinical balance is disturbed; (2) such disturbances produce blood changes out of proportion to the exciting cause; (3) lymphocytosis is pronounced. At birth the red cells average 5,742,980 to the cubic millimeter; there is an accompanying excess of from 25 to 30 per cent. in the hemoglobin with a corresponding increase in the specific gravity; and the white cells in the physiological leukocytosis of the new-born average 15,000 to the same cubic volume. The red count decreases to the end of the first year, and then rises to the twelfth, when the adult balance is acquired. The birth leukocytosis is sustained by a leukocytic count higher than in adult blood to the end of the second year, after which the number gradually sinks and, by the twelfth, the absolute count of the white cells, the differential count, have reached the adult type. Digestion leukocytosis is relatively higher in the early years. The eosinophilia of childhood varies at from 1 to 20 per cent. From 2 to 10 per cent. is doubtless normal in the early years, and an increase in the number of acid-staining cells has not the significance of later life. [T. M. T.]

5.—C. L. Gibson gives his position in regard to cholecystectomy for cholecystitis and cholelithiasis: (1) In properly selected cases it is an extremely simple and safe operation; (2) it is a curative operation, doing away with subsequent attacks of cholecystitis, and, more remotely of renewed stone formation; (3) it eliminates the disagreeable possibilities of long continued biliary mucous fistulae; (4) it is indicated in certain technical conditions, such as atrophic or inaccessible bladder, obliteration of the cystic duct, or impacted stone in the cystic duct, and in hemorrhagic conditions of the gall bladder; (5) it is a prophylactic measure against the development of carcinoma on the site of long-standing irritation; (6) it offers the prospect of a shorter and easier wound healing and convalescence; (7) it is not to be employed indiscriminately, but has its proper limitations and contraindications. [T. M. T.]

MEDICAL NEWS.

November 30, 1901. (Vol. LXXIX, No. 22.)

1. A Tribute to Dr. T. Gallard Thomas.
 2. Courvoisier's Law. RICHARD C. CABOT.
 3. Report of a Case of Diaphragmatic Hernia. H. D. HOWE.
 4. Some Observations, General and Technical, Made at the Craig Colony. SMITH ELY JELLIFFE.
 4. Recent Epoch-Making in Medicine—Annual Oration Delivered Before the Michigan State and Medical Society. SAMUEL BELL.
 6. Deformity Arising from Injury to the Lower Epiphysis of the Tibia. B. E. M'KENZIE.
 7. Dangers to Public Health and Morals. Especially to Young Persons, from Quackery, as Promulgated by Public Advertisement. E. STUVER.
- 2.—Dr. R. C. Cabot gives Courvoisier's law in regard to enlargement of the gall-bladder as follows: When the common duct is obstructed by a stone, dilatation of the gall-bladder is rare. When the common duct is obstructed by other causes, dilatation of the gall-bladder is common. In the first condition, in a great majority of cases, when a stone blocks the common bile duct, there are or have been stones in the bladder. The irritation thus produced results in chronic inflammation with thickening of the wall of the gall-bladder and the gall-bladder is no longer distensible. In a great many cases it contracts. In the latter condition in which the common duct is blocked by cancer of the pancreas or other causes outside of the ducts, the walls of the bladder are thin and easily distended, so that the blocking up of the bile behind the duct readily distends them. [T. M. T.]
- 3.—H. D. Howe reports a case of diaphragmatic hernia with the following history and postmortem. Seven months after being struck by the end of a shaft just below the left breast, from which he seemed to have entirely recovered, and after violent exertion in a jumping contest, the patient was unable to continue on account of pain in the chest. On admission to the hospital he complained of

nausea and a dull pain up and down the lower half of the sternum. There was a decrease in the respiratory movements in the lower half of the left chest with distant breath sounds. The heart was displaced to the right and upward, with normal sounds. The abdomen was somewhat scaphoid, but nothing abnormal was found. The bowels were constipated. Nothing could be kept in his stomach, so rectal feeding was resorted to. At times there was abnormal tenderness. Vomiting was relieved by lavage. The autopsy revealed extreme rigor mortis and considerable emaciation. The stomach, transverse colon, upper part of descending colon and fully one-half of the great omentum were found in the left chest cavity. The rupture in the diaphragm was one and a half by one and half inches, and was near the center of the muscular portion, one inch to the left of the esophageal opening. The edges of the hernial opening were indurated and rolled upward in the thoracic cavity. The heart was displaced to the right and upward. The lung was crowded up above the fourth interspace, but was normal otherwise. The stomach was somewhat dilated and contained about eighteen ounces of ink fluid. The hernia was not strangulated and there was no inflammatory condition of the stomach and intestines. At a point near the junction with the colon, the omentum was strongly adherent to the pleura in the sixth interspace—the site of the contusion of the chest. There was an almost entire absence of the intercostal muscles at the point of the old injury, but no fracture of the rib was perceptible. [T. M. T.]

5.—S. Bell, in his annual oration delivered before the Michigan State Medical Society says: It is an interesting fact to note that after the discovery of the anthrax bacillus by Pollenden and Davaine, in 1849, there was a prolonged period in which no important discoveries of pathological organisms were made, but during this period important methods of technic were elaborated. This was again followed by a period in which important additions followed each other in rapid succession. In 1873 Obermeier discovered the *Spirillum Obermeieri* of relapsing fever. In 1879 Hansen made the announcement of the discovery of bacilli in the cells of leprosy nodules. During the same year Neisser discovered the specific gonococcus of gonorrhea. In 1880 the typhoid bacillus was first observed by Eberth and independently by Koch. During the same year Pasteur published his work on "Chicken-Cholera" and the pneumococcus was described by Sternberg. It was in the year 1882 that Koch made himself immortal by announcing to the world the discovery of the tubercle bacillus, and in 1882 Pasteur published a work on "Rouget du Porc" and Löffler and Schutz reported the discovery of the bacillus of glanders. In 1884 Koch announced the discovery of the "comma bacillus," the cause of cholera, and at about the same time Löffler discovered the diphtheria bacillus, and before the end of the same year Nicolaier the tetanus bacillus. In 1892 Cannon and Pfeiffer discovered the bacillus of influenza. In 1894 Yersin and Kitasato independently isolated the bacillus causing the bubonic plague. In 1894 Sanarelli discovered the bacillus *leteroides*, supposed to be the bacillus of yellow fever. [T. M. T.]

5.—B. E. McKenzie, in his article on deformity arising from injury to the lower epiphysis of the tibia reports three cases in which the following operation was successful. He removed a section about one inch in length from the fibula subperiosteally, the tibia was cut through at the same level as near to the lower end as was thought safe, and the foot moved outward in its relation to the leg, to its normal position. In one of the cases, on account of the patient being quite young, it was decided that the deformity would recur, hence the epiphyseal cartilage was removed from the lower end of the fibula, but in the other two this was not done. Separation of the epiphysis is not of frequent occurrence; and of the various epiphyses, separation of that of the tibia is one of the least frequent. Mr. Hutchinson has seen 17 cases of separation of the lower radial epiphysis; 14 to 15 of the lower humeral; 13 of the upper humeral and 10 of the lower femoral. [T. M. T.]

7.—E. Stuver, after considering the subject of his article quite extensively, concludes with the following facts: (1) The great life-saving discoveries have been made by quite unobtrusive men; (2) quacks and charlatans have never made any great discoveries in sanitary science, but, on the other hand, have always opposed scientific progress and investigation; (3) quackery flourishes best in an atmosphere of ignorance, credulity and pseudo-science, and is promulgated by boastful, arrogant pretensions, and public advertising; (4) antivaccinationists, antivivisectionists, Christian scientists, *et id omne genus*, by opposing preventive sanitary measures and scientific investigations, facilitate the spread of infectious and contagious diseases, oppose the stamping out of diseases already established and impede investigations as to the causation, prophylaxis and cure of disease; (5) the newspapers, which derive a large part of their revenue from advertising, nearly always espouse the cause of the so-called commercial interests, regardless of the fact whether they are supported by truth and justice, or are opposed to the best interests of the public. This is well illustrated by the recent occurrence of the bubonic plague in San Francisco; (6) the boastful pretension and misrepresentations of quack advertisements (patent medicines) lower the public regard for truth and fair dealing, and encourage falsehood and duplicity; (7) the bold and shameless introduction of advertisements, calling attention to and suggesting vile, immoral and even criminal acts, debases and demoralizes the young, and leads to disease, crime and degeneration. [T. M. T.]

THE BOSTON MEDICAL AND SURGICAL JOURNAL.

November 28, 1901. (Vol. CXLV, No. 22).

1. One's Health in Egypt. F. GORDON MORRILL.
2. Hernia Epigastrica and Fatty Tumors in the Epigastrium. HOWARD A. LOTHROP.
3. Abscess in the Posterior Mediastinum in Connection With Pott's Disease. The Report of a Successful Operation for the Drainage of Such an Abscess. JOEL E. GOLDTHWAIT.
4. Pathological Lesions in Rheumatoid Arthritis. C. F. PAINTER.
5. A Case of Papillary Adenocystoma of the Thyroid Gland. HARRY C. LOW.

2.—Will be abstracted when finished.

3.—Goldthwait has seen four cases in which abscess of the posterior mediastinum was diagnosed in connection with Pott's disease on account of pressure symptoms. Three of the patients died, and in one the symptoms disappeared with the drainage of the abscess. Dyspnea is the chief symptom. The attacks are paroxysmal in character with more or less of the tubular or metallic breathing that is seen in acute laryngitis. [J. M. S.]

4.—Painter regards rheumatoid arthritis as a polyarticular disease, occurring usually in young and middle-aged women. It is a disease of insidious onset and development and is brought on by wear and tear. It produces marked constitutional disturbances and manifests itself by a spindle-shaped swelling, marked by synovial distension. There is no true bony enlargement, but there is decided atrophy of the soft parts and osseous erosions. He distinguishes this disease from osteoarthritis. The disease cannot logically be claimed to be an inflammatory one, because of the lack of histological elements found at the seat of the lesions in the joints involved that at all compare with the elements of other inflammatory lesions. The author thinks the bacterial etiology of the disease is not proved. [J. M. S.]

5.—Low reports a case of adenocystoma of the thyroid gland. The patient was a woman, aged 49 years, who noticed the swelling following an attack of sore throat. There was no indication of exophthalmos. The tumor was removed and the diagnosis confirmed by examination.

- Acute Cholecystitis and Cholangitis as a Complication of Gallstones. DANIEL N. EISENDRATH.
- Dissecting Abscess of the Abdominal Wall Producing Deformity Simulating Pott's Disease. JAMES B. BILLITT.

1.—Hektoen delivered the chairman's address before the Section on Pathology and Bacteriology, at the fifty-second annual meeting of the American Medical Association, in which he set forth the lines upon which the work should be carried out. He emphasizes the necessity of securing accurate minutes of the proceedings and also the necessity of exercising the most careful scrutiny in the publications of the articles in the *Journal of the American Medical Association*. He stated that there were unexcelled opportunities for the demonstration to large numbers of specimens, apparatus, and methods of working and teaching in the pathological exhibit. He also remarks that the facilities for scientific work, in this country at the present time, are highly developed, and that research and criticism flourish in the modern American University.

[F. J. K.]

2.—Zeit discusses the effect of direct, alternating, Tesla currents and X-rays on bacteria, before the Section of Pathology and Bacteriology at the fifty-second annual meeting of the American Medical Association. This author performed a large number of experiments, the results of which finally lead to the following conclusions, which we quote in substance: (1) A continuous current of 260 to 320 milliamperes passed through bouillon cultures kills bacteria of low thermal death points in 10 minutes by the production of heat—98.5° C. The antiseptics produced by electrolysis during this time are not sufficient to prevent growth of even non-spore bearing bacteria. The effect is a purely physical one; (2) a continuous current of 48 milliamperes passed through bouillon cultures for from 2 to 3 hours does not kill even non-resistant forms of bacteria. The temperature produced by such a current does not rise above 37° C. and the electrolytic products are antiseptic but not germicidal; (3) A continuous current of 100 milliamperes passed through bouillon cultures for 75 minutes kills all non-resistant forms of bacteria even if the temperature is artificially kept below 37° C. The effect is due to the formation of germicidal electrolytic products in the culture. Anthrax spores are killed in 2 hours. Subtilis spores were still alive after the current was passed for 3 hours; (4) a continuous current passed through bouillon cultures of bacteria produces a strongly acid reaction at the positive pole, due to the liberation of chlorine which combines with oxygen to form hypochlorous acid. The strongly alkaline reaction of the bouillon culture at the negative pole is due to the formation of sodium hydroxide and the liberation of hydrogen in gas bubbles. With a current of 100 milliamperes for 2 hours it required 8.82 milligrams of H₂SO₄ to neutralize 1 c.c. of the culture fluid at the negative pole, and all the most resistant forms of bacteria were destroyed at the positive pole, including anthrax and subtilis spores. At the negative pole anthrax spores were killed also, but subtilis spores remained alive for 4 hours; (5) the continuous current alone, by means of the Dullos-Reymond's method of non-polarizing electrodes and the exclusion of chemical effects by ions in Kruger's sense, is neither bactericidal nor antiseptic. The apparent antiseptic effect on suspension of bacteria is due to electric osmosis. The continuous electric current has no bacteri-

cidal nor antiseptic properties, but can destroy bacteria only by its physical effects—heat—or chemical effects, the production of bactericidal substances by electrolysis; (6) a magnetic field, either within a helix of wire or between the poles of a powerful electro-magnet, has no antiseptic or bactericidal effects whatever; (7) alternating currents of a three-inch Ruhmkorff coil passed through bouillon cultures for 10 hours favor growth and pigment production; (8) high frequency, high potential currents—Tesla currents—have neither antiseptic nor bactericidal properties when passed around a bacterial suspension within a solenoid. When exposed to brush discharges, ozone is produced and kills the bacteria; (9) bouillon and hydrocele-fluid cultures in test-tubes of non-resistant forms of bacteria could not be killed by Röntgen rays after 48 hours' exposure at a distance of 20 mm. from the tube; (10) suspension of bacteria in agar plates and exposed for 4 hours to the rays, according to Rieder's plan, did not kill them; (11) tubercular sputum exposed to the Röntgen rays for 6 hours at a distance of 20 mm. from the tube, caused acute miliary tuberculosis of all guinea-pigs inoculated with it; (12) Röntgen rays have no direct bactericidal properties. The clinical results must be explained by other factors, possibly the production of ozone, hypochlorous acid, extensive necrosis of the deeper layers of the skin and phagocytosis. [F. J. K.]

3.—Ohlmacher gives an account of laboratory observations on hydrophobia in Ohio. This author has had an opportunity of observing, during the past five years, several cases of suspected hydrophobia in the State of Ohio. He gives a brief account of the histories of five cases and reaches the following conclusions: (1) Four instances in which human beings were bitten by dogs suspected of rabies were tested by laboratory methods with positive results in two. All the patients were given the preventive treatment; (2) In three cases the patients were treated at the Chicago Pasteur Institute, and here the only one positive by laboratory test died of rabies in the midst of treatment, presumably because the inauguration of treatment was somewhat delayed and because the stage of incubation was remarkably short; (3) in the fourth case, conclusively demonstrated as rabies in the laboratory, the patients were promptly treated in the Pasteur Department of the Baltimore City Hospital, and they have no evidence of the disease six months after having been bitten. [F. J. K.]

4.—See Philadelphia Medical Journal, June 15, page 1141.

5.—See Philadelphia Medical Journal, June 15, page 1141.

6.—See Philadelphia Medical Journal, June 15, page 1141.

7.—C. L. Leonard in discussing the indications for operation in calculous nephritis and ureteritis refers to the increased frequency of diagnosis of ureteral calculi by the Röntgen method, showing that this condition is much more frequent than was heretofore supposed. It is possible for ureteral calculi to remain quiescent for a long time. The mere presence of a stone in the ureter is no indication for operation. Leonard proposes an expectant or conservative plan of treatment in many of these cases when the stone is small. The Röntgen method has been found as accurate in making negative as positive diagnoses. In over 50% of 48 cases in which calculi were found the stone was lodged in the ureter. The symptoms indicating nonoperative treatment are the presence of a small calculus, a more or less constant, dull ache in the lumbar region with recent and repeated attacks of more acute pain. If the Röntgen picture shows the kidney to be hydronephrotic, there is great likelihood of the subsequent passage of the calculus. Where no infection is present the employment of all exploratory instruments in the male is to be avoided. The segregator, the cystoscope and ureteral catheter are all of value, but their employment in antiseptic cases is still *sub judice*. Urinalysis is of doubtful value excepting as confirming the condition. The Röntgen rays not infrequently will demonstrate the presence of phleboliths in the venous plexus of the broad ligament which may be mistaken for ureteral calculi. In such cases the use of the wax-tipped ureteral catheter is of value. The presence of infection in the female should be considered a positive indication for operation. Com-

plete or unilateral anuria is always an absolute indication for immediate operation. In the male, any form of anuria, the presence of calculi too large to pass, accompanied by symptoms indicating serious injury to the kidney, are indications for operation. Leonard asserts that incision into the kidney for suspected calculus is only justified by the previous detection of the calculus by the Röntgen method. The definite location of the calculus by the X-rays has greatly diminished the traumatism of both kidney and ureter at the time of operation. Stress is laid upon the necessity of thoroughly examining the bladder with a Bigelow evacuator before operating for small ureteral calculi.

[J. H. G.]

8.—D. N. Elsendrath discusses **acute cholecystitis and cholangitis as a complication of gall stones**, and reports an interesting case of a girl 17 years of age who was operated upon for gallstones and purulent cholecystitis in which colon bacilli were found and who died 3 days after operation with symptoms of cholemia. The liver showed evidences of diffuse hepatitis and nonsuppurative cholangitis, and to this condition the death is attributed. Elsendrath reviews very thoroughly the literature regarding the etiology and pathology of infection of the gall bladder and bile ducts, and discusses the symptoms of the various forms of cholecystitis. He condemns the practice of employing any other treatment than surgical after empyema of the gall bladder has been diagnosed. [J. H. G.]

9.—James B. Bullitt reports the case of a 16 year old boy who, 4 months after a typical attack of typhoid fever, developed a **dissecting abscess of the abdominal wall**, which produced a deformity closely simulating **Pott's disease**. After discussing this subject Bullitt reaches the following conclusions: (1) Abscesses of the abdominal wall without any connection with the abdominal cavity occur most frequently as a result of typhoid fever and readily heal after incision and drainage; (2) the larger dissection abscesses of the abdominal wall communicate at their inception with some portion of the intestinal tract, occur most frequently as a sequela of typhoid fever or appendicitis, and result from an adhesion between the parietal peritoneum and a viscus, with perforation of the latter. After rupture such abscesses follow the course of fecal fistula, healing sometimes spontaneously or as a result of incision with drainage only after the communication with the intestine has become obliterated. This obliteration sometimes occurs spontaneously, sometimes must be brought about by operative procedure; (3) a dissection abscess may produce symptoms and deformity simulating Pott's disease; on the other hand, Pott's disease with abscess appearing after an attack of typhoid fever may be confounded with abscess resulting from the typhoidal process. [J. H. G.]

AMERICAN MEDICINE.

November 30, 1901.

1. The Diagnosis of Gallstones and their Aberrances. CHARLES G. STOCKTON.
2. Features Determining Permanency of Cure in Radical Operations for Hernia. A. J. OCHSNER.
3. The Neurasthenic Spine. ROBERT W. LOVETT.
4. Some Thoughts on Rheumatism and Rheumatic Simulants. JAMES J. WALSH.
5. Diagnosis of Diseases of the Urinary Bladder. JOHN R. WATHEN.
6. Shall Massage of the Stomach be Recommended? Etc. MARK I. KNAPP.
7. Tuberculosis of the Sacroiliac Joint, etc. C. O. THIENHAUS.
8. The Indications for Operation in Calculous Nephritis and Ureteritis. CHARLES LESTER LEONARD.

1.—Charles G. Stockton discusses the **diagnosis of gallstones and their aberrances**. He describes cases illustrating the more common forms of the disease, and closes with some general points upon the diagnosis: cholecystitis which is often mistaken for gastralgia. The curious signs of transient pyloric obstruction that follow adhesions of the liver and gallbladder, and the lower end of the stomach must be remembered. It should also be remembered that jaundice is a far from necessary accompaniment of cholelithiasis.

The chief symptoms of gallstone disease, including of course those of the attending cholecystitis, are. Paroxysmal pain, tenderness below the junction of the ninth rib and cartilage; vomiting; ague-like fever; jaundice; the formation of tumor; collapse, and the passage of calculi in the stools. [T. L. C.]

2.—A. J. Ochsner contributes a paper dealing with the features determining with permanency of cure in radical operations for hernia. He states the wound must heal primarily; that in order to avoid pressure-necrosis the stitches must not be drawn tightly; that the edges of the surfaces must be free from fat and other unstable tissues; the tissue should be manipulated with the greatest care during the operation; the wound should be supported by broad rubber adhesive plaster strips; the patient should be kept in bed for two or three weeks; after the operation abnormal intraabdominal pressure should be eliminated. These general conditions, being fulfilled, apply to all cases of hernia alike. He discusses, as well, the steps to be taken in order to secure permanency of cure in inguinal hernia, femoral hernia; ventral hernia following laparotomy, and umbilical hernia. [T. L. C.]

3.—Robert W. Lovett presents a paper upon **neurasthenic spine**, the term used to describe the functional disturbances in which pain and more or less disability of the spine are present. He discusses the conditions from a practical, surgical point of view, and groups them in classes: 1. Irritation of the spine due to faulty attitude. 2. Cases resulting from severe traumatism. 3. Cases resulting from slight traumatism. 4. Spinal invalidism. In this group he includes those case in which severe spinal disability occurs without traumatism or faulty attitude connected with neurasthenia. He believes that classification given is of assistance from the therapeutic point of view. The essential of treatment seems to consist in the progressively increasing use of the spine under proper conditions without too much regard to the subjective symptoms. [T. L. C.]

4.—James J. Walsh contributes some thoughts on **rheumatism and rheumatic simulants**. He discusses briefly the broad use of the term rheumatism, covering a multitude of different conditions, and mentions that finally of late years we have come to realize that acute rheumatic arthritis must be considered as an acute infectious disease of microbic origin. Besides the joint symptoms which occur in connection with mycrobic disease of various kinds there are a series of arthropathies which are due only to the presence of toxins in the blood. These toxic arthropathies represent an important portion of the rheumatic simulants, for instance, the arthropathy which occurs during the course of blood poisoning. There are also a series of cases with painful symptoms usually located in the neighborhood of joints, which have been diagnosed either by the patients themselves or by their physicians as rheumatism. When the patient was not able to give a distinct history of acute rheumatism, the case was assumed to be not rheumatic in character. Among 40 patients under treatment, 15 who presented so-called rheumatic symptoms of the lower limbs were found to be suffering from flat foot. This proportion, says the writer, a little more than one-third, represents very nearly the ratio in which flat foot symptoms are mistaken for rheumatism. He discusses also the treatment of brachialgia growing common among motormen in the cities. Salicylates while they relieve the pain of this condition, are distinctly depressing. What is needed particularly is that the men be instructed to husband their arm energy and use the body weight effectively. [T. L. C.]

5.—John R. Wathen treats of the **diagnosis of diseases of the urinary bladder**. He discusses the various forms of cystitis; the presence of benign papilloma, and the frequent and gradual malignant transformation of the stalk or pedicle of these growths as well as the symptoms of these conditions. [T. L. C.]

6.—Will be abstracted when concluded. [T. L. C.]

7.—C. O. Thienhaus presents a paper on **tuberculosis of the sacroiliac joint**, together with a description of its diag-

nosis and treatment, and the history of a patient with *sacrocoalgia frusta*. The case which he presents was in a young woman of 19 years, who first complained of pain in the lumbar region. The pain irradiated down the left iliac crest and the left side, and gave the impression of a rheumatic disorder. A year and a half previous a swelling appeared on the inner side of the anterior superior spine, above as well as under Poupert's ligament. This was operated upon. Thin, flocculent pus was encountered and the tuberculous cavity was treated in the usual manner with iodoform. In March, 1900, the patient was anemic, but fairly well nourished. Two centimeters to the inner side of the anterior superior spine a round swelling was apparent, upon which two fistulas opened which excreted, by pressure, flocculent pus. A sound introduced into the fistula passed up to the region of the left sacroiliac joint. By vaginal examination swelling and tenderness in the neighborhood of the left sacroiliac joint could be encountered. She has improved somewhat in weight and is able to walk about, but the fistulas are still secreting a thin, muculent fluid.

[T. L. C.]

8.—C. L. Leonard presents a paper on the indications for operation in calculous nephritis and ureteritis, in which he states that the differentiation between the cases that demand immediate operation and those in which a conservative, expectant line of treatment should be pursued, is based upon the results of the Röntgen method of diagnosis. The position and size of the calculi are determined by it, and when taken in conjunction with the symptomatology, furnish accurate data upon which the indications for operation can be based. [T. L. C.]

VRATCH.

September 1, 1901. (Vol. XXII, No. 35).

1. On the Question of Mixed Infection in Bubonic Plague. V. P. KASHKADAMOFF.
2. A Method of Increasing the Amount of Fat in Diluted and Sterilized Cow's Milk to Approximate the Normal Fat of Mother's Milk. A. A. ROMANOFF.
3. On Extravasations into the Spinal Cord. M. O. SCHAIKEVITCH.
4. Stinging Nettle (*Urtica Dioica*) in Uterine Hemorrhages. I. S. KALABIN.
5. A Case of Cesarean Section by Porro's Method in a Woman with a Kyphotic Pelvis. I. A. DISK.
6. Phenosalyl in Gummatous and Varicose Ulcers. F. I. TSCHITSCHERIN.
7. On the Question of Treatment of Intestinal Obstruction by Batsch's Method (Injections of Atropin). S. N. IVANOVSKI.
8. A Case of Rupture of the Spermathecal Cord. A. ABUTKOFF.

1.—Kashkadamoff instituted a series of experiments with the view of determining whether the inhibitory effect of the staphylococci on the plague bacilli observed by Tartakovsky in vitro holds true also in the animal organism. He found, as did Tartakovsky, Kanski and others, that when the plague bacilli are grown in culture media together with the staphylococci, the latter seem to completely inhibit the growth of the former, and on examination are the only organisms found. This, however, does not take place in the animal body. Experiments on guinea pigs and mice have shown that when a virulent culture of the plague bacillus is injected subcutaneously and followed in 24 hours by the injection of a culture of staphylococcus, or vice versa, the animal invariably dies of plague septicemia, the staphylococcus infection remaining localized. A slight antagonism between the two microorganisms was, however, observed also in the animal body. At the point of inoculation of the staphylococci, the subcutaneous tissue, blood vessels and lymphatics became infiltrated with staphylococci, but no plague bacilli could be found, although the animal succumbed to a general plague septicemia. In

white mice the mixed infection seemed to have increased the virulence of the plague bacillus. [A. H.]

2.—Romanoff describes a method of obtaining cow's milk with the proper proportion of fat. The milk is diluted one-half, 4% sugar added, and poured into 6 ounce flasks which are then sterilized for 10 minutes. The flasks are placed on ice for 2-3 hours, when the lower half of the milk in each is removed by means of a siphon. The latter is made of a bent glass tube, the shorter arm of which communicates through a double-perforated stopper with a bottle; through the other perforation another glass tube bent at right angles is passed, somewhat in the fashion of a spritz-bottle. By means of suction any portion of the milk can be readily removed. Repeated analyses showed that the remaining upper half of the milk contains the requisite proportion of fat. [A. R.]

3.—Schaikevitch, from a study of 3 cases and the literature on the subject, draws the following conclusions: 1. Together with the described forms of *hematomyelia* there may be met also such which do not present the *syringomyelic* interruption of sensation and in which the white matter of the cord is principally affected. 2. In these cases the membranes of the cord participate in the morbid condition. 3. This fact is not sufficiently emphasized by other observers. 4. It is not always that the band of *syringomyelic* interruption of sensation is noticed above and below the area of injury and pressure due to fracture of the vertebrae, as shown by Minor. 5. There are cases in which for a long period after the hemorrhage it is impossible to suspect the development of *gliomatosis*. [A. R.]

4.—Kalabin reports 6 cases of *metrorrhagia* from various causes in which the administration of an infusion of *nettle* (10 grms. to 200 cc. of water) in tablespoonful doses had a beneficial effect. He considers this drug a very good hemostatic in certain cases of *metrorrhagia*. [A. R.]

5.—Disk reports a case of a *kyphotic pelvis* in which a 7-months pregnancy was successfully interrupted by a *Porro* operation. He considers the latter preferable to *craniotomy*. The decision as to whether a simple *Cesarian* section or a *Porro* operation should be performed should rest with the woman. [A. R.]

6.—Tschitscherin employed *phenosalyl* in a number of cases of *gummatous* and *varicose ulcers* of long standing, with remarkable success. *Phenosalyl* is composed of carbolic acid, 9 grms., salicylic acid, 1 gm., lactic acid, 2 grms. and mentol, 0.1 gm. It was found by Christmas to be next to bichloride of mercury in its germicidal properties, while it is far less toxic than the other germicides. The most obstinate ulcers yielded to external applications of 10-25% glycerin solution of *phenosalyl*, without the aid of any other treatment. [A. R.]

7.—Ivanovski treated successfully 2 cases of *intestinal obstruction* with hypodermic injections of *atropine*. [A. R.]

8.—Abutkoff reports a rare case of *complete severance* of the *spermathecal cord*, resulting from a slight injury to the testicle. Except a slight hydrocele and temporary pain, no ill effects followed. The patient was seen 5 years after the injury took place. [A. R.]

2.—Waterhouse is convinced that the majority of grave complications of purulent otitis media result from the neglect of treatment of otorrhea. In the majority of cases, aurial polyp, which may be mucous, fibrous, or myxomatous, are caused by purulent otitis media. The polypus, when once developed, tends to aggravate the purulent process by increasing and tending to dam back the flow of pus from the middle ear. They are generally attended by a flow of fetid pus often mingled with blood and, at times, by neuralgic pains, tinnitus, giddiness and attacks of vomiting, symptoms which are dependent, in large part, on the presence of a foreign body that offers an obstacle to the escape of pus from the middle ear. Removal of the polypus is, of course, the treatment to be adopted, but before attempting its removal the cavity of the tympanum should be purified as far as possible by the use of a 1 to 3000 solution of biniodide of mercury in rectified spirit. Purulent inflammation of the mastoid antrum and mastoid cells, if very acute, should cause immediate opening of the mastoid antrum. The author recommends operation upon the mastoid in cases of chronic otorrhea associated with (1) continuous or frequent pain in the ear, mastoid or side of head, particularly when such pains are aggravated by percussion over the mastoid process, (2) total loss of hearing, with frequent attacks of giddiness, suggesting purulent involvement or destruction of parts of the internal ear; (3) caries or necrosis; (4) polypi and granulations that recur after removal, and resist careful treatment with the biniodide and spirit ear drops; (5) caseous deposits and cholesteatomata; (6) facial paralysis, which is so frequently due to caries or necrosis of the facial canal; (7) distinct symptoms of intracranial abscess, meningitis or infective thrombosis of the lateral sinus. The most fatal complication of purulent otitis media is purulent leptomenigitis. The symptoms are frequently modified by the coexistence of abscess of cerebrum, cerebellum, or an extradural collection of pus. There is but one treatment for intracranial abscess; namely, evacuate the pus and drain the abscess cavity; no case must be considered hopeless. The result of operative treatment in intracranial abscess uncomplicated by the coexistence of meningitis or lateral sinus pyemia, is far more favorable than is generally believed. Do not put off operation in the absence of localizing signs. Pyogenic lateral sinus thrombosis is more common than is generally considered to be the case. The symptoms are headache and vomiting, pain on tapping over the situation of the lateral sinus and pain on pressure over the upper 2 or 3 inches of the course of the internal jugular vein and sometimes a hard swelling, the size of the little finger, in the upper part of the course of that vein. The temperature fluctuates between 105° and 106° and 100°F., the pulse is very quick, 120 to 150 per minute. Rigors, edema of the mastoid and occipital regions, icterus, dry and dirty tongue and very foul breath. Diarrhea is constant in the later stages. The lungs suffer on account of fragments of the infective clot, forming pulmonary emboli. Cough is noticed for a day or so, then a sudden sharp pain in the chest, which lasts for half a day, and then subsides. This is repeated perhaps in 2 to 6 other parts of the lungs, and a few hours later the characteristic prune-juice expectoration makes its appearance. The invariable rule of practice must be incision of the sinus and clearing out the clot and puriform debris, with division of the internal jugular vein between two ligatures. [J. M. S.]

3.—The tabetic must learn to forget the "movement memories" that served his purpose while in health, and proceed to acquire a new series of "movement memories," representing the impressions that he now receives in his diseased state through the neurons that remain intact. The amount and rapidity of the improvement is largely influenced by the personal equation of the patient. Without doubt, the best results are obtained in persons who take an intelligent interest in the exercises, and who are at the same time gifted with mental concentration and perseverance. In the presence of a mental defect or disorder, where the foregoing qualities are deficient, little benefit is to be expected. The beneficial effects of the treatment are not limited to a diminution of the ataxia. The change

in the patient's mental disposition which occurs during the course of the treatment is often remarkable. A list of exercises for the lower limbs follows. A quarter of an hour, 2 or 3 times a day, will probably be sufficient at first. An exercise must be stopped on the earliest appearance of fatigue, or if there are any signs of the patient's attention beginning to wander. [J. M. S.]

4.—It is more than doubtful if the attention of the heart muscle with tuberculosis is ever primary. Nearly all the cases are secondary to tuberculosis of the thoracic organs. Adherent pericardium is almost constant, but tuberculosis of the myocardium may exist without any affection of either pericardium or endocardium. In a very large proportion of cases the mediastinal and tracheobronchial glands and the lungs have been extensively and obviously tuberculous. The usual mode of propagation to the heart muscle is by direct extension, but in other instances perfectly healthy heart muscle intervenes between the adherent pericardium and the tuberculous deposit. The infection of the myocardium may be due to carriage by the blood or by the lymph stream. The anterior and upper aspect of the right auricle is the part of the organ most frequently involved in the process. Tuberculosis of the heart muscle may take the form of the large tubercle, the miliary tubercle, or tuberculous myocarditis. [J. M. S.]

5.—The thorax of young and adult men often presents a remarkable development of the veins, which is known as the venous sternocostal festoon. It consists of a band of small veins passing downward and outward from the lower end of the sternum towards the sides below the nipple. The festoon is composed of venules that unite to form the veins that correspond to the terminal branches of the internal mammary artery. In the very great majority of cases, in which Thin observed this condition, the lungs were healthy. The condition occurs in men who take occasionally long-sustained and violent exercise when their ordinary mode of life prevents their being in "hard" condition; and if this suggestion is correct, it would indicate that, in young men in a "soft" condition, the walls of the small veins are less resistant and more dilatible than in those whose condition is described as "hard."

[J. M. J.]

6.—See Philadelphia Medical Journal, Vol. VIII, No. 3, p. 290.

7.—In a considerable proportion of cases of typhoid bacilluria pyuria is present, although not necessarily in large quantities. The fresh urine is slightly turbid. Lewis has noticed that the condition usually commences in the second or third week of typhoid fever and continues for a varying length of time. On the other hand it may not begin until convalescence is progressing and then may last for a long time. The urine is a more or less pure culture of the bacillus typhosus. The author believes that some breach of the excretory membrane is necessary for the escape of the bacillus from the kidney and that there is no true elimination by that organ. Proof that the typhoid bacillus is excreted in the urine, in a condition capable of infecting other persons, has been very definitely forthcoming. It is possibly met with in 10% of cases of typhoid fever. The best internal remedy is urotropin, given in doses of 10 grains, 3 times daily. During the continuation of the attack the urine should be boiled to kill the bacillus.

[J. M. S.]

9. Experimental Investigations Upon the Disinfection of the Hands. Eighth Paper. PAUL and SARWEY.

1.—Hegar, after an eloquent summary of the history of Semmelweis' efforts and results, discusses the present status of puerperal infection. Ordinarily infection occurs from without, giving rise to endometritis, salpingitis, disease of the uterine blood vessels, etc. The diagnosis is sometimes difficult, on account of the difficulty of differentiating from other febrile conditions. The commonest cause is infection from the hands or instruments of the accoucheur. The treatment varies of course with the nature of the process, if there is gangrenous process associated with thrombosis, very little can be done, a reliable antistreptococcic serum not yet having been produced. Prophylaxis consists in thorough cleansing of the patient, and in prohibiting all persons suffering from even the slightest form of infectious disease, such as onychia or furuncles, from attending a woman in labor. Perhaps the most useful therapeutic measure is a careful douching of the uterus, occasionally associated with persistent drainage. The douching should be repeated every hour or two. For this purpose Hegar prefers chlorine water diluted one to four times. [J. S.]

2.—Heinz having noticed that a tendency to nausea or vomiting may be overcome by producing a state of apnea, as for example, by means of forced respiration, has employed this in one case of severe sea-sickness with excellent results. The method is to direct the patient to take one half dozen deep, forcible in- and expirations every time there is a slight sensation of nausea. [J. S.]

3.—Lüthje believes that the following conditions should be fulfilled before we make a diagnosis of renal diabetes. (1) The absence of sugar from the urine before the disease of the kidneys; (2) the presence of sugar shortly after the disease of the kidney; (3) the independence of the amount of sugar excreted from the amount of carbohydrates administered; (4) the diminution of the amount of sugar in the blood. He reports the following interesting case, which appears to satisfy these rigid requirements. A man of 22 acquired gonorrhoea from which cystitis resulted. Later the amount of albumen in the blood was apparently in excess of the amount that should have been present as a result of the mixture of pus and blood, and hyaline and granular casts were found. There was a slight reduction of copper sulphates; there was no increase in thirst, and the spleen and liver were not enlarged. Four days later the presence of sugar was positively determined, and it could be detected in all samples examined until his discharge nearly a month later. Moreover the patient from time to time reported at the hospital for further examination, and sugar was always present. This sugar was not affected by the quantity of carbohydrates administered, but varied irregularly between 3 and 16 grms. per day. An examination of the blood showed the presence of .55% of sugar, a considerable reduction. Of course, in this case it is impossible to determine what is the exact disturbance in the function of the kidney. [J. S.]

4.—Heusner gives a history of the various methods that have been employed for the purpose of reducing deformities of the bones. In the early portion of the last century considerable success was obtained by means of subcutaneous fractures or forcible straightening. Later with the introduction of antiseptic measures, open operations became popular, and practically all cases were treated by incision and then fracture or sawing of the bone. As, however, the results were not as good as was expected, surgeons gradually recurred to the old methods of forcible reduction and then keeping the parts in place by means of plaster bandages. For this purpose numerous instruments have been devised which all consist essentially of clamps for holding the limb in a fixed position, and a screw that produces a steady powerful pressure upon the deformed part. The operations that have given rise to the greatest interest are knock-knee and club-foot. Heusner has devised an osteoclast for the purpose of reducing the former condition, that has certain advantages over those formerly in use. This instrument cannot be well understood without

illustrations, and the reader is therefore referred to the original article. For the reduction of club-foot he prefers the apparatus of Phelps, but also mentions a number of other instruments. [J. S.]

5.—Jochmann reports the following case. A man of 17 had been sick for some time, and in a state of delirium fell down two flights of stairs. When brought to the hospital it was found that both malleolar processes in the right foot were broken. The diazo and Widal reactions were positive, and the patient was delirious. He developed a few superficial abscesses of the skin, progressive weakness of the heart, and a culture of the staphylococcus aureus was obtained from the blood of an arm vein. The patient finally died of exhaustion, and at the autopsy, in addition to the characteristic changes in the intestines, there were abscesses in the lungs, and an area of softening in the upper portion of the sternum, which had given rise to spontaneous fracture. The author regards it as a case of osteomyelitis of the sternum occurring in typhoid fever as a result of the infection with the staphylococcus pyogenes aureus. The case proves that in some instances suppuration after typhoid fever is not the result of the typhoid bacillus. [J.S.]

6.—Kelling has made a series of experiments in order to determine to what extent the intra-abdominal pressure can be increased by enveloping the abdomen with rubber bandages and pumping air into the stomach with a stomach tube. For this purpose, after the air has been pumped in, he attaches a dynamometer to the end of the tube, and has found that under favorable circumstances it was possible to produce a pressure equivalent to 10 cm. of mercury, that could be increased by pressure with the hands upon the abdomen to 18 cm. This method, however, really produces very little effect upon the viscera of the abdomen, in order to treat hemorrhage from the intra-abdominal vessels it is necessary to produce considerably more pressure, and Kelling suggests that the peritoneal cavity be filled with air or water, and has attempted to answer the following questions. First, the approximate amount of pressure from the bleeding vessels; second, whether enough intra-abdominal pressure can be produced to check the hemorrhage; third, the effect of the procedure; fourth, whether any injuries arise; and fifth, the best method of operating and the contra-indications. Upon dogs he found that the blood pressure from the mucous membranes and from the arteries of the stomach varied from 15 to 60 mm. of mercury. In human beings it appears that the pressure is not very much greater than in dogs, and as a matter of fact during operations upon human beings the pressure in the coronary artery of the stomach was measured in 3 cases, and the value found to vary from 40 to 80 mm. In regard to the amount of pressure that can be exerted in the abdomen after it is filled with air or fluid, we know that in cases of ascites it often reaches 40 mm. of mercury. In a series of dogs on whom the operation was performed it was found that it was entirely painless, and that pressure of from 40 to 70 mm. was easily obtained. [J. S.]

7.—Hölscher has made experiments with a number of different bacteria that in many respects are similar to the tubercle bacillus, in order to determine the results of their actions upon the tissues. He found that as a result of intra-venous injection there was a formation, in various parts of the body, particularly the lungs, of giant cells and nodules, but instead of caseation these nodules underwent suppuration. The bacteria other than the tubercle bacillus did not multiply very extensively beyond the point of lesion when injected into the tissues, as for example, into the epidermis. The proliferative action was also present, but on the other hand there was a pronounced exudation of fluid injected into the peritoneal cavity. The pseudo-tubercle bacilli soon lost their vitality, and at the end of 5 days could no longer be stained. At the time there was an exudation of polynuclear cells. The pseudo-tubercle bacilli could be found in the polynuclear leukocytes and endothelial cells, whereas the true tubercle bacilli could only be found in the leukocytes. Nodules were formed in the peritoneal cavity, which in the case of pseudo-tubercle bacilli underwent suppuration or occasionally organization. The chief difference appears to be in the termination of the process. [J. S.]

8.—Frédéric has attempted to determine the bacteriological cause of eczema. He has been unable to find the moro-

coccus described by Gauer. Gilchrist and Saboroud have noted the frequency with which streptococci occur in skin lesions, and Frédéric therefore has devised a method by which it was possible for him to detect small numbers of this organism. He uses Saboroud's medium and inoculates it by means of a long capillary tube from which he aspirates the fluids or crusts to be investigated. In more than 100 cases he was able to detect staphylococci in 53.7%; 27 of these cases were eczema, and in these streptococci were present 17 times. In order to determine in what proportion of normal skins streptococci were present, Frédéric investigated 160 areas in 55 human beings, and found streptococci present in 7.5%. They are most frequent in the axilla and on the back. These streptococci resemble exactly those found in skin lesions. The artificial forms of dermatitis are sometimes sterile, sometimes bacteria in considerable numbers can be obtained from them. In the histological appearance, however, there are some differences between the two forms. In view of the extreme obscurity of this subject it is important to study all cases of eczema in two directions, first as to whether there is any internal condition that may produce them, and second, the possibility of some external irritant. [J. S.]

9.—Hägler has modified Fürbringer's method for disinfection of the hands in the following manner. He removes the fat by means of a paste formed of white clay and water, in which the hands are placed for one or two minutes. They are then thoroughly brushed with soap and water for 5 minutes, dried on a rough cloth, brushed with 70% alcohol, and placed 3 minutes in a solution of 1 to 1000 bichloride of mercury. Paul and Sarvey have tested hands sterilized by this method, and have invariably been able to obtain numerous cultures. Hahn employs a somewhat different method; he places the hands in water heated to a temperature of 43°, then cleanses them thoroughly with soft soap and a soft brush for a considerable period of time; then places them in a solution of bichloride of mercury in alcohol, and finally washes in a 2 per thousand solution of bichloride of mercury. The results showed that typical skin bacteria are frequently obtained from the hands after employment of this method. Various other methods have been suggested, for example, solution of bichloride of mercury in acetone and in methyl alcohol. These seem to produce much better results than any of the other methods, although germs could still be obtained from time to time. Experiments were also made with solutions of citrate of mercury and sulphate of mercury combined with ethylen diamine according to the method of Krönig and Blumberg, but results were not especially favorable. Finally the hands were thoroughly rubbed in a mixture of sublimate and alcohol, but even this failed to produce complete sterilization. As a general result they found that none of the methods for sterilization of the hands at present employed, are capable of producing absolute sterilization of the skin. Nevertheless they believe that it is better to attempt a partial disinfection of the hands than to neglect it altogether.

1.—Edinger and Treupel have found that **subcutaneous injections of rhodanalkali** were entirely inactive against tuberculosis, and even that clinolin rhodan was equally useless, although much more efficient in cultures, the injections, however, produced an increase in the sulphur and nitrogen of the urine. Schlagel in association with them,

has performed a series of experiments, and found that in culture media mixed with various percentages of clinolin rhodan, tubercle bacilli failed to grow, although they grew luxuriantly upon control cultures. The same was true of cultures of septicemic anthrax. If administered to animals in whom an experimental tuberculosis had been produced, absolutely no beneficial results could be observed. They therefore undertook to administer it by the mouth to cases suffering with phthisis, and to make careful studies of the metabolism in these cases, having first determined just what the changes were in a series of experiments on 2 dogs. They found that in these animals the urine became more and more alkaline in reaction, in part at least due to very active fermentation. The investigations upon patients showed for one thing, that the acidity of the urine was not markedly influenced. The rhodan reaction appeared in the sputum one hour after administration; in the urine several days after administration.

[J. S.]

2.—Struppler reports the case of a man, 19 years of age, who, from early childhood had suffered from epilepsy. He was brought to the hospital in an unconscious condition, and a careful examination failed to reveal any serious pathological condition, with the exception of a very slight albuminuria, some increase in the patellar reflexes of the left side, and slight tonicities of the muscles of the arms. From time to time the patient had twitching in the muscles of the eyes. He gradually grew worse; the coma grew more deep, the extremities were finally completely paralyzed and the patient died. Uremia was excluded, partly on account of the history, and partly on account of the condition of the urine. At the autopsy numerous minute punctiform hemorrhages were found scattered throughout the pons and the medulla oblongata, occurring apparently in groups, and occasionally confluent and arranged around the blood vessels. It is possible that the explanation of status epilepticus given by Kazowski is correct, that there is a gradual increase in the neuroglia atrophy of the tissues around the blood vessels, and finally hemorrhages as a result of these conditions, which produces the status epilepticus. [J. S.]

3.—Baumgarten gives the following causes which produce **pain in the tongue**. Among these are varicose veins on the under surface, defective teeth, badly fitting false teeth, diseases of the stomach and intestines, chronic constipation, Bright's disease, climacterium, which produces a dry catarrh of the pharynx, occasionally disturbances of menstruation, uterine disease, paresthesia, and occasionally in neurasthenia, locomotor ataxia, and Duchenne's paralysis. In one case Baumgarten has seen pemphigus of the tongue, and in 2 cases he observed a curious condition occurring in old women which he explains by supposing it is senile pruritis. In one of these the diagnosis was confirmed by gradual transference of the itching to other parts of the body. [J. S.]

4.—Burgl reports two cases in which, as the result of a mistake, young children were given doses of pure lysol. The first, a boy of 5 days, was given a coffeespoonful. He died twelve days later, and the mucous membranes of the entire gastrointestinal tract were found seared by the caustic action of the drug. The kidneys were congested and the bladder contained urine mixed with blood. The second case, a girl of 8 years and 4 months, received a teaspoonful. She soon became unconscious and deeply cyanotic, and there was trismus. Vomiting was induced by the insertion of the stomach sound, but it did not benefit the patient. The mother of the child subsequently declared that the stomach tube had caused death by being passed into the trachea, but as it was proven that it had been inserted for a distance of 30 cm., it was concluded that this was impossible. Burgl has collected 16 cases of **lysol poisoning** from the literature, all of which were produced, as were his own, by the ingestion of pure undiluted concentrated lysol, either taken inwardly or applied outwardly, with the exception of one in which a large quantity of a 1% solution was employed. In this case, however, one in which uterine irrigation was given immediately after birth. It is possible that death was due to other causes. Of these 18 cases, 13 were produced by internal administration, of which 7 recovered, and 6 died; five by external application, of which 2 recovered and 3 died. The majority of fatal cases produced by internal poisoning

were in children. The fatal dose for children is about 1 teaspoonful and even less; for adults in one case, 100 grms. The largest dose which was followed by recovery was 60 grms. in an adult, and 25 grms. in a 4-year-old child. The treatment of lysol poisoning consists practically of repeated washing out of the stomach. Thus, 5 of the cases that recovered were treated in this manner, and 5 of the cases that died were not treated in this manner. In the remaining cases it was employed, but only when the child was moribund. Unquestionably it should be employed, no matter how late the physician sees the case, as lysol is nearly always found in the stomach after death. In addition the patient may be given vinegar to neutralize the free alkali, and in case of unconsciousness, persistent high lavage of the intestines. In view of the poisonous action of the drug it should never be used inwardly in children or adults, and should only be applied externally in children with the greatest care and in weak solutions. [J. S.]

5.—Schwabe reports the case of a man who was exposed to carbon dioxide while performing some work in a sugar factory. He became unconscious, then was weak, confused and delirious. He was finally taken to the hospital in a semi-comatose state with bradycardia, and vomiting. When he finally recovered consciousness, he complained of pains in the lower extremities, as if his legs were lost. There was peripheral paralysis in the right leg with loss of the electric reactions, and there was some weakness of the right arm. His mental condition was querulous, the patellar reflexes were normal, the Achilles reflexes, and plantar reflexes diminished on the right side. A diagnosis of polyn neuritis was made, and as it was noticed that vision was impaired, a careful examination of the eyes was made, showing diminution in the visual acuity and contraction of the color fields, apparently without inversion. The patient recovered. The remarkable features of this case are the wide distribution of the lesions, and the absence of trophic lesion, with the exception of a slight cyanosis and diminished temperature in the right leg. The involvement of the optic nerves has not hitherto been described. [J. S.]

6.—Brunotte reports the interesting case of a man, 36 years of age, who was kicked in the right lower quadrant of the abdomen, by a horse. He was able to work for three quarters of an hour, although he suffered from pain, then went into collapse, and in the course of four hours developed fever. An operation was suggested and refused. In the course of 2 days the condition of the patient was worse, and he had developed an inguinal hernia of the right side. There was persistent hiccupping, vomiting and great tenderness over the abdomen. On the 4th day the patient was brought to the hospital, and at the operation a fibrinous peritonitis was found, although no point of perforation could be discovered. The following day the patient was without fever and pain, although there was frequent vomiting and a desire to urinate. On the second day it was necessary to remove the stitches and to allow the wound to gape, on account of the tympanites. On the 4th day there was a rise of fever, which was relieved by a copious evacuation of the bowels. However, a fecal fistula developed in the wound which was rendered much more difficult to manage on account of a profuse fetid diarrhea. The patient developed a vigorous appetite, gradually recovered his strength, and finally was discharged cured. The case proves the importance of operative interference in all cases of traumatic peritonitis. [J. S.]

7.—Kelling has found that dogs will sustain an intra-abdominal pressure of from 10 to 60 mm. of mercury, produced by the injection of air. This causes considerable increase of pressure in the blood vessels, although not invariably. By a special method of examining the abdomen during the period of greatest pressure, with a modified cystoscope, it was possible to see that when the pressure reached 50 or 60 mm. of mercury the diaphragm ceased to share in respiration, the liver and spleen were contracted, and the stomach and intestines were compressed against the posterior wall of the abdomen. If the organs are injured, as for example, by cutting into the liver, very little blood flowed forth. If the air was allowed to remain in the abdominal cavity for several days the wound healed. If the animals were killed whilst the pressure was kept high, it was found that the abdominal organs were anemic. Other experiments prove further that if the organs were in-

jured whilst the pressure was still high, and the pressure then released, considerable hemorrhage occurred. Experiments upon the cadaver showed that the pressure of 150 mm. of mercury could be readily sustained without danger of injury to the peritoneum. There seems to be considerable difference in regard to the resistance shown by different human beings to intra-abdominal pressure. Two out of 20 days had serious interference with respiration. For clinical use he suggests that the apparatus consists of an ordinary double air pump and Fiedler's trocar, with a mercury manometer. In the tube through which the air passes to the abdomen, a large tube is inserted, containing sterilized cotton in order to filter the air. For the purpose of arresting hemorrhage, the pressure must be at least 30 mm. of mercury. Hitherto clinical experience has been lacking. [J. S.]

8.—Treupel gives a sympathetic account of the life of Christian Bäumler, upon the occasion of his completion of 25 years of service as Professor of the Medical Clinic in the University of Freiburg. He was born in 1836; was educated at the Gymnasium of Nuremberg, and subsequently at the Universities of Erlangen and Tübingen, and later extended his studies in Berlin, Prague, Vienna, Paris, and London. For nine years he was physician to the German Hospital in London, in which city he practiced and had a position in one of the other hospitals. At the end of this time he was recalled to Erlangen as Extraordinary Professor. Two years later he became Ordinary Professor, and finally in 1876, he was called to the Chair in Freiburg, which had been vacated by Kussmaul. His life has been particularly distinguished for his great interest in young physicians, and his willingness to help them at the cost of every sacrifice to himself. A long list of articles that he has written in German and English, is appended. [J. S.]

REVUE DE CHIRURGIE.

1.—Quénu reports a case of outward dislocation of the metatarsus upon the tarsus, which occurred in a man of 20, who had fallen while on horse-back, the weight of the horse resting for a few seconds upon his foot. There was much swelling and the diagnosis remained uncertain. The inner side of the foot projected just above the plantar surface, and the plantar arch was obliterated. Radiographs showed the first metatarsal bone adjoining the second cuneiform not in opposition with the first cuneiform bone which protruded on the internal surface of the foot; the second metatarsal bone was in contact with the third cuneiform; and there were fractures of the second and third cuneiform bones. The remaining three metatarsal bones held their normal positions, while none of the metatarsals were fractured. In spite of reduction, weeks passed before the patient could walk, and the pain still persists. Quénu gives the case-histories of seven other luxations of the metatarsus, none of which were lateral. This is the first case of outward luxation of the metatarsus reported. Quénu believes that whenever any violent movement forces the anterior part of the foot upon the posterior part, dislocating the articulation of Lisfranc and breaking its ligaments, a rotatory movement occurs which determines the type of dislocation resulting. [M. O.]

2.—Fracture of the terminal phalanx of a finger by muscular action is exceptional. Yct Féré, while at work upon Mosso's ergograph, raising a weight of over six pounds a second by the flexion of his middle finger, broke the terminal phalanx of his ring finger, which, with the index finger, was being used as a support for the middle finger. There was no pain or abnormal mobility, but the phalanx was

much swollen. The signs rapidly subsided. Röntgen photographs show the two fragments plainly. A undigital clubbing with a wide, flat nail is the only permanent result of the mishap. [M. O.]

3.—Devle and Gallavardin first report two cases of malignant leiomyoma, one in the thoracic wall of a man of 70, which was successfully excised; the other upon the hip, recurring three times in the space of one year, for which amputation at the hip was performed, with death following. Then they relate in full the history of their case, a woman of 41, over whose external iliac fossa, on the right side, a tumor had existed for years. During the past year this increased rapidly, was subcutaneous, not adherent to the deeper tissues, not ulcerated, and about the size of two fists. Six months later a large tumor appeared in the left hypochondrium, with ascites and tympanites. The liver was hypertrophied, its surface distinctly nodular to palpation. The autopsy revealed a malignant leiomyoma of the subcutaneous tissue of the buttock, with multiple metastases, the kidneys, liver, lungs, pancreas, and thyroid being affected. Such tumors are very rare, though they have been found in the uterus, stomach, and subcutaneous tissue. Many others have been described under the name of fasciculated sarcoma, or fuso-cellular fibroma. These tumors contain bundles of distinct, adult, unstriped muscle cells, crossing in all directions; no or almost no connective tissue at all; possibly some areas of myxomatous degeneration; and possibly some giant cells. The diagnosis of malignant leiomyoma is an extremely difficult one to make. [M. O.]

4.—Neuralgia causes the most severe pain of all the diseases known. It is the main cause of the cocaine and the morphin habits. Yet the treatment of neuralgia is still obscure. After Mears' opinion, that the cause of facial neuralgia was not peripheral, but existed in the Gasserian ganglion, had appeared, Rose, in 1890, performed the first resection of the Gasserian ganglion through the sphenoid bone. Horsley, Hartley and Krause operated through the temporal bone. The most delicate part of the operation is the separation of the first branch of the trifacial. Sapejko reports the case of a man upon whom he performed resection of the Gasserian ganglion with temporary relief. He believes the cause of facial neuralgia is in most cases peripheral. When the neuralgia recurs after peripheral resection of the nerve, it is due to regeneration of the nerve. But he considers the operation upon the Gasserian ganglion of importance theoretically, anatomically, physiologically, and clinically. The operation is full of difficulties; the ganglion lies deep, the hemorrhage is abundant, and some cerebral compression occurs. Sapejko gives the detailed technique of the operation. He concludes that when peripheral resection causes relief for six months or more, the neuralgia is peripheral; that when the three branches are affected, the cause is intracranial; that if the pain passes from one side of the face to the other, the centers of the trifacial nerve are affected; that for peripheral neuralgia the Thiersch method of resection should be done; that when the three branches are affected, the Gasserian ganglion should be resected; finally, in violent cases of peripheral neuralgia, with rapid recurrence after peripheral resection, resection of the Gasserian ganglion is also indicated. This extirpation of the ganglion should be as complete as possible. The symptomatology and etiology of facial neuralgia are given briefly. The literature of the subject is fully cited. [M. O.]

46.—In the last seven years, statistics of 339,429 people anesthetized were collected by von Mikulicz, with only one death among each 2429 patients. 219,566 of these took pure chloroform, with a mortality of one in 2375. But most striking of all is the advance made by local anesthesia in the last few years. For the dangers and after-effects of a general anesthetic are altogether absent when local anesthesia is employed. Yet when too much cocaine has been injected, death may result from local anesthesia. While freezing solution are much in vogue for deadening the pain of an operation, the cocaine solution is the favorite. Cocain injections into the spinal canal were performed by von Mikulicz but 35 times, 24 of which were completely, 6 incompletely successful, and 5 unsuccessful. Local anesthesia has displaced general anesthesia in all small operations, and in those of moderate gravity and length, while major operations are still performed under a general anesthetic. The tendency to pneumonia after operation is even greater when local anesthesia is used than with ether or chloroform. The general condition of the patient, the gravity of the operation, the sensitiveness of the patient to pain, nervousness, etc., all enter into the decision between local and general anesthesia. A local anesthetic should not be used for important operations, for collapse may occur from the pain which may be felt by the patient. The case-histories of two such patients are reported by von Mikulicz. For short laparotomies, such as gastrotomy, etc., he employs local anesthesia. Ether, while less dangerous than chloroform, is but little used in Germany. Death may occur during the administration of ether or chloroform, generally from the use of too much of the anesthetic. Von Mikulicz believes that a general anesthetic should only be used when a local anesthetic is impossible. Search should always be made for possible contraindications to the administration of the anesthetic. The anesthetic should be carefully given, by someone who is experienced in its administration and knows its dangers. For short operations, when both ether and chloroform are contraindicated, bromide of ethyl can be used. Morphin, injected before operation, will increase the intensity and the duration of the insensibility to pain. For a minor operation, only enough of the anesthetic is needed to produce semi-narcosis. The statistics of the subjects are given in full. [M. O.]

47.—Einhorn reviewed the histories of 68 cases of fracture of the leg, 18 of the tibia, 16 of the fibula, and 34 of the malleoli. Next in frequency to fractures of the forearm come the fractures of the leg. These fractures are found at all ages, occurring more often in men than in women, except in old age, when women seem more prone to them. More of these fractures are seen in winter than at any other season of the year. Numerous fractures of the tibia have taken place *in utero*, probably due to faulty ossification; others occurred during labor, from injury. The length and position of the bones of the leg, their substance, and the age, occupation, season, and sex are all physiological predisposing causes; while atrophy, osteomalacia, malignant tumors, osteomyelitis, caries, rickets, scurvy, and syphilis are pathological predisposing causes. The external exciting cause may be direct or indirect violence; the internal exciting cause may be strong muscular contraction. Besides fracture of both bones of the leg, each bone may break singly, at any point, and the epiphyses of either bone may become separated. Besides, the fracture may be longitudinal, oblique, or spiral in form. Fracture of the malleoli may occur by the ankle becoming

twisted toward either side, from pressure or from traction. The malleolus may be fractured by avulsion, or division, or anastasis. The diagnosis is easy, the prognosis excellent, with good treatment. The treatment is reduction and the maintenance of the fragments in good position by a plaster cast for three or four weeks. The results are splendid. The case-histories of the 68 cases follow in detail. [M. O.]

48.—Heidenhain reports four cases of brain tumor which he has seen in the past three years. Three of them were successfully extirpated, the other one, a sarcoma of the cerebellum, killed the patient after a useless operation. In the first case, a man of 32, a solitary tubercle as large as a walnut was removed from the right paracentral lobule, with epileptic attacks after operation. In the second case, a man of 52, a cystic gliosarcoma of the right hemisphere, as large as a hen's egg, embracing the arm center, was extirpated. The tumor had evidently existed for years, but had lately undergone malignant degeneration. No symptoms remained after operation. In the third case, a man of 19, a melanotic carcinoma of the telachoroidea and ependyma of the inferior cornu was removed, with the right temporal lobe. He died three months after operation. In the last two cases, while double optic neuro-retinitis occurred, the hemorrhages were more abundant in the retina of the eye opposite that containing the tumor. These case-histories are given with full details. Heidenhain believes that operations upon the brain should be done slowly, those reported lasting from two to four hours. A nutritive enema is given an hour before operation. Chloroform is administered by the half drop, only sufficient being given to keep the patient anesthetized. Besides this, the patient is kept warm. Hemorrhage, which occurs mainly from the veins of Galen, is stopped by ligating the separate veins. The wound is then covered with sterile gauze to prevent infection. Dangerous hemorrhage may occur from the tumor itself. Heidenhain uses a special spatula to separate the tumor from the brain tissues. The space left after extirpating the tumor is packed with iodoform gauze. In the fourth case, a boy, the operation failed to discover the tumor. He died suddenly during the night which followed the operation. The autopsy showed a sarcoma as large as a potato, in the center of the cerebellum. The technique of Heidenhain's operations is given in detail. [M. O.]

49.—Heidenhain reports the case of a man of 43, in whom resection of the major part of the lower lobe of the left lung was performed for purulent bronchiectasis. This was done in two operations, with good results in spite of the severe hemorrhage. In some of the tissue removed, carcinomatous nodules were found. While the resulting deformity of the left side of the chest was marked, the bronchial mucous membrane covered the site of the operation, forming a thick cicatrix. A fistula persisted. Unfortunately he died with the symptoms of embolism five months after the last operation, a month after he had left the hospital in good condition. [M. O.]

50.—After a historical review of fracture of the os calcis, Martens reports fifteen cases in which Röntgen photographs were made. Two were double, and two were complicated. In two cases the bone was torn apart, in eight there was compression. In four cases the diagnosis was certain without the Röntgen photographs, while in four others the diagnosis was only made by the Röntgen photographs. Martens notes that, in his cases, the fracture was generally horizontal or oblique, and that the calcaneum alone was affected. The Röntgen photographs and the case-histories follow in detail. The literature of the subject is cited. [M. O.]

51.—Kohlhardt describes his experiments upon rabbits. He injected a 10% solution of cocain hydrochlorate deep into the muscles of the fore-leg which had previously been ligated. If this was loosened before three quarters of an hour had elapsed, thus letting the poison into the general circulation, the rabbit died with symptoms of acute poisoning. But, if this ligature upon the rabbit's leg was withdrawn an hour after injection, the effects of the poison were hardly noted. Large injections gave the most strik-

ing results. The intensity and duration of the poisoning is inversely proportionate to the length of time the leg is kept ligated. In similar experiments with strychnin, the results were unsatisfactory, the animals dying from the poison in all cases. The details of the experiments follow. [M. O.]

52.—Rehn believes that the mortality in appendicitis can only be reduced by operation at the correct time. Not only is appendicitis more often correctly diagnosed, but it seems to occur more frequently than formerly. Whenever possible, Rehn removes the appendix. Out of 180 cases operated in the the past year, 134 recovered and 46 died, 38 with purulent peritonitis. Out of 71 cases of purulent peritonitis, 33 recovered. Of 85 cases with circumscribed abscess formation, 77 recovered. In 24 cases the appendix was removed before pus had appeared. Out of 33 cases of total gangrene of the appendix, 22 recovered. Rehn concludes that not only is a prophylactic operation between attacks justified, but the removal of the appendix in the acute stage of the disease is often the means of saving life, for many cases never recover from the first attack. Peritonitis, which is most frequent with total gangrene of the appendix and widespread perforation near the cecum, is due to the quantity of the bacteria, their virulence, and the power of the peritoneum to counteract their invasion. When no tumor is palpable, the condition is grave. Early operation is advised in all severe cases, the expectant plan of treatment being justified only where but moderate local and general symptoms exist. Rehn's technique is described. The prognosis is always uncertain. [M. O.]

53.—Wolff terms the division of all fibrous or bony ligaments of a joint, without resection of the bones, *arthrolysis*. He has performed this operation upon nine patients, seven of which cases have already been reported. Fibrous ankylosis existed in four, while bony ankylosis was found in five. He reports his last case of arthrolysis, performed upon the elbow-joint of a woman of 22, for ankylosis of six months duration, from an unknown cause. The elbow formed an angle of 118°, half way between pronation and supination. After separating the ligaments, enough bone was chiseled off the olecranon and the radius to permit flexion, extension, pronation, and supination. Passive motion was begun, but the patient would not continue on account of the pain. Finally the elbow was put at rest at a right angle. Passive movements were given daily under an anesthetic. The final result was excellent, active motion including all normal movements. Wolff also reports a case of resection of the elbow which was performed 28 years ago upon a child of three. The result in the woman of 31 is also excellent. The little shortening is hardly noticeable, but its cause is seen in the Röntgen photograph. Wolff believes that in childhood total resection of the tuberculous elbow-joint is to be preferred to arthrectomy. Several Röntgen photographs illustrate this article. [M. O.]

54.—Wolff reports an osteoplastic operation performed upon a man of 40, in whom a patella had been fractured 15 months before. The patella was in three pieces. After laying the fragments freely open, he sutured two of them together, employing a special screw-apparatus, leaving them adherent to the edges of the wound. The tuberosity of the tibia was chiseled off and raised, while bits of bone were used to bridge over the line of fracture. Then the skin was closed over the screw-apparatus which held the bony fragments together. Firm bony union resulted, the screw-apparatus being removed six week later by operation. Now, almost two years after operation, the patella is no longer than the normal patella upon the other side. Wolff believes osteoplastic operation to be the only method of curing an old fracture of the patella. Excellent Röntgen photographs accompany the article. [M. O.]

55.—The separate ligaments of the joint-capsule are rarely broken singly, dislocation generally occurring with this condition. A full review of the literature revealed only 44 reported cases. Von Hints reports a case of the isolated rupture of the external ligament of the knee-joint, in a man of 37, who fell from a wagon, his foot, which caught upon

the wheel, being so twisted that he felt the external ligament snap. This is the third reported case of isolated rupture of the external ligament of the knee-joint. There were intense pain and some swelling. The knee was put at rest for eight weeks, the dressing being changed three times. Later he had massage and baths. Six years after the injury he shows a slight failure in the power of adduction and cannot rotate the leg outward. He walks well and is in perfect health. von Hints' experiments upon the knee-joints of fifteen cadavers, cutting the separate joint ligaments, established his diagnosis in this case. The loss of the power of adduction is due to atmospheric pressure, the action of the separate thigh muscles, and the static relations of the human body. The broken collateral fibular ligament is replaced by the sound joint-capsule. Von Hints believes that rupture of the external ligament is so much less frequent than rupture of the internal ligament, because the external ligament is so constructed that it allows freer movement than the internal ligament normally, and because the shock of a fall, etc. is borne mainly by the internal ligament of the knee-joint. The differential diagnosis of rupture of the external ligament of the knee-joint from fracture of the head of the fibula is extremely difficult. Many cases and opinions are quoted. [M. O.]

56.—Schanz describes the physical laws which govern the development of the static deformities due to pressure upon the human skeleton. When bony deformity follows, there is generally some compensatory hypertrophy of the sustaining ligaments. This paper is exceedingly technical. [M. O.]

1. The Differential Diagnosis Between Concretio Pericardii and Organic Tricuspid Disease.

WILHELM TUERK.

2. Instrumental Amusia in Beginning Progressive Paralysis. JULIUS DONATH.

1.—Treated editorially.

2.—Donath reports an interesting case of **instrumental amusia** in a gypsy aged 39, at the beginning of progressive paralysis. Without unconsciousness or paralysis, he suddenly lost the ability to speak. Then he found that he could not play upon his violin. Examination showed that he could play one piece, but only that one, no matter what he was asked to play. Words soon came back, and in time his ability to play the violin again returned. Donath notes that music-deafness, musical alexia, and musical agraphia may exist. He also reports the case of an idiotic child who could only say a few words, yet could sing 50 different songs. Word-deafness and music-deafness generally occur together. He believes that the lesion causing music-deafness is situated in the temporal lobes. In the case of the gypsy violinist, with complete motor aphasia, word-deafness, and partial instrumental amusia, it was especially interesting, psycho-physiologically, that one piece remained *in toto*. This Donath explains by believing that this piece of music occupied its separate memory compartment. [M. O.]

REVUE DE MEDECINE.

5. On the Treatment of the Paroxysm of Malarial Fever by an Iodized Iodin Solution. REGNAULT.

1.—Vaschide and Marchand report a case which illustrates the different degrees of **pathological emotion** on the respiration. [J. M. S.]

2.—Will be abstracted when concluded.

3.—Thomas and Itoux report the case of a woman who complained of lancinating pains in the right leg and thigh, which was diagnosed sciatia. Eight months later the pains returned in both lower extremities and the patient experienced some trouble in walking. Gradually both upper and lower extremities developed a tremor. Speech was difficult and jerky and the patient had a sensation as though the tongue turned with difficulty in the mouth. Then the vision became weakened. The symptoms increased in severity, and the patient died 10 years later of tuberculosis. At the autopsy it was noticed that the central nervous system was smaller than normal but the difference in size was more noticeable in relation to the spinal cord than to the other parts. The central nervous system was examined histologically. The anterior and posterior roots of the spinal cord were smaller than normal, and were composed of a large number of small fibers. There was partial atrophy of the ganglion cells in the anterior horns of the spinal cord, together with atrophy of the small cells at the base of the anterior horns. The cells of the columns of Clark were atrophied, a large number of the reflex collaterals had disappeared and the wreath of medullary fibers in the gray matter was destroyed. There was partial degeneration of the posterior columns, which was at first localized in the column of Burdach in the lumbar and sacral regions, and thence extended into the thoracic region. In the cervical region the degeneration was exclusively limited to the posterior portion of the column of Goll. There was partial degeneration of the anterolateral tract, best marked in the thoracic region, and a total degeneration of the column of Gowers. The absence of the direct cerebellar tract was indicated by a line of degeneration in the thoracic region, slightly marked in the cervical region. There was degeneration of the lateral tract of the medulla, and atrophy of the corresponding nuclei. The restiform body was degenerated in its central portion, whilst its periphery was healthy. From a study of the case, the author concludes that there is a group of **family and hereditary diseases**, in the evolution of which **cerebellar symptoms** play an important role. The anatomical explanation of this disease is a lesion situated either in the cerebellum or in the cerebellar peduncle. They resemble each other by the small size of the central nervous system which is common to them, but they differ from each other by the seat or the extent of the lesion or by its nature. [J. M. S.]

4.—Dopter and Tanton report the case of a man suffering from an old attack of syphilis, who was treated by injections of calomel into the muscles of the buttock every other day. At the time of the sixteenth injection he experienced a sensation similar to the passage of a strong electric current. Later it became impossible for him to walk on account of painful contractions and a very accentuated hyperesthesia of the entire posterior surface of the thigh, the leg and the plantar surfaces of the foot. After treatment by electricity and massage the condition was cured. In a second case of a man who had been treated for syphilis by intramuscular injections of mercury biiodide administered in the buttock, one of the injections was followed by a sense of burning deep in the buttock. Eight hours later he had tingling on the dorsal and plantar surfaces of the left foot. At the same time the foot became numb, and violent pains appeared in the leg. The region of the last injection presented an extravasation of blood, the gait was painful and somewhat resembled steppage. Under electrical treatment there was some improvement, but atrophy of the muscles was only slightly diminished, and the muscles of the leg always presented the reactions of degeneration. The authors made several experiments on guinea pigs, injecting solutions of calomel and mercury biiodide. The injections rapidly produced in all the animals intense nervous lesions. The course of the sciatic nerve is represented by a line passing 2 fingers breadth outside the posterior spine of the ilium to a point in the gluteo-femoral fold, corresponding to the mid-line of the posterior surface of the thigh. About 3 cm. on either side of this line is the dangerous zone, and any injections practiced within the limits of this area would risk injuring the great sciatic nerve. [J. M. S.]

5.—Regnault means by **iodated iodine solution**, a solution composed of tincture of iodine and potassium iodide, each

4 gm.; and distilled water, 100 gm. This solution ought to be considered a complement of quinine and methyl blue in the treatment of malaria, and not as a substitute. Quinine is a specific for malaria, but it should be given before the appearance of the fever, so as to arrest the evolution of the protozoa. Methyl blue may be a possible substitute for quinine, but ought to be administered before the beginning of the attack. Iodized iodine solution is indicated at the beginning of or during the attack, whether quinine has already been administered or not. Treatment by this solution does not prevent the administration of quinine in order to prevent the attack on the following day.

[J. M. S.]

JOURNAL DE MEDECINE DE BORDEAUX.

September 1, 1901. (31me. Année, No. 35).

1. Pharyngo-mycosis. E. J. MOURE.

1.—Liaras reports a clinic held by Professor Moure upon pharyngo-mycosis. This affection is characterized by the appearance of tiny white points on the pharynx, tonsils, base of the tongue, etc. It was first noted by Fränkel in 1873, and is due to the *leptothrix buccalis*, which, proliferating upon the mucous membrane, forms the white spots. Buccal fermentation and acidity of the saliva seem indispensable to its growth. Symptoms are generally absent, though there may be slight sore throat with fever. The diagnosis, while often difficult, can be settled by bacteriological examination. Moure recommends the application of zinc chloride (1 to 15), followed by iodine in solution (1 to 15). Cocain may be applied first (1 to 10), as an anesthetic. In some cases, tincture of the chloride of iron, chronic acid, or the cautery may be needed. An alkaline gargle, cleanliness of the mouth, diet, and hygiene should supplement the local treatment. [M. O.]

JOURNAL DES PRATICIENS.

August 24, 1901. (15me. Année, No. 31).

1. Epidural Injections into the Spinal Canal.

FERNAND CATHELIN.

2. Latent Cardiopathy and Sudden Death in the Army.

KELSCH.

3. Arnica. LIEGEOIS.

1.—Vide Abstract of *La Presse Medicale* for June 15, 1901, in *The Philadelphia Medical Journal* of August 24, 1901, page 304.

2.—Kelsch states that tuberculosis often remains latent among soldiers for a long time, suddenly breaking out in an individual, or only being found at the autopsy. Heart disease may also be latent in soldiers, and sudden death without previous symptoms is not uncommon in the army, 100 cases having been reported in 15 years, without any known disease existing. In the majority of these cases three was some latent cardiopathy. Symptoms may be noted after the first military exercises. Kelsch reports 23 such cases, showing myocardial lesions as a rule. In 6 patients aortitis alone was found. The myocarditis follows atheroma and arteriosclerosis, often terminating with rupture of the aorta. Kelsch divides cardiopathies into simple cardiopathy with hypertrophy and perhaps fatty degeneration; cardiopathy with valvular degeneration; and aortic cardiopathy. Rheumatism was not present in a single case; while aortitis, atheroma, etc., were found in 8 patients. Previous infectious diseases seem to have been the predisposing causes in these cases, alcohol, possibly, also in a few. Kelsch's cases were all vascular, the myocarditis following aortitis, atheroma, etc. Valvular conditions resulted in some. No symptoms exist in these cases, except hypotension, which is generally unrecognized. Exertion will at once upset the equilibrium of the diseased heart, and severe symptoms will result. This is especially noted in the army, among new recruits, and during war, maneuvers, etc. [M. O.]

3.—Arnica is used externally on bruises, sprains, etc.; locally for furunculosis, ulcers, etc., and with ammonium salts, for orchitis, hydrocele, and adenitis. It has been employed in a tooth wash, and is given internally for gout, renal calculus, dropsy, and serous effusions. In large doses, it has been prescribed in shock, and hemiplegia. Liégeois recommends its use in the chronic bronchitis of

old age, as a carminative and emenagogue, and in paralysis of the bladder. It is useful in the malignant fevers, dysentery, tuberculous diarrhea, etc. [M. O.]

PRESSE MEDICALE.

August 24, 1901. (No. 67).

1. The Surgical Treatment of Hydatid Cysts of the Kidney.

ALBARRAN.

2. The Diagnosis and Treatment of Peritonsillar Abscess.

E. J. MOURE.

1.—Albarran reports a case of renal hydatid cyst in a woman of 33. Pain over the left kidney and ureter began over a year ago. Her urine was alternately clear and cloudy. The pain grew more severe. The left kidney was not palpable, a mass being felt which reached up to the eighth rib, as was shown by the percussion dulness. From the white seeds found at times in the urine, the diagnosis of hydatid cyst was made. The cystoscope showed that the opening of the left ureter into the bladder was red and dilated. Catheterization showed the urine from the right kidney to be normal. The cyst was removed by a lumbo-iliac incision, and the patient recovered without a fistula. The cyst opened in the pelvis of the kidney. The ureter was dilated to three times its normal size. The wall of the cyst was calcified in places. Very little of the kidney substance remained. Albarran reviews the literature of the subject, describing four operations, Delbet's extirpation of the cyst membrane, partial resection of the kidney, nephrostomy, and nephrectomy. In hydatid cyst of the kidney Albarran advises nephrostomy in most cases in which laparotomy has been done. If a lumbar incision has been made, open the cyst and find out whether the cyst membrane can be extirpated. If the kidney still seems functional, and total extirpation of the cyst is possible, do renal resection; if the kidney still functionates and these operations are impossible, perform nephrostomy after partial resection of the cyst; if the kidney is useless, nephrectomy should be done. Should many adhesions exist, or should the patient be very weak, nephrostomy may be best. [M. O.]

2.—Moure divides peritonsillar abscesses into the antero-superior, the posterior, and the external forms, in the order of their frequency. The last, while the rarest, are also the most grave forms of peritonsillar abscess. Moure believes all cases should be opened as soon as possible, in the first three or four days. While a trocar will do to open some abscesses, the galvano-cautery is preferred by Moure. He uses cocain (1 to 5) or Bonain's solution, before inserting the cautery, which goes 1 or 2 cm. deep. If the abscess is superior, the cautery goes above, if posterior, behind, and if external, it goes through the tonsil. If the case is so far advanced that the patient cannot open the mouth, external intervention is justifiable. A mouth wash should be used. Zinc chloride (1 to 30) may be applied to the abscess cavity a day or two after operation. The tonsils should be washed and thoroughly examined before the patient is discharged cured. [M. O.]

September 4, 1901. No. 71.

1. Congenital Macroductyly. BOINET.

1.—Boinet, after reviewing this rare subject in detail, reports a case of congenital macroductyly. The middle finger alone was affected in 28 out of the 43 cases reported. The condition is more frequent in men than in women. In Boinet's case, a man of 38, the left middle finger was already hypertrophied at birth. This continued to grow larger, ankylosis beginning in the phalanges, about his nineteenth year. For the past six years the ankylosis has been complete. The volume, length, deviation, and ankylosis of the middle finger of his left hand are all shown in Röntgen photographs. Boinet concludes that bony lesions probably favor the occurrence of macroductyly; that it may rarely be hereditary; that the middle finger may reach the length of 14 cm.; that the skin may remain normal; that, though bony lesions appear in the radiographs, the pathogeny of the condition remains obscure. It may be due to an error in development. [M. O.]

Original Articles.

CONGENITAL DEFECT OF THE FOREARM, ABSENCE
OF THE RADIUS, CLUB HAND, &c. PLASTIC
OPERATION.

By ROSWELL PARK, A. M., M. D.,

of Buffalo, N. Y.

Professor of Surgery, Medical Department, University of Buffalo.

The patient, a little girl of four years, from Saginaw, Michigan, was brought to me in the summer of 1900, with a condition which is perhaps better portrayed by the accompanying illustration than by any description that I can write. Suffice it to say that there appeared to be complete absence of the left radius, which appearance was corroborated by the skiagraph, while the ulna was shortened and curved, with the hand set at nearly right angles to the forearm, the hand turning at almost a right angle to the radial border. There was defect also in the bones of the hand proper, especially in the absence of the metacarpal bone of the thumb, whose two phalanges could be pushed up and down on the side of the hand. Control of the fingers was quite uncertain and the phalangeal joints of the third and fourth fingers were stiffened with the fingers in the flexed position. The ulna was $1\frac{1}{2}$ inches shorter than that of the other arm. The child was otherwise in perfect health. There was no history attaching to the mother's pregnancy or of other congenital troubles in the family.

Congenital Defect of the Forearm.

The question naturally was as to what could be done in the way of remedying the defect and producing a better cosmetic result. The prospect of transplanting the radius did not seem encouraging enough to warrant the attempt. I did think best, however, to attempt transplantation of bone for absence of the first metacarpal bone. It seemed to me that the most hopeful thing that I could do would be to straighten the forearm by bending the ulna and then to impale the carpus upon the sharpened end of this bone, maintaining the hand in the proper position, and hoping

for a sufficient union between the ulna and carpus to make the hand useful and straight.

Operation was done September 1st, 1900, at the Buffalo General Hospital. The tendons on the radial side of the forearm were so much shortened that my first plan to merely expose the end of the ulna, shorten and sharpen it, could not be carried out. I therefore exposed the carpus, which apparently was also defective in its arrangement, and removed parts of two bones of the first row. Then freshening, and, at the same time, sharpening the end of the ulna after the fashion of a picket, I tried to fasten it into the carpus, but had to keep it from sliding by passing a needle with kangaroo tendon suture through the bones, thus lashing them together. I also made an incision over the location of the first metacarpal bone and transplanted therein a piece of bone about 1 inch long and $\frac{1}{4}$ inch in diameter, taken from the humerus of a still live rabbit anesthetized for the purpose. Both of these wounds were closed without drainage, and the arm dressed upon a splint in a perfectly straight extended position. At the end of ten days, the dressings were changed, the wounds found to be perfectly healed, and the splint was then shortened up so as to encourage motion in the fingers. This was the more necessary because the stiffened phalangeal joints had also been loosened under the anesthetic, and I wished to get restoration of motion here, if possible.

The subsequent course of the case has been uneventful; the child lives at such distance from me that I have not since seen it, but the accounts of the case sent by the family are exceedingly encouraging. It was necessary to fit a very light moulded splint upon the arm in order to maintain it in the position in which it should grow and develop. The child wears this splint nights and part of the day time, is getting very good use of the hand, and appears so far as they can tell me to have developed some new bone, at the point where the rabbit bone was transplanted.

SPLANCHNOPTOSIS.

Factors: A. Relaxed Abdominal Walls (including Pelvic and thoracic diaphragm);

B. With Consequent Distalward Moving of Viscera;

C. Gastro-Duodenal Dilatation, (with report of two operations for its relief and a rubber air pad as a supporter).

By BYRON ROBINSON, B. S., M. D.,
of Chicago.

(Continued from Page 958.)

Etiology of Splanchnoptosis.

1. Intra-abdominal pressure.

Factors

which

increase

intra-

abdominal

pressure.

1. Gestation.

2. Food.

3. Fluid.

4. Meteorism.

5. Adipose deposits.

6. Ascites.

7. Tumors.

8. Pleurisy.

9. Feces.

10. Urine.

11. Gastro-duodenal dilatation.

12. Coughing.

13. Contracted pelvis.

14. Blood and lymph volume.

2. Relaxed abdominal walls.

This consists in elongation and separation of fascial and muscular fibres of the anterior abdominal walls, the thoracic and pelvic diaphragm.

3. Compression of the transverse segment of the duodenum by the superior mesenteric artery, vein and nerve.

4. Congenital defects in the nervous, muscular and visceral systems.

5. Defective food and excessive labor.

6. Lordosis or anterior curvature of the vertebral column enhances splanchnoptosis.

7. With the progress of relaxed abdominal walls there is a disproportionate or abnormal relation established between the nervous and muscular systems, and coordination is defective and hence nourishment and function are also defective. The trauma to the sympathetic nervous system produces excessive, deficient or disproportionate secretions and peristalsis in the viscera, hence nourishment is again defective. With the advance of splanchnoptosis the blood and lymph vessels become stenosed, their mechanism disturbed, producing irregular circulation and hence nourishment is again defective.

Splanchnoptosis is a kind of neurosis. It is devitalizing of the sympathetic system in which vitality of the neuro-vascular visceral pedicle is impaired, it becoming elongated, stretched. Perhaps the elastic tissue is degenerated.

FIG. 10. Illustrates a transverse section of the abdomen, about the umbilicus of a splanchnoptotic. The fascial and muscular fibres of the abdominal wall are elongated and separated, the primary factor in the splanchnoptosis. 1, rectus; 2, linea alba; 3, 5, linea semilunaris; 4, skin; 7, fascia; 8, external oblique; 9, internal oblique; 10, transversalis; 11, transversalis fascia; 12, the peritoneum; 13, vena cava; 14, aorta; 16, quadratus lumborum; 15, psoas; 17, vertebra; 16, spinal nucleus.

Notwithstanding the manifold theories and dreams of respected authors and the easily recognized original work of industrious investigators in splanchnoptosis, I am still convinced that one of the great factors of splanchnoptosis is the waist band, not merely the corset, for a corset may be worn so loose that it practically does no damage. During the past 10 years Dr. Lucy Waite and the author have dissected over 35 female bodies for practical topographical and applied anatomy of the abdominal and pelvic viscera. We opened the cadaver and then with the two hands as a corset band or any form of waist band the body was compressed and the result on the abdominal viscera noted. What will happen in tightening the waist band? The answer is clearly evident in watching the progress

of tightening the band. First the right more mobile kidney moves medianward and ventralward, compressing the junction of the descending and transverse duodenal segments, ending in a position almost in the middle of the abdomen. The kidney suffers the most movement dislocation of any abdominal organ. The liver is compressed as is shown in autopsies in the corset liver, the gall-bladder projects ventralward, allowing stagnation of bile and subsequent formations of hepatic calculi. The daily effect of the waist band is diminutive, but continued from week to week, month to month, and year to year, its end results are enormous in changing and damaging structure and function. It constricts the right colon, compromising cecal evacuation, the canalization of the ureter, renal and ovarian veins and inferior vena cava. The nephroptosis elongates the renal vessels especially, the artery which is sheathed in a network of ganglia not only traumatizing them, but, by tugging and dragging on the abdominal brain, the trauma produces the stigmata of hysteria and other neuroses.

FIG. 11. Nephroptosis. 1, diaphragm; 2, coronary ligaments; 3, right lobe of liver; 4, ligamentum suspensorium hepatis; 5, transverse colon forced distalward by the wandering hepatoptotic liver; 6, loops of enteron forced into the lesser pelvis.

The Effect of Relaxed Abdominal Wall (and consequent splanchnoptosis) in Nephroptosis.

Women with relaxed abdominal walls frequently suffer with nephroptosis. In regard to the nephroptosis, the renal secretion is deficient, excessive, or disproportionate. The exact relations of factors of the nephroptosis and relaxed abdominal walls to the disturbed renal secretion are not easy to be determined.

The disturbed renal secretion would appear to be mainly due to disturbed renal mechanism. The renal artery, vein and ureter become compromised in relation to the nephroptosis. The passing distalward of the kidney from relaxed abdominal walls

stenoses the ureter and renal vein. The blood pressure in the renal vein is low, and hence light disturbed renal mechanism will easily compromise its blood flow.

In nephroptosis the distal pole of the kidney approaches the vertebral column disproportionately, and hence compromises the lumen of the ureter, damming the urine. Outside of disturbed urine flow from changed renal mechanism, equally disturbing factors in nephroptosis arise from trauma to the renal plexus. The renal plexus is a large collection of nerve plexuses and ganglia, and besides it is directly connected with the ganglia coeliacum, the abdominal brain, the largest ganglia in the body, which, being a reflex center outside of the spinal cord, reorganizes the reflexes and sends them to all other abdominal viscera. Thus the patient with nephroptosis complains of nausea and vomiting and dragging pains. She gradually becomes neurotic from reflexes due to trauma on the renal plexus. The damage in nephroptosis is, perhaps, in order:

1. Trauma of the renal plexus (and abdominal brain), producing a vicious circle by continuous reflexes on the abdominal viscera.

2. Traumatic stenosis of the vena cava, ovarian and renal veins.

3. Stenosis of the ureter with dislocation of the kidney, preventing drainage.

4. Trauma of renal artery.

5. A combined dislocation of the renal mechanism is changing the relation of the renal vein, artery, and ureter: a disturbed mechanism of the uretero-ureteral triangle.

6. The producing of deficient, excessive or disproportionate renal secretion.

7. The subject with right nephroptosis suffers nausea, headache, foul breath, gastric disturbances and constipation, accompanied by the stigmata of hysteria and other neuroses.

As nephroptosis is only part and parcel of general splanchnoptosis, nephropexy, which should be done by placing the kidney in the abdominal wall without sutures, must be limited in its local and general utility.

The Uretero-Venous Triangles.

In dissecting, one finds on the left side of the body a triangle formed by the ureter on the left side, the ovarian vein on the right side, and the renal vein on the proximal end or base. The sides of the triangle are about 2 inches and the base (the renal vein) is about 1 inch. The apex of the triangle is at the proximal arterio-ureteral crossing of the utero-ovarian, located just proximal to the iliac crest.

This is the left uretero-venous triangle. Its outlines are distorted in left nephroptosis.

On the right side of the body the uretero-venous triangle is formed by the ureter on the right side, the vena cava and ovarian vein on the left side, and the renal vein on the proximal end or base. The right uretero-venous triangle is about an inch at its base (the renal vein) and 2 inches on its sides. Its apex is at the proximal arterio-ureteral crossing of the utero-ovarian artery, and is located $1\frac{1}{2}$ to

2 inches distal to the iliac crest. The significant factor in the right uretero-venous triangle is that in nephroptosis it becomes markedly distorted, compromising the lumen of the ureter ovarian and the renal veins. The uretero-venous triangles, distinct, constant structures, are significant landmarks in topographical anatomy. I have never seen them named or described. They vary considerably in size from the varying location of the apex at the crossing of the ureter by the ovarian vein and artery. The apex of the uretero-venous triangle I have designated as the proximal arterio-ureteral crossing (of the utero-ovarian artery). In any and all nephroptosis the uretero-venous triangle is distorted and the lumen of the vein and ureter is compromised.

FIG. 12 Illustrates gastroptosis. The colon transversum forced distalward into the pelvis by the stomach. 1, liver with hepatoptosis; 2, stomach in the lesser pelvis; 3, 4, duodenum dilated; 5, the jejunum, normal caliber; 6, transverse colon. This cut represents gastro-duodenal dilatation—the second stage of splanchnoptosis.

Result of Relaxed Abdominal Walls (With Consequent Splanchnoptosis) in Genital Ptosis.

The same causes which produce the relaxed abdominal walls frequently produce the genital ptosis. To this class belongs the genital ptosis with relaxed pelvic floor. However, we can have genital ptosis from disturbed pelvic mechanism, without relaxed abdominal wall or thoracic diaphragm. Genital ptosis can exist with merely relaxed pelvic floor as in a relaxed or ruptured levator. In such case the muscle and the levator ani fascia superior and inferior is relaxed by separation, elongation or rupture of its fibres. The peritoneal genital ligaments become slacked, the vagina suffers ectropion, the uterus is retroverted. The vagina and uterus suffer bending with consequent disturbed circulation and peripheral nerve trauma, the bladder is traumatized, especially in the region of the trigone, where nerves and blood vessels congregate.

As a rule, genital ptosis is found to follow relaxed

abdominal walls. Genital ptosis without relaxed, soft, abdominal parietes is perfectly amenable to local treatment and genital surgery. The genital ptosis that is consequent or follows relaxed abdominal walls is accompanied by disturbed genital mechanism, viz.: compromised circulation (lymph and blood), traumatized nerve periphery with pathologic changes in the genital organs, and malnutrition. In genital ptosis from relaxed, soft, abdominal parietes, congestion arises in the pelvis, hyperemia, and there is especially a wide dilatation of the pelvic veins and plexus pampiniformis. Obscure endometrial hemorrhages without apparent cause arise with dragging pains in the terminal branches of the sacral plexus, viz., the pudic (genitals) and the sciatic (limbs). There is quick tiring when standing on the feet. In this category belong the hypertrophic myometritis, which drags and tugs on the uterine ligaments and invaginates the proximal end of the vagina, disturbing the mechanism of the pelvic structures, resulting in compromised blood and lymph circulation, traumatizing of nerve periphery, and accompanied by pathologic genital changes, with malnutrition.

FIG. 13 Illustrates the third stage of splanchnoptosis, viz.: gastro-duodenal dilatation. It shows the transverse colon (5) in the lesser pelvis. The widely dilated stomach (1) is drawn leftward by hooks (10) from its bed to show the duodenum (2) dilated by the superior mesenteric artery, vein and nerve, (3, 4), the normal caliber loops of enteron; 5, right colon; 6, cecum; 7, the appendix. Note the enteron loops crowded into the lesser pelvis.

The chronically engorged uterus is in turn a source of hypersecretion from the endometrium, thus creating a viscous pathologic circle. The genitals, in relaxed abdominal walls, suffer much pain from excessive congestion as they are liberally supplied with blood, especially large veins. Genital ptosis causes pain in the sacro-lumbar region and in the hypogastric region, because the dragging of the genitals on the genital center in the lumbar cord induces reflex pain on the ileo-inguinal nerves and ileo-hypogastric nerves—branches from the lumbar cord. This pain in the hypogastric region is often

mistaken for ovarian pain. The dragging of the enlarged and dislocated genitals on the sensory nerves and ganglia induces discomfort, debility, and pain. The pain in genital dislocation from relaxed abdominal walls is not infrequently taken for ovarian or uterine diseases, and the patient then suffers from excessive treatment. From the relaxed and weak abdominal parietes a disturbed mechanism extends through the tractus intestinalis with its appendages, through the tractus urinarius and tractus genitalis, with accompanying compromise of the circulation and respiration and traumatizing of nerve periphery, followed by pathologic changes in the viscera, and malnutrition. I have noted, however, that patients with similar grade of relaxed abdominal walls do not suffer alike. With those who can take considerable horizontal rest and nourishing food, the deficiency is held in check, especially if the system be well drained and abdominal supporters are employed. In splanchnoptosis the kinking, stenosis, of the tractus intestinalis, fluid-carrying ducts, vascular tubes, etc., is modified because the whole abdominal viscera in toto pass distalward.

Perhaps this is compensated by a change in attitude of the vertebral column. In observing the complex symptoms of relaxed abdominal walls and consequent splanchnoptosis, not only the disease itself should be directly noted, but also compensating processes require attention. In genital ptosis defects in the pelvic floor should be repaired, as well as excessive elongation and separation of the fascial and muscular fibres composing the supports of the genitals. There may be fixation from peritoneal adhesions of the genitals in genital ptosis, or the genitals may be forced through a range extending through the distal half of the abdomen from the pelvic floor to the umbilicus. Besides, the relaxed pelvic floor increases the distal range.

Diagnosis of Relaxed Abdominal Walls With Consequent Splanchnoptosis and Gastro-Duodenal Dilatation.

Inspection.

A hanging belly is recognized by observing the person in the erect and horizontal position. Requesting the patient to control the abdominal muscles by coughing or by attempting to arise from the horizontal position, shows the disordered muscular and fascial relation of the abdomen. On coughing, the linea alba will project forward between the diastatic musculi recti abdominales, with an astonishing deformity. The abdominal walls show extensive distension without corresponding power to contract. In the horizontal position with relaxed abdominal walls the abdomen flattens and bulges out laterally. In the erect position the distal end of the abdomen extends over the symphysis and hides the genitals from view. In the sitting position, the abdomen rests on the knees like a tumor. The skin is dry and shiny and stretched. Frequently the abdominal wall is so thin that peristalsis of the tractus intestinalis is plainly observed. The patient in pronounced splanchnoptosis assumes a position of lordosis as a compensating balance similar to advanced pregnancy. The respiration assumes a typical costal type and the wide diastasis

of the recti abdominales allows the viscera to project between the diastatic recti muscles at every respiration. The linea alba is elongated and stretched to a thin blade. To test the relaxed abdominal wall, place the patient in half-reclining position and request a deep inspiration, when the linea alba will bulge forward with the rigid diastatic recti abdominales projecting one on each side.

FIG. 14 represents ileopectocolitis (?). The spleen is in the lesser pelvis. General splanchnoptosis exists. In another autopsy the spleen rested on the pelvic floor accompanied by general splanchnoptosis. The spleen glides ventral to the colon.

Palpation.

A practical method to test relaxed abdominal walls is to stand behind the patient, place hands on each side of the abdomen, drawing the abdomen proximalward and then suddenly taking the hands away, when the abdomen will fall distalward according to the grade of its relaxation; high grades fall with such considerable force as to shock and traumatize the patient. Also by means of bimanual vaginal palpation one can force the hand between the recti abdominales when diastatic and touch almost all the abdominal viscera. The grade of relaxation of thinning of the abdominal walls is tested by the amount of fold the hands can grasp. One can test by the size of the folds grasped by the hands the capacity of the abdominal cavity.

Percussion.

The percussion completes the findings through inspection and palpation. Percussion locates solid organs whether normal or dislocated.

Mensuration.

One expects more from mensuration in the beginning than in the end results would show. It is true that in mensuration the form of the abdomen in relaxed abdominal walls changes prominently in the horizontal and erect position, but the tiresome, numerous measurements required are not very fruitful or practical.

Relaxed abdominal walls can be mistaken for

fatty abdomen. The massive fat accumulation may project over the symphysis like a bag. However, the lifting of the fat masses or skin folds includes the whole abdominal wall, and clears up the case.

Treatment of Relaxed Abdominal Walls and Consequent Splanchnoptosis, With Gastro-Duodenal Dilatation.

Since the primary factor in splanchnoptosis is loss of elasticity of skin and peritoneum, and loss of muscular contractility of the abdominal walls, the object of the treatment is the restoration of the strength, firmness and elasticity of the abdominal walls. Unfortunately for therapeutics the restoring of elasticity to the structures is difficult. The following methods have proven practical in the treatment of splanchnoptosis in the various stages, viz.:

(a) relaxation of abdominal walls, (b) splanchnoptosis, and (c) gastro-duodenal dilatation from pressure of the superior mesenteric artery, vein and nerve on the transverse segment of the duodenum. The duodenum is compressed in splanchnoptosis because the fixation apparatus of the duodenum will not allow it to pass distalward.

FIG. 15.—A female splanchnoptotic, a multipara, front view of relaxed abdominal walls of umbilicus. Observe that the relaxed abdominal walls pass sufficiently distalward to conceal the genitals from view.

A—Drainage (hydrotherapy).

The most important treatment for splanchnoptosis from first to last is regular and ample drainage. The sovereign drainage fluid a half normal salt solution (5i. NaCl to the quart), 8 ounces of which should be drank every two hours for 6 to 8 times a day. I add to each glass full of half normal salt solution one tablet containing (soct. aloë, NaHCO₃, KH CO₃, Fl., extract cascara-sagrada and mg. SO₄ 2 grs.). After 4 to 6 weeks' use, the tablet is omitted, the (3 to 4 pints) half normal salt solution, with established habits, is sufficient to insure daily drainage, evacuation and renal and cutaneous secretion. The half normal salt solution, aided by the tablet, not only drains the tractus intestinalis, the tractus urinaris and tractus perspiratorius, but thoroughly washes the internal tissues of the body, leaving them in an aseptic condition. The patient suffers chiefly from non-drainage and from deficient and disproportionate secretion, with consequent fermentation and meteorism. Constipation is the fate of the splanchnoptotic from lack of expulsive power. Such a patient requires continual drainage, hydrotherapy. The dyspepsia frequently accompanying splanchnoptosis is mainly owing to non-drainage of stagnant contents in the digestive tract. The more the subject is drained, the less waste-laden blood with mental and physical depression, the less meteorism and intra-abdominal pressure.

B—Massage.

The massage of the abdominal wall as well as that of the tractus intestinalis aids materially in the treatment. However, it is of limited value.

C—Electricity.

Electricity is of considerable value in relaxed abdominal walls, especially faradization of the muscles.

D—Abdominal Supporters.

Much utility and comfort arise from the use of properly fitting abdominal supporters. The kinds we have used are: (1) non-elastic, (2) elastic, and (3) the author's rubber air pad placed inside of an elastic or non-elastic abdominal binder. The objection against the use of an abdominal binder in splanchnoptosis because it does not teach the muscles self-strength, is as worthless as the objection against the use of a splint in fractures. The fact to remember is that the abdominal muscles are stretched beyond self or independent help. Abdominal supporters do not cure, but properly fitting ones help the patient to comfort and usefulness. It is not sufficient to recommend a binder. The physician should examine it to be sure that it fits properly, both for the grade of splanchnoptosis and for the avocation of the patient. The difficulty of fitting a proper support is due to the varying position of the patient—walking, sitting or lying. The author has invented a rubber air pad which has the shape to an axe. This is placed inside of the binder and subsequently filled with air to the desired size. The rubber air pad insures a fitting of the abdomen like a water bed, whether spare or fleshy, and also the size may be adjusted to the comfort of the patient. The binders are useful in moderate nephroptosis,

which is the easiest of all splanchnoptosis to aid, but when it has become advanced, binders are not only of little value but frequently harmful. In severe or distinctly diagnosable hepatoptosis I have seen none or little utility in binders. All tight waist bands should be removed, and clothing should be suspended from the shoulders or from hooks on a corset waist. If one experiments on a dead body with a tight-fitting corset, the organ which will suffer the widest displacement will be the right kidney. All tight corsets should be abandoned, but a so-called waist corset is useful to adjust and from which to suspend the clothing.

Since binder is to restore elongated and separated fascial and muscular fibres of the abdominal walls, it must fit snugly, especially the distal abdomen. Two rubber tubes must be employed passing between the limbs to fix the binder so that it will not slip proximally. The binder generally only forces posteriorly and proximally the abdominal wall, but the addition of the author's rubber pad adds to this the forcing of the viscera proximalward by acting like a pregnant uterus which lifts the viscera toward the thoracic diaphragm. If the splanchno-

FIG. 16.—A lateral view of a female splanchnoptotic, a multipara, showing relaxed abdominal walls and umbilicus.

ptosis is not too far advanced, the rubber visceral air pad being adjusted and blown up while the patient lies on the back, will prevent the viscera gaining the lesser pelvis—the dangerous ground for stenosis of ducts, vessels and viscera, and traumatizing nerve periphery. The binder should be removed or loosened for the night's rest.

(To be concluded).

STATISTICS OF TYPHOID FEVER AT THE PHILADELPHIA HOSPITAL FROM JANUARY 1, 1897, TO DECEMBER 31, 1899.

By HERMAN B. ALLYN, M. D.,
of Philadelphia

Instructor in Physical Diagnosis, University of Pennsylvania; Clinical Professor of Medicine, Woman's Medical College, Physician to the Philadelphia Hospital.

It has only been since 1897 that a satisfactory method of preserving the histories has been adopted at the Hospital. It may seem almost incredible, but it is nevertheless a fact, that the enormous amount of clinical material in the shape of histories of cases at the Philadelphia Hospital has practically been worthless, because, until the past three years, there was no card catalogue of the histories kept, and no index of the cases exists prior to 1897. It is for this reason that the statistics which form the basis of this paper have been limited to the cases which have been dismissed from the hospital or have died in the wards between January 1, 1897 and December 31, 1899.

The whole number of cases in the period mentioned was 184; 135 were males and 49 females; 146 were white and 38 black or mulattoes. The fatal cases numbered 31, a mortality of 16.84 per cent. The average age of patients was 26.24 years, the oldest being 53, and the youngest 5; 93 of the 184 being 25 or under, 50.5 per cent; and 87 being between the ages of 15 and 25 years, inclusive, 47.3 per cent.

The average duration of the fever after admission in cases ending in recovery was 18½ days. The average stay in hospital of the non-fatal cases was about 40 days. This long duration is due to the fact that many of the patients were homeless, and partly to their retention as orderlies when convalescent. In fatal cases the average duration of life was 11.83 days, 14 living only a week or less.

The Fatal Cases.—A study of the fatal cases is always of interest.

1. One, a woman (A. K., aged 39 years) died on the second day after admission. She had exhibited marked nervous symptoms with nephritis and abdominal tenderness. The autopsy showed nephritis, congestion, and edema of lungs; incipient pericarditis; ruptured ectopic gestation; ovarian cyst and incipient typhoid fever. The death was evidently due to rupture of the Fallopian tube, and not to typhoid fever or any of its complications. If this death were excluded, the mortality would be 16.39 per cent.

2. In a second case, (L. G. B., colored, aged 25, the patient was a dipleptic from the nervous ward who had high temperature, receiving 71 tub baths in the ten days he lived. The autopsy showed old adhesive pleurisy, hypoplasia of the arterial trunks, and typhoid fever.

3. In the third case (J. J., colored, aged 19) the disease seems to have begun abruptly, four days before admission, with chills and high fever. He presented marked evidences of typhoid fever on admission, and subsequently developed nephritis and pneumonia, dying of the latter on

the 13th day after admission. The temperature kept pretty constantly 103°-104° throughout, except under the immediate influence of baths. It was highest (105 4/5°) on the 10th day. No autopsy.

4. The fourth case (F. O., aged 19) exhibited marked toxic symptoms from the very beginning of his illness. One week before his admission he had high fever, diarrhea with incontinence of urine and feces. The day after admission albumin and casts were found in the urine. The stools continued to be passed involuntarily, even in the tub baths. Twenty days after admission he was better, passed urine voluntarily, and asked for food. The next day, however, he had a chill, and pneumonia of the left lung developed, the temperature rose to 106 2-5°, the pulse to 144, respiration 40, and he died the following day cyanosed. No autopsy.

5. In the fifth case (M. D., colored, aged 28) the patient succumbed to a complication of pneumonia and nephritis on the 45th day.

6. In the sixth case (A. E., aged 32) the patient was alcoholic. For the two weeks before admission he had been drinking harder than usual. On the 20th day after admission he developed a pleuro-pneumonia. The exudate became purulent, and the patient died during aspiration on the 41st day after admission.

7. In the seventh case, (S. S., colored, aged 22) the patient had been ill three weeks before admission. There was marked toxemia, with delirium, nephritis and high temperature. Four days after admission he had an intestinal hemorrhage of about one pint. The rash was petechial. The next day there was a large hemorrhage from the bowels, and death occurred. Highest temperature 105° on fourth day. Pulse 88 to 160. No autopsy.

8. In the eighth case (D. P., aged 27) the patient was syphilitic. Three weeks before admission the patient had a decided chill, lasting an hour. He had had diarrhea for two weeks before admission, the stools containing a little blood on the second day before admission. On the day of admission there was an intestinal hemorrhage of a quart. Three days after admission he had severe abdominal pain, and two small bloody stools. He presented also delirium and tympany. On the fourth day there was vomiting of fecal matter, followed by death on the fifth day.

9. In the ninth case (G. S., aged 34) the patient developed pneumonia on the fifth day and died the following day.

10. P. L., male, white, aged 24, Ireland, laborer. Admitted January 11, 1899; died January 14, 1899. Admitted very delirious with a history of several weeks illness. The tongue was dry, brown, leathery; there were sordes on teeth. The spleen was much enlarged and there were numerous typhoid spots. Heart's action rapid, sounds weak, pulse feeble. Bronchitis marked. Excessive twitching of tendons. Patient took nourishment very poorly, and had vomiting and diarrhea. January 13th, intestinal hemorrhage. Was comatose for twenty-four hours; the pulse was almost imperceptible. Highest temperature 104 4-5° on the day of admission. Pulse ranged from 120 to 160. Duration, two and one half days. No autopsy.

11. C. D., male, white, aged 30, Penna., cigar maker. Admitted January 24, 1899; died January 27, 1899. Illness said to date back nine days. Complained of sore throat, weakness and dizziness. Prominent symptoms were loose bowels; abdomentympanitic, tense and tender; pulse rapid, spleen enlarged. Had two large hemorrhages January 21st, losing about one quart of blood in each. The following morning had another hemorrhage from bowels. Autopsy showed numerous ulcers in large intestine and in lower part of ileum. Lymph glands enlarged and rather soft.

12. J. McD., white, male, aged 40, Penna., laborer, admitted January 7, 1899; died January 30, 1899. After about two weeks illness, entered complaining of weakness, headache, and pain in back, legs, and feet. Nausea, vomiting, and diarrhea. Prostration. Abdomen distended and tender. Spots present. Widal positive. January 10, pneumonia. January 12, vomited clots of blood. January 16, left parotiditis, incised January 25. January 29, sharp pain with frictions in left mammary region. Died of exhaustion January 30. Highest temperature 104 2-5° on third day. Pulse 80 to 120. No autopsy.

13. A. G., white, male, aged 17, Mass., laborer, admitted December 22, 1898; died December 30, 1898. On admission complained of pain in stomach. His illness began two weeks before admission with languor, anorexia, head-

* Read at the meeting of the Pennsylvania State Medical Society Sept. 26, 1901.

ache, nausea, and occasionally vomiting and nose bleed. Abdomen tympanitic and painful all over. Typhoid spots present. December 24, delirium noisy, occasional incontinence of urine; cough. December 27, Widal positive. December 29, wild delirium, incontinence urine and feces. Urine contained hyaline and granular casts. Died December 30. Highest temperature 195 2-5° on second day; it was frequently 104° or over. No autopsy.

14. P. D., white, male, aged 32, Canada, weaver, admitted December 9, 1898; died December 17, 1898. On admission complained of weakness and fever. About two weeks before admission, developed headache and vertigo, followed by extreme weakness and diarrhea. Typhoid spots were present on the 13th. The prominent symptoms were delirium, weakness, pulse rapid and feeble, dyspnea, and edema of lungs. Widal positive. Highest temperature 105 2-5 on sixth day. It was also 105° on fifth and eighth days, and as a rule was over 104° in the evening. No autopsy.

15. D. McG., white, male, aged 28, Scotland, teamster, admitted December 12, 1898; died December 24, 1898. On admission complained of pain and soreness all over the body. About two months before admission caught cold and had coughed since; had nausea but no vomiting; headache; languor; pneumonia; spleen enlarged; typhoid spots present. Widal positive. Pulse weak, running, dicrotic. Delirium; incontinence of urine and feces. Diazo positive. Death on the 12th day. Highest temperature, 103 4-5° on the third day; pulse 128 to 140. No autopsy.

16. M. J., white, male, aged 37, Penna., cook, admitted February 17, 1899, died February 26, 1899. On admission complained of fever, diarrhea, anorexia, and prostration. Illness began about ten days ago. He 'took cold,' and had a number of chills, severe headache, some pain in right iliac fossa, anorexia, diarrhea, and bronchitis. Pulse dicrotic. Heart's action very weak. Additional symptoms were tympany, gurgling, typhoid spots, Widal positive, delirium constant and at times violent, incontinence of urine and feces, progressive failure of strength and increase of heart weakness. Death on the ninth day. Highest temperature 104 4-5° on the first, second, third, and fourth days. Pulse 104 to 130. No autopsy.

17. E. O., white, male, aged 21, Philadelphia, tinsmith, admitted January 31, 1899, died February 11, 1899. About three weeks before admission began to suffer with headache, aching over body, languor; three days later became prostrated, and suffered with intense headache, anorexia, vomiting and diarrhea. Abdomen slightly distended and markedly tympanitic. Additional symptoms were enlarged spleen, typhoid spots, insomnia, incontinence of feces, tremor of hands and of lower jaw, positive Widal reaction, carphologia, subsultus tendinum, and coma vigil. Subsequently there occurred delirium and suppression of urine. Death on the 12th day. Highest temperature, 105 4-5° on the fourth day; it was often over 104°. Pulse 100 to 128. No autopsy.

18. A. G., white, male, aged 36, Poland, laborer, admitted February 8, 1899, died March 2, 1899. On admission complained of cough and pain in the breast. Patient says he had been ill four weeks beginning with severe headache, followed by cough, pain in the breast, and nausea. Tongue was coated, dry, and fissured. Prominent symptoms were bronchitis, typhoid spots, positive Widal reaction, marked tremor of hands, incontinence of urine and feces, pulse rapid and weak. Hypodermoclysis was employed, but the patient died exhausted on the 22d day.

19. A. L., white, male, aged 38, Scotland, teamster, admitted April 11, 1899, died May 14, 1899. On admission complained of general pain over the abdomen. One week before admission felt very weak, and was obliged to give up work and go home. No headache, but fits of chilliness. Anorexia and loose bowels. Tenderness over abdomen, tongue brown and fissured, sordes on teeth, breath foul. Hebetude. Sleeps with eyes partly open; muttering delirium. Albuminuria; typhoid spots. Seemed about second week of disease at entrance. Small hemorrhage from bowels on fifth day. From this time until death, which occurred on the 32d day, there was a constant struggle to overcome exhaustion and heart failure. Highest temperature, 104 2-5° on the second day, 104° twice on third day. Pulse 90 to 116. No autopsy.

20. M. L., white, female, aged 23, married, Philadelphia, housewife, admitted to gynecological wards July 30,

1899, died August 6, 1899. Admitted with a history of abortion on the previous day, and with a history of chills and fever which had lasted five days. Uterus curetted and decomposed membrane removed. Spleen enlarged, Widal positive, tympany. Patient transferred to medical wards. Here typhoid spots appeared, the pulse became rapid and weak, the lungs congested, and the patient died soon after a convulsion on the seventh day. Highest temperature, 105° on the fourth day; it was 104° or over thirteen times. Pulse 96 to 130. No autopsy.

21. J. C., white, female, aged 23, Germany, domestic, admitted August 23, 1899, died September 2, 1899. On admission complained of anorexia, and pain in back, legs, and abdomen. Illness began two weeks before admission. Prominent symptoms were rapid and dicrotic pulse; arteries sclerosed; typhoid spots, Widal positive, tympany gurgling. Yellow, liquid stools. Delirium supervened and became violent. Occasional incontinence of urine, with albuminuria. Highest temperature, 104 2-5° on admission, generally 102° or under. Pulse 100 to 144. No autopsy.

22. A. M., white, male, aged 27, Philadelphia, laborer, admitted November 30, 1898, died December 18, 1898. On admission complained of cold and sore throat. Often gets drunk on beer. Illness began two weeks before admission with numbness of left side of face and right side of body. He fell to sidewalk and was removed to hospital. Prominent symptoms were hebetude, cough, pain in epigastrium, lips dry and parched, sordes, tongue dry and coated brown. Congestion of lungs, followed by fall of temperature to normal on the fifth; recurrence of fever on the sixth, with enlarged spleen, typhoid spots, positive Widal, several slight hemorrhages from the bowels, and then a large hemorrhage on the 15th. December 16, pulse weak, but gained in strength. Respiration frequent and accompanied by bronchial breathing over bases of lungs. Cyanosis. Large liquid stool, but no blood. Vomited 1.30 P. M. and died almost instantly. Duration, 18 days. Highest temperature, 104 4-5° on the fourteenth and fifteenth days. Pulse 78 to 124. No autopsy.

23. W. J., black, male, aged 22, Virginia, laborer, admitted April 23, 1899, died April 27, 1899. Entered hospital delirious, but with history of illness for five days. Complained of headache, cough, diarrhea and epistaxis. Pulse rapid and dicrotic. Bronchitis. Spleen enlarged. Widal positive. Delirium persisted; there was incontinence of urine and feces, and the pulse became progressively weaker. Death occurred on the fourth day. Highest temperature 105 1-5° twice on third day, and over 104° on three other days. Pulse 108 to 136; respiration 32 to 40. Autopsy: Typhoid ulcers of small and large bowel. Hyperplasia mesenteric glands, moderate enlargement of spleen; cloudy swelling of heart, liver, kidneys; beginning interstitial nephritis; no cerebral meningitis and no disease of cord.

24. G. T. B., black, male, aged 21, admitted December 19, 1898, died December 22, 1898. When admitted the patient was delirious and refused to talk. The abdomen was tympanitic and tender, urine and feces were passed incontinently, respirations were rapid and shallow, the breath sounds were rough over both lungs, Widal positive. The patient took nourishment poorly and refused to take medicine. He died on the third day. Highest temperature 105 2-5° on the first day. Pulse 128 to 130. No autopsy.

25. J. H., black, aged 26, North Carolina, laborer, admitted December 10, 1898, died December 23, 1898. Illness apparently dates back four weeks, when he began to sweat profusely, became weak and dizzy, and fell from exhaustion on the way home. Prominent symptoms, languor, anorexia, headache, enlarged spleen, Widal positive, incontinence of urine, delirium. No plasmodia. Sputum negative. Died on 12th day. Highest temperatures 105° on fourth and eighth days, 104° on first day. No autopsy.

26. E. W., colored, female, aged 20, Virginia, housemaid, admitted January 14, 1899, died January 22, 1899. Complained on admission of headache, fever, and nausea. Nine days before admission began to have vague pains and headache, but kept up until January 7, when had to go to bed. Intense headache and nausea. Tongue dry, sordes on lips. Pulse frequent and feeble. Slight bronchitis. Spleen enlarged. Tremor, restlessness, delirium, incontinence of urine, Widal positive. Highest temperature, 106°, often 105°. Duration, eight days. No autopsy.

27. R. H., black, male, aged 24, Virginia, laborer, admitted April 7, 1899, died April 13, 1899. On admission

complained of weakness and fever. Illness dates back fifteen days, when he developed headache, chilliness, pains in neck and back; no appetite. Prominent symptoms were drowsiness, hebeticity, foul breath, fissured lips, sordes, bronchitis, positive Widal. Patient said to be doing well. Tympanites was noted on the 13th, and he died suddenly. Duration, five days. Highest temperature, 101.4-5° on fifth day, 101.2-5° on second day. Pulse 78 to 108. No autopsy.

28. W. E. H., black, male, aged 28, Virginia, laborer, admitted March 23, 1899, died March 29, 1899. On admission complained of headache. Uses tobacco and alcohol to excess occasionally. Two weeks before admission began with severe headache and cough. Later free expectoration, some pain in chest, severe dyspnea, cardiac palpitation, loss of appetite, nausea and vomiting. Diarrhea marked. Abdomen distended, tympanitic; gurgling in right iliac fossa. The day after admission he was stuporous, and had incontinence of urine and feces. Widal positive. On the 27th he had a serious intestinal hemorrhage, and on the 28th and 29th, he had a number of hemorrhages from bowels, most of them small in amount. The pulse was very feeble and rapid. Coma, followed by clonic convulsion closed the scene. Duration, four and one half days. Highest temperature, 103.1-5°. Pulse 100 to 140. No autopsy.

29. L. R., black, male, aged 26, Virginia, admitted December 10, 1898, died December 15, 1898. On admission complained of pain in the epigastrium. Illness began about three weeks before admission with chilliness, headache, languor, anorexia, pain in stomach, nose bleed. Bowels constipated. Fever and delirium at times. Heart weak. Some blood was found in stool on day of admission. The next day there was a bloody stool, and on the 12th, a large intestinal hemorrhage. On the 13th there were four hemorrhages, three occurring in an hour and a half. Severe nephritis existed. Patient died on the 15th, being in the hospital four and one half days. Widal positive. Temperature was low, only once reaching the sponging point. No autopsy.

30. H. B., male, black, aged 25, North Carolina, laborer, admitted January 31, 1899, died February 10, 1899. On admission had cough, rapid respiration and pulse, high temperature, pain in the left chest, and extreme prostration. Said to have 'taken grippe' one month before admission, but worked until three weeks before admission. Tongue dry and heavily coated, sordes. Rusty sputum. Dulness over left lung, posteriorly and anteriorly, and over right lung anteriorly. Heart rapid and weak. Abdomen tympanitic, and gurgling in right iliac fossa. Muttering delirium. Diarrhea. Widal positive. February 8, better, but incontinence of urine and feces. Subsequently he gradually became weaker and died on the ninth day. Highest temperature 104° during first four days. Pulse 100 to 120. No autopsy.

31. M. W., black, female, aged 28, Philadelphia, cook, admitted February 20, 1899, died February 23, 1899. On admission patient too delirious to give an account of her illness. Expression of face vacant, tongue dry and brown, sordes on teeth. Pulse very rapid and small. Lungs show at right base, posteriorly, areas of dulness and crackling rales. Tenderness in splenic area and also in right iliac fossa. Spleen enlarged. Delirium and great restlessness. Incontinence of urine and feces. Vomiting. The abdomen became distended, the breathing labored and gasping, the face pinched, the pulse imperceptible. Death occurred at the end of two and a half days. Highest temperature, 104.2-5° on second day. Pulse, 120 to 160. Respiration, 44 to 76. No autopsy.

The mortality in 184 cases was 16.84 per cent; or, if we exclude one dying of rupture of the Fallopian tube from ectopic gestation, the mortality is 16.39 per cent. In seeking the cause for such a high mortality, the class of patients forming the great majority of the admissions to the Hospital must be born in mind. They are made up not simply of the poor, but of the homeless, neglected, dissipated, and outcast. Of the last 113 cases, 43 were born outside the limits of the United States, and 28 outside the limits of the State of Pennsylvania. Most of the

negroes came from other states, particularly Virginia. Moreover, 11 of those born in Pennsylvania were born outside of Philadelphia, so that only 33 of the 113 cases were born in Philadelphia. The significance of this I take to mean that more than two-thirds of the patients were either foreign-born, or belonged to the wandering class which is less likely to form fixed home ties, and hence cannot be expected to be so well cared for in sickness. I think it a very fair assumption that the great majority of these patients with typhoid fever never experienced good medical care until they came to the Hospital. Again, it is well known that the earlier a patient with typhoid fever comes under proper medical care, the better the prognosis, and conversely. Now more than two-thirds of these patients were admitted in the second week or later, and one-third in the third week or later. Of the fatal cases, six (6) were admitted during the first week; fourteen (14) after the disease had lasted about two weeks; seven (7) after it had lasted three weeks or longer, and two (2) after four weeks illness; three (3) were too delirious on admission to answer questions, and it is assumed that these three were in the second week. In two (2) cases the duration of the disease before admission could not be ascertained. Thus only one fifth of the cases (6) were admitted during the first week, and twenty-three (23) after the disease had lasted about two weeks or longer. Delay in sending these patients to the Hospital was all the more fatal because they were either ambulatory cases, or lacked proper care at their homes or boarding places. In Osler's series of 229 cases, the mortality was 9.6 per cent. Of the 22 fatal cases, 10 were admitted during the first week, 5 during the second, and three in the third, and two in the fourth. The percentage of deaths to patients admitted in the first week was 9.5; 6.2 for patients admitted in the second week; 12 per cent for the third and 25 per cent of those admitted in the fourth week. The statistics of the German Hospital, as reported by Dr. J. C. Wilson, cover 408 cases up to October 1, 1894, with a mortality of 7.8 per cent. These cases were treated by the Brand method of tub-bathing. In speaking of the contention of Brand that the influence of the treatment upon the mortality is proportionately favorable as it is instituted early in the course of the attack, Dr. Wilson says:—"Taking series 4 and 5 together, we note that of the 32 cases admitted not later than the fifth day, 1 or about 3 per cent terminated fatally. In 78 cases admitted prior to the tenth day, the death rate was 7.7 per cent; and in 18 cases admitted after the tenth day, the death-rate was 22 per cent."

As autopsies were obtained in very few of our cases, the causes of death have to be inferred from the clinical histories. The causes of death, following Osler's classification, were as follows:

1. **Asthenia**, a result either of the rapid or slow action of the toxins, or a sequence of the severe diarrhea—14.
2. **To intercurrent affections**—in the Hospital

cases principally to pneumonia, with or without nephritis, and in one case with empyema—8.

3. To accidents of the lesion, erosion of a blood vessel,—5, or perforation—3.

In one case the cause of death was a rupture of the Fallopian tube from ectopic gestation. There was also pericarditis. It will be noticed that half of the fatal cases occurred in negroes or mulattoes, although they constituted about one-fifth of the whole number of cases. This fact accounts in part no doubt both for the mortality and for the relatively large number of deaths from pneumonia; for it is well known that negroes offer less resistance to disease than whites, and that they are especially susceptible to pneumonia. On the whole, when it is borne in mind that the great majority of the patients who come to the Philadelphia Hospital are from among the poorest and most depraved in the city—patients therefore in many instances already weakened by bad hygiene, insufficient food, and vicious habits—the results obtained from the treatment and the nursing cannot but be regarded as highly satisfactory. Nevertheless the mortality from pneumonia, as a complication (8 cases), would have been lessened by treating the typhoid fever patients in a ward where no pneumonia cases were admitted. Such separation has not been accomplished yet. In future, also, some of the patients who have died from hemorrhage (5) or perforation (3) will be rescued by prompt surgical interference.

Complications and Special Symptoms:—Chills and fever:—Chilliness and chilly sensations of course occurred in many of the cases, (in 30 of the last 113) but in 8 cases there were marked chills which recurred and were followed by fever, and three simulated malarial chills, but no plasmodia were found in the blood. This agrees with Osler's statement that among 685 cases of typhoid, in not a single instance were the plasmodia found in the blood during the course of the disease.

Incontinence of urine and feces:—Incontinence of urine and feces occurred in 21 of the cases ending in recovery, and in 13 of the fatal cases; in two there was incontinence of urine alone. In one of the former the feces were passed while the patient was taking tub-baths. Dr. J. C. Wilson says he has never known an instance in which fecal incontinence occurred during the bath.

Nephritis:—Nephritis occurred in 22 of the cases ending in recovery, and in 7 of the fatal cases. Tub baths do not appear to influence unfavorably the course of the nephritis. In one instance, at least, in which the urine became scanty and contained casts and considerable albumin, under a continued use of tub baths, or perhaps one should say, in spite of a continued use of the baths, the urine became abundant and the nephritis improved.

Sweating:—Free sweating occurred in 14 of the cases.

Blood Stools:—Bloody stools occurred in nine cases ending in recovery, hemorrhage in seven cases and, as already mentioned in speaking of the fatal

cases, hemorrhage occurred in six cases, and hemorrhage followed by perforation once.

Diarrhea:—Twenty of the fatal cases were characterized by diarrhea, and in 38 of the cases ending in recovery (including the 9 who had incontinence) diarrhea or loose bowels were mentioned. In many of these cases, however, the diarrhea was not marked, and in a number of these existed before entrance to hospital, and at the time of entrance, subsiding after the patient had been put to bed and kept on suitable diet. Diarrhea certainly cannot be looked upon as characteristic of the disease as we see it at the present time.

Vomiting:—Vomiting occurred in 9 of the fatal cases.

Tuberculosis:—Three of the patients who recovered were tuberculous before the onset of the typhoid fever, and in one of the fatal cases tuberculosis also existed. There was no autopsy.

Boils:—Boils, I am sure, occurred oftener than the ward notes of the cases would lead one to suppose. In one case numerous boils were succeeded by ulcers which, for the most part, extended through the skin only, but in a few instances through the muscle also, becoming bed sores on the sacrum and hips. They were very sluggish and difficult to heal, owing to the greatly reduced vitality of the patient.

Pregnancy:—One of the patients was pregnant, but there is no record of abortion following, so that the presumption is, pregnancy was not interrupted, which is very unusual. Abortion occurred in three cases.

Orchitis:—Orchitis as a complication occurred in two cases, one of which has been reported by a member of the Staff (Dr. A. A. Eshner*) who also gives a valuable review of the literature of the subject. In the other cases the records unfortunately are imperfect; but the orchitis appears to have involved both testicles, and to have developed early in the disease. The patient was ill three weeks before admission to the hospital, where he was first assigned to the surgical ward. It may be that the orchitis was in origin independent of the typhoid fever.

Phlebitis:—Phlebitis occurred in three cases, but was not especially noteworthy.

Purulent Otitis:—This complication occurred in 15 of the cases, and appears to have been readily amenable to treatment.

Relapse:—Relapse occurred in 8 cases. These of course were relapses in the strict sense of the word, not merely recrudescences. One patient had three relapses. This patient developed typhoid fever about 15 days after confinement in the Maternity ward of the hospital. She remained altogether four months in the medical ward, and at the end of that time was transferred to the Gynecological ward for an Alexander operation.

The Gruber-Widal serum reaction was reported positive in 95 of the last 113 cases, in 13 it was negative, and in 5 the blood was probably not examined. This gives a percentage of 88 in which the serum reaction agreed with the final clinical diagnosis.

Other symptoms which are not common, and

* Philadelphia Medical Journal, May 21, 1898.

which occurred in a few of the last 113 cases are the following:—Retention of urine—5; petechial eruption—2; convulsions—3; and cellulitis of scrotum, tender toes (acroparesthesia), pleural effusion, insomnia, glossitis, tonsillitis, parotiditis, in one case each.

HYPODERMOCLYSIS IN PEDIATRIC PRACTICE.*

By W. C. HOLLOPETER, A. M., M. D.,

of Philadelphia.

Professor of Pediatrics, Medico-Chirurgical College; Pediatricist to the Medico-Chirurgical Hospital, Philadelphia Hospital and St. Joseph's Hospital; Visiting Physician to the Methodist Hospital.

Hypodermoclysis has most probably found its field of greatest usefulness in the hands of the surgeon to combat shock, uremia, toxemia and the various acute surgical procedures. The physician has also found it a remedy of great power in a large variety of cases. Its use, however, has been frequently abused. Like all new remedies that have been efficient, its application has been too widespread. Its reception has been so favorable that the too enthusiastic physician has made many indiscriminate uses of it. In this way many failures were the result. It is, in this manner, that many of the new remedies have received their death-blow. Its value has been overestimated. Its shortcomings have been based on too narrow experimentation. Failures crept in, that a recoil from its usefulness is unavoidable and oftentimes embarrassing to those who would adhere more closely to a fixed line of procedure. Its employment, however, has frequently saved life, and its judicious employment in many hopeless cases in trying times has been deeply appreciated. Its value in surgical and adult medical practice has been undoubtedly adjusted to its just merit.

During the past two years, I have been using hypodermoclysis in some of the ailments of early life and found it already of great power in properly selected cases. It is with the idea of showing its efficiency, as well as its limitations, when judiciously used, that this brief paper is devoted to the more clinical side of the subject. The cases I will cite will be better appreciated if a brief outline of the technic of hypodermoclysis as applied to diseases found in children is better understood. Unfortunately many physicians have abandoned its applications, because of frequent failures found by reason of improper selection of cases and a nebulous knowledge of the necessary technic. Thus many have made a mistake by using the solution too cold, producing a shock on the susceptible nervous system of a growing child. Frequently a non-sterile apparatus has been used, resulting in local inflammation. Others have used it too hot and thermic abscesses have been the result. The most frequent error is that the salt solution has been introduced so freely into the subcutaneous tissue that it has practically drowned the patient by being introduced faster than the excretories could eliminate or the tissues could distribute. Many have found the procedure irksome and as they have termed it "time-wasting." In conversation among physicians, a number of questions have arisen, which leads me to

believe that the technic has been wholly misunderstood, or the methods of application have been carelessly or unsatisfactorily carried out. In the administration of hypodermoclysis, you will find that it cannot be hurried; it requires time, care and some skill. Neither can you entrust it to inexperienced hands. Briefly my technic in the application to children is about as follows. In afebrile cases, such as are found in general atrophy, wasting as following the infectious diseases, the solution should be at least 115° or 120° and delivered to the tissues at 106°. This temperature must be sustained throughout the procedure. The injection may be made in very young children through a large hypodermic syringe or, if a suitable apparatus is obtainable, by gravity. I have found in young children the most satisfactory way of administering it is with the old-fashioned, now abandoned, large antitoxin syringe, which holds one to two ounces. This, after being thoroughly sterilized by boiling, is filled with the normal saline solution of the proper temperature and may be injected into the flanks or into the inner surface of the thigh, above the knee, or preferably near the great trochanter, on the outer aspect of the lower extremities, this being the area of the least sensibility in children. I have selected this spot as being the point of freedom from pressure when the child is lying down. Frequently it is necessary to numb the skin by the application of a piece of ice for a few minutes. In some cases I have used a common hand-ball atomizer, and sprav the spot with sulphuric ether, which numbs the skin sufficiently for the insertion of the needle, the only painful part of the operation. I might add that the low condition of the nervous reflexes in children that have been wasted by disease have never been such as to cause pain. Frequently I have timed myself in giving the injection, and it is generally advisable to consume five to ten minutes, to empty one to two ounces of solution in the sub-cutaneous areolar tissue. The gravity bottle, which at first was universally employed, I have not found very convenient, for a good many reasons. First, because the fluid enters so very slowly that the temperature becomes too low, that you lose the thermic influence for good. This loss of temperature, however, may be overcome by using the water-bath for the fluid and thus sustaining the heat, or by having the delivery tube coiled in a hot-water bag, continually sustaining the temperature. It is never necessary to introduce the fluid with a large syringe so rapidly to produce a swelling, which necessarily means pressure and pain, such a condition oftentimes resembling a hematoma. When the tissues are starved by the loss of blood from the hemorrhage or wasted by long sickness, they will drink up the fluid much more quickly than when the body is full of fluid and toxins, as we find in acute nephritis. In such cases the rapidity of inhibition of fluid must vary with the nature of the case. Oftentimes the tissues are overwhelmed by a large quantity of fluid as given to the patient rapidly, yet we wish to dilute and eliminate the toxic fluid chiefly through kidneys or skin. In such cases I precede the hypodermoclysis with a glycerin enema, which drains the tissues and affords a more rapid entrance to the

* Read before Philadelphia County Medical Society (Northern Branch) October 17, 1901.

subcutaneous injection. The quantity of fluid injected in young children has usually been too large. I have found marvellous results in the application of one to two ounces. My application of hypodermoclysis has been most useful in the following diseases of early life: anuria, usually found in the first three weeks of life, due to deposit of uric acid crystals in the tubules of the kidney, from various causes—surface-chilling, etc.; various forms of uremic coma encountered in the different stages of nephritis, following the eruptive diseases. Shock: shock resulting from intestinal intoxication; depression following any acute febrile disorders incident to any specific diseases, and atrophy following malnutrition.

The various stages of marasmus, the great stumbling block of the physician, offer a very hopeful and encouraging field for the application of hypodermoclysis, especially in the last stage, when all forms of food are refused by the digestive tube, evidently due to atrophy of the peptic gland to receive the pabulum. I have found the patient to respond to a marked degree to this remedy. I have been using concentrated sterile saline found in the market in one-ounce bottles. This properly diluted with boiled, sterile water offers the quickest form of preparation.

CASE 1.—The first illustrative case I will mention is that of a young child, ten days old, born of a weak mother. The child was in a moribund condition when I saw it, and had, as the attending physician represented it, hemorrhage from the penis, which was probably due to uric acid infarction to such an extent as to block up the tubules of the kidney sufficiently to produce frequent hemorrhage from the penis. The child was given one ounce of the normal saline solution three times daily, and after the first injection passed a perfectly clear urine, the general condition immediately changed for the better, and during the three days on which the injections were continued the child's vitality seemed to revive, it was able to nurse and the ordinary functional activity of its young life was brought into existence and continued uninterruptedly to a perfect recovery.

CASE 2.—Male child, three months of age. Was nursed by its mother for one month and during this period its growth was quite normal. The mother unfortunately lost her milk and the child was placed on the bottle, as closely adjusted to the wants of the child as modified milk could be, yet it quickly lost weight and drifted into a wretched condition of marasmus. When brought to my notice, the child's weight was somewhat less than at birth. Hypodermoclysis of one ounce of normal saline solution at a temperature of 120° (delivered into the tissues at 110°) was given every four hours during the day, and the child's weight increased. Coincident with the increase of body weight came a greater capacity for digestion and the child soon comfortably assimilated the carefully modified bottle. The whole organic life of the child, which had seemed nearly lost, was again set in motion, and the child filled out and exhibited all the evidence of returning life. The subcutaneous injection of the salt solution was continued faithfully for two weeks, slowly increasing the amount to two ounces, when enteroclysis was substituted as the less painful and less irksome procedure. This was continued for two more weeks, after which the child made uneventful progress.

CASE 3.—Female child, six years of age, wasted from long continued intestinal intoxication until it resembled a case of advanced phthisis. After a thorough purgation with sodium phosphate and a high enema, hypodermoclysis of eight ounces was commenced, alternating with three ounces of the solution by enteroclysis, with the happiest results. Gastric digestion was quickly restored, the tis-

suess filled up, and the normal bodily activity resumed by the substitution of proper food.

In conclusion we may observe that this method of treatment offers a very wide field of clinical usefulness. Some of the barriers that hinder its constant application are the appearance of a surgical procedure, which may intimidate young children or the family, and the great drain upon the attending physician's time in its application. Yet, in the face of all these obstacles, I feel that it is an unusually powerful remedy, and has given me far better results than any single therapeutic procedure heretofore tried in similar cases.

To recapitulate, its chief fields of usefulness are in hemorrhage in the new born, from the genitals or umbilical cord; in purpura; in cases of general wasting from intestinal disturbances; and especially the toxemias associated with the acute eruptive fevers, scarlet fever and diphtheria claiming an especially high degree of usefulness. In syphilis and in tuberculosis it is a therapeutic measure which aids very materially the uses of other means to effect restoration.

If I have succeeded in encouraging other members of the profession in the use of this therapeutic measure, which I have found so thoroughly efficient, then the object of the slight review encompassed in the paper will have been accomplished.

AMYOTROPHIC LATERAL SCLEROSIS: WITH REPORT OF A CASE.*

By THOMAS LUTHER COLEY, A. B., M. D.,

of Philadelphia.

Chief of the Medical Clinic and Assistant Physician to the Methodist Episcopal Hospital, etc.

The case, which I have the privilege of reporting, is an atypical one and therefore of more than usual interest. It does not seem to fit precisely in the accepted classifications. The diagnosis of the malady from which this patient suffered depended entirely upon the clinical picture presented; for it was not possible to obtain a post-mortem for verification. Therefore, however logically the symptoms may go to show the existence of combined system-disease, it will be well to emphasize the fact that the pathological confirmation of the diagnosis of spastic paraplegia and to a much less extent of amyotrophic lateral sclerosis is rare and that, very frequently, suspected cases prove to be disseminated sclerosis, transverse or focal myelitis, or syringomyelitis, etc.

This patient afforded the rather unusual example of having been under observation from the incipency of the disease, and carefully watched during the course of the malady. This is in marked distinction to the familiar experience in hospital practice, where the average cases of brain and cord disease have assumed usually full development when admitted, and the history of the earlier symptoms can be but inaccurately, if at all, set down. The rare affection from which this patient suffered had certain trophic changes associated

*Read before the Medical Society of the State of Pennsylvania, at the Philadelphia meeting, September 26, 1901.

with it, to which attention will be directed in the proper place.

Mr. S. M., aged 41 years, had been a patient of mine for two years for slight ailments, none bearing the condition present when I called to see him in December, 1897. At this time I found him suffering from an acute bronchitis and complaining of "rheumatic" pains in the calf of the right leg, as well as a dragging sensation and feeling of heaviness and lifelessness in both legs. The bronchitis soon disappeared and the patient's lungs were normal, as was the heart. He has always been fairly healthy, having escaped all the exanthemata of childhood. There is a history of three convulsions in his infancy, all ascribed to traceable errors of diet. When he was 12 years old, he fell from a heavily laden farm wagon into a newly ploughed field and the back wheels of the wagon passed over his abdomen at the umbilicus. Following this incident he was seriously ill for several weeks, but all the facts of the illness were not obtainable. He did not, however, suffer from any form of paralysis or bladder or rectal disturbance, and therefore it would appear that myelitis may be excluded. He recovered complete health, but always after this time experienced a sensation of stiffness of the erector spinae muscles, when he was greatly fatigued, and said that he felt as if there were an iron rod in his spinal column. He is one of a family of seven children; six of whom are living. Five are in good health. A sister is neurasthenic and has been for years a sufferer from ovarian neuralgia. His father had been a sufferer from locomotor ataxia for many years and died of intercurrent disease at 73. His mother died at 60 of carcinoma. His paternal grandfather died at 68 of phthisis, his maternal grandfather of capillary bronchitis at 88, his maternal grandmother of hemorrhage, and his maternal great grandmother of apoplexy at an advanced age. An older brother died of phthisis. The patient is unmarried, has led an exemplary life, is not addicted to the use of alcohol or tobacco, and there is no history of venereal disease. On examination there is no loss of co-ordination of the upper extremities which are in every respect normal. Station is good. The masseteric reflex (jaw jerk) can be readily elicited, but this being found frequently in health, is not of importance. The cremasteric reflex was much increased and elicited on the slightest provocation. Vision is 5/5 and there are no ocular changes. The pupils are somewhat large, $4\frac{1}{2}$ m.m., but respond actively to light and accommodation. The patellar reflex in the right leg is greatly increased. Ankle clonus can be elicited and the calf muscles are spastic. The foot is kept in a position of extension and slightly inverted. The left knee-jerk is also increased and the muscles of the calf are less tense than in the right leg. There is no ankle clonus. The finer movements can be executed with left leg (touching objects with great toe, etc.), but not with the right. The right leg unassisted can be placed across the left knee with difficulty. In walking the toes of the right foot drag the ground and the patient walks on the inner side of the foot. There are no signs of ataxia present. He was advised to use a cane in walking and was able to continue his business, that of book publishing, without interruption until March, 1898. In the blizzard of that date he was obliged to walk a long distance from his office to his home and suffered greatly from exposure to cold. From this time the spastic condition of the left leg became more marked, soon equalling the right and a condition of true spastic gait developed which was typical and which familiar condition I shall not describe at length. There was the usual tendency to tripping and he had several bad falls. The spasticity increasing, he was compelled in a few months to seek an invalid's chair (September 1899), but could still walk with great difficulty by grasping a chair for support. Sensation in the lower limbs continued normal and there was no involvement of the arms. A condition of edema developed in the paralyzed parts which was greatly benefited by massage.

There was no alteration of sensation save cramp-like seizures in the calves, worse at night, and some sense of formication at times. The tactile, thermal and pain senses were normal.

Up to this point and until December, 1899, the case pre-

sented a typical example of the symptom-complex spinal spastic paraplegia, and I believed I was dealing with this rare condition as a pure system disease. At this time the upper extremities showed signs of being affected. The patient first noticed this experiencing difficulty in guiding his pen while writing. The involvement was very rapid. The muscles were for a short time tense and the tendon reflexes were greatly increased. This condition gave way to a progressive wasting, beginning in the thenar and hypothenar eminences and advancing, fasciculus after fasciculus, until the whole muscular structure of the hand, arm and shoulder girdle, as well as the chest, had almost totally disappeared. For a number of months he was able to use his hands but with increasing difficulty. Along with the atrophy described a similar state soon obtained of the muscles of the head and neck. His upper arm could be spanned readily between the thumb and index finger. With the development of the atrophic condition, contractures of the hand appeared, giving rise to the characteristic claw hand. The upper arm rested tightly against the ribs, the lower arm was semi-flexed and in pronation, and could be placed in supination with difficulty. The involvement of the head increased the patient's pitiable state. When seated in his chair, a backward tilt of the head was assumed with the chin high in the air, and when efforts were made by the patient to move his head, they would invariably result in its dropping forward on the chest. This caused him many attacks of nervous dread on account of the sense of suffocation to which this position gave rise. Ability to move the head except to a slight degree laterally was quite impossible. About the first of March, 1901, bulbar symptoms appeared. They consisted in constant dribbling of saliva, difficulty in swallowing and marked interference with speech, which up to this time had been unaffected. The relaxed uvula hung low down and was constantly dripping with mucus. The tongue showed almost constant fibrillary twitchings, not worse when it was protruded. Swelling of the feet, before mentioned, had been present from an early period of the loss of power of the legs, and with the paresis of the upper extremities an edematous condition of the hands appeared. Sensation in the upper extremities as in the lower was practically normal. There were no areas of anesthesia, no loss of temperature sense, but the tactile sense was slightly dulled. The right leg and right hand respectively were first affected of the upper and lower extremities, but at the full development of the disease all the extremities were equally involved. The swelling of the hands and feet persisted until one week before death, when it disappeared rapidly. The patient died suddenly on the second day of July, 1901. The urine was examined repeatedly throughout the course of the disease and barring a slight albuminuria two weeks preceding death (but no casts were found) it had been normal. The urea estimation was also made several times with approximately normal results. Five careful estimations of the electrical reaction of the muscles to both the faradic and galvanic current were made. In the arms there was no apparent loss, either quantitative or qualitative, until the muscles had wasted completely, when no reaction could be obtained. In the legs no appreciable changes were observed. In this place I wish to mention the trophic lesions which were present in the hands and feet. Late in the autumn of 1900, after the arms were paretic, there was noticed a progressive enlargement, especially of the ends, but to some extent of the whole bone of the metacarpal, phalangeal and tarsal and metatarsal bones respectively. A considerable degree of edema was present and it was a difficult matter to differentiate between the swelling of the soft parts and the increase in size of the bones themselves. However, a few days before death the edema having disappeared, I was enabled to satisfy myself as to extent of the trophic changes. In health the patient had worn a seven and a quarter glove. Three days before death a measurement showed that he would have worn a nine and a quarter: a proportionate increase in size of the feet was apparent. Careful examination proved that there was no involvement in the long bones, the vertebrae or head, so that acromegaly or pulmonary osteo-arthritis were not to be considered. The latter was also excluded on the approximately normal condition of the patient's lungs.

The etiology of the condition from which this patient suffered may have had some causative relation with the fall from the farm wagon, although the number of years, which elapsed before the onset of the spastic symptoms, would tend to make this theory untenable. The exposure to cold furnishes, as in so many other cases of cerebro-spinal disease, some claim to etiological importance. For a number of years this patient complained of a peculiar stiff feeling in the back which, as we have said, gave rise to the sensation of an iron rod in his spinal column. It is important, however, to mention, that this was not a constant symptom, but only occurred after fatigue. The gait of the patient when I saw him in December, 1897, was not typically spastic, but there was a peculiar forward tilt of the body from the hips; the elbows were slightly projected from the body and there was a slight tendency towards tripping. By March, 1898, the full clinical picture of spastic spinal paraplegia had developed and this lasted until January 1899.

In this connection the statement of Bruns and Windscheid will bear repetition. These writers say it should not be forgotten that many diseases often reveal themselves for years by the spastic symptom complex, until finally a symptom which does not belong to it appears, and makes the primary disease known.

In this patient the involvement of the upper extremities gave excellent illustration of this point.

Again, primary spastic paraplegia is a very chronic and slowly progressive condition and this case progressed with comparative rapidity. Many cases observed among children (Marie) show complete arrest, and the patients are enabled to earn their livelihood and to live for many years, finally dying of intercurrent disease. Rare as primary spastic paraplegia is in adults, it is sometimes seen in general paralysis of the insane (Westphal).

It would appear that the pathologic process in the case we have described was at first limited to the lateral columns and that there was a final involvement of the anterior cornua at the level of the upper extremities.

The final picture was one of amyotrophic lateral sclerosis. The mode of onset in this case is very unusual. In the vast majority of cases the arms are first affected. Gowers says that the condition begins in the arms in nine-tenths of the cases.

As to the differential diagnosis, the condition is especially to be separated from syringomyelia and multiple sclerosis, although a number of other conditions might have presented some symptoms in common; yet others, which would have been absent, which have excluded these diseases.

Besides syringomyelia and multiple sclerosis, chronic myelitis, pachymeningitis, cervicalis hypertrophica, the spinal form of progressive muscular atrophy, the ataxic paraplegia of Gowers (combined lateral posterior sclerosis) peripheral polyneuritis might present some symptoms in common, and hysteria must also be considered.

Multiple sclerosis it may be said cannot be positively excluded with certainty. However, typical cases present, besides the characteristic symptoms of amyotrophic lateral sclerosis, scanning speech,

intention tremor and optic atrophy. When the areas of sclerosis are limited to the lateral columns, the symptoms are identical and a differential diagnosis is impossible until the multiple sclerosis makes further localization.

Syringomyelia also presents excessive tendon reflexes and amyotrophy of the upper limbs, but the muscular atrophy is usually localized and not at all symmetrical. There is also present a widespread non-typical hemianesthesia and more especially analgesia. Atrophic disturbance such as perforating ulcer, whitlows, dropping off of the phalanges, and readily fractured bones belong under this picture.

In the *combined forms of lateral and posterior sclerosis*, symptoms of incoordination are characteristic. The lower extremities, when the disease occurs in adults, are ataxic and parietic. The walk is uncertain and swaying. Paresthesia occurs together with weakness of the sphincters and loss of sexual power.

Chronic myelitis sometimes presents atrophy of the arms and spasms of the legs, but the disturbances of sensibility are much greater and especially the functions of the bladder and rectum.

In *transverse myelitis* there exists the ascertainable cause of the condition and the upper boundary of the paresis is stationary. Paraplegia is developed more rapidly and completely, there is vesical weakness and bed-sores appear. In this disease the condition of the reflexes (in this classification I quote Hirt) depends upon: 1. The state of the reflex arc in the spinal cord, and, (2) On the state of the fibres coming from the brain which have probably an inhibitory function. If the reflex arc is normal, but the conduction of the inhibitory fibres is interrupted, then the corresponding reflex is increased, while if the reflex arc is diseased, the reflex is lost, no matter whether the inhibitory fibres are intact or not. This holds for the skin as well as the tendon reflexes.

In case of lumbar myelitis, not only the skin but the tendon reflexes are diminished or lost in the lower extremities. Those concerned are the patellar reflex, the reflex arc of which corresponds to the cord between the second and fourth lumbar nerves and the tendon of Achilles reflex which corresponds to the first sacral nerve. The cremastic and abdominal reflexes are at the level of exit of the first lumbar and that portion of the cord between the fourth and seventh dorsal nerves respectively. On the other hand, in a dorsal or cervical myelitis a marked reflex action begins, caused by the inhibitory reflexes being cut off. For localization of myelitic processes neither bladder nor rectal symptoms can be used. They are always present at whatever level the lesion may exist.

Peripheral polyneuritis is characterized by amyotrophic symptoms in the arms with disturbances of sensation, but there is a decrease in the tendon reflexes. The spinal form of progressive muscular atrophy always begins in the muscles of the hands and is never attended by disturbances of sensation or by spasms of the legs.

The treatment of the case which I have described represents a series of disappointments.

Electrotherapy and massage seem to give some degree of comfort for a time. General tonic treat-

ment was pursued with indifferent results throughout the course of the malady. The greatest benefit was derived by the patient from the use of salt water baths early in the malady, and of the thermal cabinet later in the disease. After these baths the spasticity would be remarkably lessened for several hours, but nothing in the way of permanent relief could be obtained.

A CASE OF STERILITY IN THE MALE, DUE TO DEAD SPERMATOZOIDS—CURED BY GALVANISM.

By GUSTAVUS M. BLECH, M. D.

of Chicago.

Professor of Casualty Surgery, Jenner Medical College.
Member American, Mississippi Valley, and Northern
Tristate Medical Association, Secretary West
Chicago Medical Society.

It is generally believed that whenever lifeless spermatozooids are found in the semen, soon after ejaculation has taken place, the man is irreparably sterile (*impotentia generandi*). For this reason I believe the following case not to be without interest:

Last fall, a healthy looking, well-built woman, aged 30, called on me and asked to cure her sterility. She stated that she was married about 11 years and had always enjoyed fairly good health. One sister, married 8 years, was the happy mother of 3 healthy children, while another sister married 5 years was still barren.

She had been treated by several prominent gynecologists. The nature of the treatment she did not know, but consisted, no doubt (judging from her description), of tampons, antiseptic applications, etc.

I proceeded to systematically examine the woman. Nothing abnormal could be discovered save a sear in the *linea alba*. She explained that years ago a laparotomy was performed on her at Michael Reese Hospital—for what purpose Heaven only knows (for she claims to have been in good health all the time). The mucus in the cervix is faintly acid. Urine: No albumen or sugar.

The woman was told to send her husband.

He visited me the next evening. The following notes are copied from my record slip:

"Mr. J. F. Age, 32. Nativity: Russo-Poland. In U. S. 20 years. Religion: Moslem (orthodox). Business: Owner of ladies' tailoring establishment. Habits: Smokes 2-3 cigars a day. Drinks very little, has never masturbated, and previous to his marriage had but few times illicit intercourse with neighboring women. He never dealt with a prostitute. Since marriage, he never copulated more than a dozen times each month, if anything, less often. His wife is frigid, he enjoys the act, but is not very passionate. Can complete the act without difficulty. Patient looks anemic (conjunctiva and lips not blanched). He is suffering from a mild form of cerebro-spinal exhaustion (neurasthenia).

He denies syphilis, but tells a story about some discharge from the urethra, when single. From the conversation it cannot be made out whether it was an attack of gonorrhea, diurnal pollutions or prostaticorrhea. Penis and testicles well developed. Was told to bring specimen of semen."

So far the notes. The semen asked for was brought by his wife the following Saturday at 9.30 A. M. Sexual congress had taken place at 8.45 A. M., 45 minutes before. A drop was at once examined on the slide. Three or four spermatozooids were found in each microscopic field—but dead. There was not the slightest perceptible motion, even after the addition of saline solution. The spermatozooids were well formed, though. No pus cells were found in the semen.

I felt like abandoning the case, but fearing to commit an indiscretion, I told the woman that I want to see her

husband for further instructions. He came and was advised to have no intercourse for three months. Tonics were prescribed and hydropathic measures instituted.

An examination of the patient's semen after the lapse of that time showed no alteration in the man's condition, nor was even the number of the lifeless spermatozooids increased.

During the interval I have searched through many treatises on the genito-urinary apparatus, but found little illumination and less consolation.

I told the man the case looked hopeless, but that I would try electricity. He consented just like a drowning man grasping a straw. I admit that I simply lacked the moral courage to tell the man that nothing could be done.

The treatment consisted of negative, galvanic applications to the prostatic urethra, 5-12 milliamperes, each sitting lasting from 5 to 8 minutes. The indifferent pole was placed on the back. Twelve treatments were given, on the average of about two a week. After that a drop was again examined and I had hardly brought the picture in proper focus, when, to my astonishment, I saw thousands of spermatozooids wiggle and cross the microscopic field as lively as any I have ever seen.

My patient, who has become accustomed to look through lenses, did not believe me, looked himself, saw the spermatozooids and exclaiming: "I see them, I see them!" began to cry like a child.

His wife was examined by me a few days ago. I have every reason to believe that she is pregnant.*

The only explanation I have to offer is that Mr. F. really had an attack of specific urethritis which left his urethra in a damaged condition or perhaps inflamed ejaculatory ducts—not noticeable by ordinary physical examination and that the galvanic current produced a cure. Or was there a chemical abnormality in the tissues, killing the fertilizing principle of the semen, altered by the electric current?

I appreciate that it is not likely for a subacute inflammation to exist eleven years without restitution. Why the sudden increase in the number of spermatozooids? The limited literature at my command offers no explanation. I do not believe that scientists know all there is to be known about these phenomena.

I deserve censure for not having made an endoscopic examination of the man's urethra and for having omitted to instill a few drops of silver solution in the posterior urethra. The purpose of this article is to elicit opinions from competent surgeons.

General Staphylococcic Septicemia.—In 1895 Etienne reported two cases of general staphylococcic septicemia without visceral manifestations or dominant localization. At a recent meeting of the Medical Society of the Paris Hospitals (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 13, 1901) he reports five more cases. These are divided into the very acute, the rapid, and the prolonged forms of the disease. Three of the observations come under the very acute heading, due as a rule to secondary infection with staphylococci. Death occurs inside of a week. Under the rapid form one case is mentioned, which recovered after fever of over a month's duration. The last case was prolonged, lasting many months, followed by recovery. Bacteriological examination of the blood in every case gave pure cultures of staphylococci. In all cases there were great prostration, pallor, cyanosis, fever, irregular and rapid respiration and circulation; the liver and spleen were occasionally enlarged, and nervous symptoms sometimes develop. When death does not follow, the convalescence is very slow, improvement only becoming noticeable after some time. [M. O.]

* Since writing the article the woman was again examined and quickening admitted. I could not make out fetal heart sounds, but heard the characteristic bruit.

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended November 30, 1901:

NEUROLOGISCHES CENTRALBLATT.

October 1, 1901.

1. Fecal Vomiting in Hysteria. L. BREGMAN.
2. Stab Wound of the Third Left Dorsal Nerve and Spinal Ganglion. A. WALLENBERG.
3. A case of Injury to the Pons Without Injury to the Skull. S. ORLOWSKI.

1.—Bregman reports a case of fecal vomiting occurring in a girl of 23 who presented the following symptoms: Tympanites, pain, vomiting, and for 10 days no fecal evacuation. The patient was etherized and examined, when all the phys-

ical signs promptly disappeared. The history showed that they developed after a fall in the street, consisted at first of spitting of blood, and then intestinal disturbances. During 6 months' observation in the nervous clinic she had a number of convulsions without complete loss of consciousness. She was capricious, egotistic and impatient. The abdomen remained distended, fecal evacuation could not be obtained by any form of purgative or enema; she vomited frequently food, blood or feces, although the last was sometimes absent from the vomit for weeks at a time. At the end of this time as a result of violent straining the patient had prolapse with copious bleeding. This produced a state of partial collapse, and the hemorrhage was only controlled by cauterization under narcosis. As the prolapse persisted it was resected, and the patient recovered completely, having normal evacuations of the bowels. She left the hospital, but soon returned suffering from disturbance of urination. Finally she developed a new prolapse of the rectum and became extremely anemic; there was profuse hemorrhage from the bowels, and the condition was very threatening. In addition to the symptoms mentioned she had from time to time aphonia, and there can be no question apparently that the case was one of hysteria. [J. S.]

2.—The patient, a policeman, was stabbed 3 times in the back. He had dyspnea, and expectorated a small quantity of blood; he complained of a feeling of intense anxiety in the region of the heart. Careful study of the case showed the existence of a narrow oval band of anesthesia on the anterior side of the left arm, indicating some injury to the third nerve. [J. S.]

3.—A man of 21 was brought to the hospital with a history that he had been injured in a quarrel on the street. A stab wound was found on the back of the head about the level of the external ear. The patient had paralysis in the right facial region, evidently due to injury to the peripheral portion of the facial nerves. There was slight paralysis of the abducens; convergent strabismus, and diplopia. There was loss of hearing on the right side; inability to stand or sit; complete loss of coordination in the right arm and leg; normal movements in the left arm and leg; anesthesia of the left half of the trunk and the left extremities. The right knee reflex was slightly diminished; the skin reflexes were normal. The patient improved slowly and the symptoms gradually disappeared, so that in a month he could stand and the sensory disturbances were less. The changes in the motor nerves of the eye and in the facial were permanent. It appears likely that the knife did not injure the skull but produced concussion involving the medulla oblongata. [J. S.]

Symphysiotomy with Living Child.—Professor G. Fleury reports a case of symphysiotomy performed upon a tiny woman of 20. She was 130 cm. high, and had already been in labor for two days. The face presented at the superior strait, the diameter of which was undoubtedly under 7 cm. A bag was inserted in the vagina and left inflated for two hours, when it was expelled, the amniotic fluid following. Symphysiotomy was done in three minutes, one incision opening the pelvis. Forceps were then applied without effect, and version was attempted in vain. Then the cord stopped beating. Finally the head was forcibly flexed, and the child born with forceps. He seemed dead, yet recovered in 10 minutes. The symphysis was sutured with cat-gut. For three days she showed no symptoms, then signs of septicemia appeared. She recovered, however, a week later, and left the hospital three weeks after the operation. Both mother and child are now well. Fleury states that he considers the after treatment the cause of the excellent results which he has obtained in performing symphysiotomy. (*Bulletin Medical*, June 22, 1900.) [M. O.]

Penetrating Wounds of the Heart.—Nothing better illustrates the advance which surgery has made in recent years than the modern treatment of penetrating wounds of the heart. In another column of this issue of the Journal will be found a most interesting and instructive paper by Dr. Nietert, of St. Louis, who reports a case of stab wound of the left ventricle in which he exposed the heart and sutured the wound. It is unfortunate that this patient should have died of that most distressing post-operative complication, suppression of urine. The case presents many unique symptoms; in the first place the pleura was not injured and the patient at the time of operation was unconscious, a condition resulting from pressure upon the heart exerted by the blood in the inelastic pericardium. It is interesting to note that after the pericardium had been emptied the patient immediately regained consciousness and was able to converse with the operator. Nietert presents briefly the reports of twenty-two other cases of penetrating wounds of the heart, all of which were operated upon and seven of which recovered. Since ninety per cent. of such wounds which are not operated upon result in death, the mortality of the cases in which operative interference has been undertaken is very encouraging. This paper of Nietert's brings before us a subject of the utmost interest to all medical men, and we regret to say that there has been little written upon the subject by American surgeons.

Splanchnoptosis.—When Glénard, in 1884, wrote his classical paper on enteroptosis, he struck deeper than he thought. As we see it in these later days, his paper ranks in importance with the papers of Goodell on Premature Separation of the Placenta, Breisky on Kraurosis Vulvæ, and Hodgkin on Pseudoleukemia. At once the attention of the acute clinicians was directed to the new etiological and clinical factor, and many of the obscure pelvic and abdominal manifestations began to be traced to their point of origin. Gastropoptosis, splanchnoptosis, or enteroptosis, whichever term we may choose to select, assumed immediately an important place in clinical medicine, and this condition is now always looked for in individuals presenting

more or less protuberant abdomens, or who complain of gastrointestinal, pelvic, or reflex manifestations of obscure etiology. In the interesting and scientific paper by Dr. Robinson, which has been running through recent numbers of the Journal, we have an exceedingly satisfactory exposé of the whole subject. The author condenses the etiology of splanchnoptosis into the three factors of relaxation of the abdominal wall; elongation of the mesenteries with distal movements of the viscera and mesenteric insertions; and gastroduodenal dilatation resulting from obstruction in the colon and other portions of the bowel subsequent to prolapse of the intestine. An associated obstruction of the splanchnic circulation with irritation of the pelvic plexuses of sympathetic nerves will account for the diverse reflex manifestations that are attendant upon the disease. The suggestions of Dr. Robinson as to the treatment of this complicated condition are most valuable and timely, and the entire paper is one well worthy of careful perusal.

Adami vs. Koch.—In the *Canadian Journal of Medicine and Surgery*, for November, 1901, Adami publishes a letter in which he refers to the habit that Koch has of neglecting to give credit to observers who work along the same lines that he himself does. Adami refers to a paper which he read at the meeting of the Canadian Medical Association, at Toronto, on August 30, 1899, in which he claims to have thrown doubt upon the frequency of infection with tuberculosis through milk. This paper was published in the *Canadian Journal of Medicine and Surgery*, for December, 1899, and in the **Philadelphia Medical Journal**, for December 30, 1899. In an editorial in the *Canadian Journal of Medicine and Surgery*, for November, 1901, it is shown that while Adami's position, in 1899, is not identical with Koch's position concerning the transmissibility of bovine tuberculosis to man, in 1901, yet Adami deserves credit for throwing doubt upon the frequency of the transmission of tuberculosis from cattle to man. We have reread Adami's paper and note that he asks this question: "If infectious from animal to animal, is it infectious from animal to man, and thereby a grave source of danger to the human

race?" In answer to this question, the author points out that while the consensus of opinion requires an affirmative, there is a very small amount of reliable evidence upon which to base this opinion. He distinctly stated that cattle were relatively insusceptible to tuberculosis from human sources. But, after referring to the work of Still, Demme, the Cattle Commissioners of Massachusetts, Ernest and Ollivier, he concludes the discussion of this question with the following statement: "Thus the evidence, while not absolutely convincing, is strongly in favor of the view that tuberculosis can be conveyed through the milk of animals extensively diseased, and this being the case we cannot sit with hands folded and regard the extension of bovine tuberculosis with indifference, but must make such regulations as will diminish the possibility of such infection." While Adami deserves credit for his work, his contention evidently was not the same as that of Koch and he may be very glad that it was not, because Koch's opinion is by no means universally accepted. Koch's position in the scientific world has caused his statement to be accepted literally by many of the unthinking and thus he has delayed the advance in the battle against tuberculosis. On the other hand, a man in such an assured position as that held by Koch can afford to give credit where credit is due; but he cannot afford to ignore the work of such a man as Theobald Smith, for example. It would be no discredit to Koch to acknowledge indebtedness to American observers, if not for actually pointing out new lines along which to work, at least for having conducted similar experiments successfully and independently.

The Boo-Hoo Fever.—The annual report of the Surgeon-General of the United States Navy is an interesting volume, and not the least interesting part of it is a paper by Dr. George A. Lung. This surgeon was medical officer with the First Regiment of Marines in the Peking Relief Expedition, and he has submitted a report that is a contribution to genuine literature. Dr. Lung has the descriptive talent well developed; and we doubt not that some future historian of war, with an eye for realism not unmixed with the picturesque, will seize upon his narrative as a bright particular chapter in the annals of the Chinese episode.

When we consider for a moment what it was that Dr. Lung saw and described, we can readily appreciate that there was much to engage his facile pen. The long and exhausting march over the heated plain in a strange and distant land, and the unknown hazards with a cruel and relentless foe, were such as to try the health and rack the nerves of even the most buoyant of American troops. The

peculiar circumstances, the extreme hardships and the unknown perils of the expedition conduced to some unusual affections, which Dr. Lung describes. Most noteworthy among them perhaps was the characteristic heat exhaustion, with subsequent derangements of the nervous system.

This heat exhaustion, in spite of the untoward circumstances, does not appear to have been of a severe type. The temperature of the atmosphere on some days was as high as 104°, and the country was ill supplied with shade or with pure water, and yet the soldiers succumbed in but few instances to genuine heat stroke. The affection rather was a heat exhaustion, from which prompt and even surprising recovery was the rule. The symptoms were extreme fatigue, mental depression, weak circulation and partial or complete unconsciousness. In some few cases there were convulsions, a hard pulse and delirium. The onset was sudden, the patient often falling in his tracks. The most remarkable feature was the rapidity with which the victims recovered with practically little treatment. With a little rest and a little assistance the sick men would be taken along; by night they would be better, and in the morning they would take their places in the ranks. Djarrrhea and emaciation were common on the march.

Dr. Lung observed a peculiar emotional instability in these patients. There was a marked tendency to weep. When the patient applied for treatment and began to discuss his symptoms, his lip would tremble and tears would run down his cheeks, all the while he was conscious that he was acting rather ridiculously. The paroxysm was uncontrollable. Dr. Lung likened it to the so-called "boo-hoo" fever which is said to occur in the Hawaiian Islands. We could readily imagine that the depressive emotions might make great havoc among troops under such trying circumstances. Melancholia and nostalgia are not uncommon military psychoses; and to Dr. Lung we owe the description of another, but one which fortunately had neither a high mortality nor many severe or lasting consequences.

A Question of Responsibility.—We publish elsewhere a newspaper criticism of the medical profession. The *New York Times* is a thoroughly sane and responsible journal and its comments are worthy of note. It is rather difficult, however, to understand what the *Times* would have the medical profession do in reference to the prevalence of tetanus after vaccination and after the use of antitoxin for diphtheria.

Apparently it thinks that there should be a great medical convention called at once to deliberate on

the subject. This is not our idea, nor the idea of those best qualified to judge of this grave matter. The medical profession is thoroughly alive to the gravity of the situation, but it also recognizes thoroughly that investigation can be conducted only by experts, and that the process must be slow and careful in order to be complete and convincing. This is a matter for laboratory work, not for medical conventions. The fault in the St. Louis laboratory was the fault of one or of a very few persons, and in no wise discredits scientific medicine. On the contrary, it proves both the doctrines and the practice of preventive medicine when these are properly applied. The medical profession is no more responsible for that individual fault than for the fault of a drug clerk who dispenses a poison by mistake.

We agree with the *Times*, however, that public confidence must be restored by a full investigation and criticism of all these cases, and we believe the way is already being led by those most competent to do so.

Phthisophobia.—According to a newspaper report a stir has been raised in New York over the refusal of the immigrant authorities to admit a tuberculous Irish immigrant. A Philadelphia lawyer, it is alleged, will endeavor to bring the case before the United States Supreme Court. If he does so, we have little doubt how it will be decided. The question involves the abstract right of this country to exclude undesirable immigrants, and the Supreme Court is not likely to decide against such a natural right. As a purely legal or academic question, we should suppose there was but one solution of it possible.

Practically, however, there are many difficulties in the way of controlling what may be called undesirable immigration. We referred to some of them last week. There are certain considerations of humanity, at least, that should be entertained, and there are problems in the etiology, pathology and diagnosis of disease that will tax the capacities of the average immigrant commissioner beyond reason.

We are promised much legislation by Congress on the subject this very winter, but all the legislation in Washington cannot convert an immigrant bureau into a college of medicine. To diagnose individual cases of disease may be easy enough, but to detect heredity and, above all, to break up families, are not easy or nice problems.

An irate medical critic in New York has coined a new word. The crusade against tuberculosis is dubbed by him "phthisophobia". For him the fear of the tubercle bacillus has become a craze, and the claim that pulmonary tuberculosis is a "dangerously

contagious" disease, is an exaggeration. There may be some thoughtful heads in the profession who will agree with him that the pendulum of opinion has swung rather far.

The Fetal Heart.—Considerable interest cannot fail to attach to the clinical observation made not long since by the eminent Italian obstetrician, Professor Rivolta. It was his good fortune to be present at a birth of more than usual importance from a scientific point of view. The woman, who was suffering from placenta prævia, the hemorrhage occurring at the fifth month of gestation, was hastily delivered of an apneic and exanimate fetus. The fetal thorax was opened immediately and the pericardial sac freely exposed. A curious discovery was then made which, if it be found to represent a normal state of affairs, would revolutionize in part our knowledge of the fetal circulation. It has generally been believed that, with the exception of the two characteristic fetal conditions of patent foramen ovale and the guiding Eustachian valve, the fetal heart behaves, when in action, precisely as does the adult heart, that is, as pertains to its method of contraction. Until compelled to leave the fetus to attend to the after-treatment of the mother, Professor Rivolta was privileged for about the space of eight minutes to observe the pulsations of the exposed fetal heart, and was surprised to note that the contractions of the four heart-cavities were not as in the adult. The rate of pulsation, when first noted, was twenty-four beats per minute, and at the end of the observation this had fallen to seventeen beats per minute. The order of rotation was as follows: Beginning with the pause, the right auricle contracted first, being immediately followed by the left auricle, the wave of contraction in both cavities moving from above downward; a brief pause followed and then, the auricles still being in systole, occurred the contraction of the right ventricle and immediately afterwards that of the left ventricle. The cardiac impulse began with the ventricular systole and reached its maximum at the height of the systole, that is, when the ventricle was empty. The heart was practically bloodless during the time of the observation; hence it is probable that the production of the impulse did not arise from the amount of blood in the ventricular cavity, but was purely muscular in origin, a contraction of the fibers of the ventricular walls. Notwithstanding this absence of blood, the heart showed the same impulse, the same rotation on its longitudinal and transverse axes, and the same rising of the apex and descent of the conus arteriosus and base of the aorta, as if there were the usual full blood-stream in the cardiac cavities. It is unfortunate that the condition of the mother pre-

vented a close observation of the fetal heart until complete cessation of its action. Aside from the interest attached to an actual observation of a pulsating heart for a comparatively protracted period, the unusual sequence of events, unusual as far as our knowledge goes, is most suggestive. We have been informed by eminent embryologists that but little is known concerning the action of the fetal heart other than the points already mentioned, and that it has always been believed that the contraction of the cavities followed the rule in the mature heart. The observation of Professor Rivolta will doubtless stimulate other obstetricians to a closer observation of this matter. It may be that many of the prematurely discharged fetuses of five-and-a-half to six months, apparently giving no signs of vitality, would reveal for short periods after birth cardiac contractions which would well reward the time given to the examination of their thoraces.

Chicago has established an unevitable reputation as a suicide center. Her population, 1,698,575, represents one forty-fifth of the population of the United States, but her suicides for the past year were 385 as against 5340 for the whole country in 1900. Hence, Chicago, having only one forty-fifth of the population had one-thirteenth of the suicides of the nation. According to the *Philadelphia Press*, the suicide-rate for Chicago is four times as great as that for London. Life in all its phases is fast and furious in Chicago, and these melancholy figures help to tell the story.

Current Comment.

THE HEALTH OF OUR TROOPS.

With reference to the subsequent sanitary history of our troops, I again point with pride to the reports in the present volume relating to health conditions in the United States, and especially in our island possessions. I believe that new levies of troops serving in a tropical country have never, in the history of the world, had so good a health record as that shown by these reports for the troops stationed in the Philippine Islands, in Cuba, and in Porto Rico. My recent inspecting trip to the Philippine Islands has convinced me that when proper sanitary regulations are enforced, the health of troops stationed in these islands will be quite as good as if they were stationed in our own "Gulf States." I would say further, with reference to this trip, that I found wherever I went well-equipped hospitals, ample and efficient medical attendance, and an abundance of medical supplies of all kinds.

—Report of The Surgeon-General, U. S. A.

MORTALITY IN THE CONCENTRATION CAMPS OF SOUTH AFRICA.

The death rate of these camps has given rise to somewhat harsh criticism of the policy of the British Government in establishing the same, and of its assumed neglect

in not keeping them in a good sanitary condition. The mortality is stated to be excessively high; indeed, among children, if accounts be true, appalling.

The *London Daily News*, a journal of pro-Boer sympathies, gives a most ghastly description of the state of the camps, and the British public seem inclined to take up the matter and to insist upon a thorough investigation.

Manifestly, the question as to how to dispose of the Boer women and children, during the progress of the war, is a most difficult one for the British authorities successfully to solve; but certainly every effort should be made to render these camps as healthful places of abode as circumstances will allow.

—The Medical Record.

THE VACCINE SCARE AND MEDICAL RESPONSIBILITY.

In view of the incalculable injury which has been done to the cause of progress in preventive medicine by the widespread popular distrust of vaccine virus and antitoxin sera resulting from the occurrence of tetanus and less dangerous diseases in those vaccinated and inoculated, the apparent apathy of the medical profession is difficult to understand. It would seem that every consideration of professional pride and business interest should have brought together the physicians of every community of this country and Europe to study the subject, investigate the essential facts, and take such steps as are best calculated to restore public confidence on the only basis on which it can rest secure—a belief that the physicians understand the subject and have adopted measures to exclude from use by reputable practitioners organic preparations which are open to suspicion. If they have done this, or taken any steps in that direction, the public has not heard of it.

This condition of affairs calls for immediate action and authoritative declaration by the societies representing the medical profession. If the growing popular distrust of these organic preparations cannot be checked and confidence restored, the most beneficent protective agents known to science will be so thoroughly discredited in the popular esteem that incalculable evils will follow. It is not a momentary sensation which will subside when some new fad catches the popular fancy. Those who think so are living in a fool's paradise. To correct the mischief already done, and which should never have had a beginning if the medical profession had done its duty in the matter, will take a good deal of time and much hard work.

—The New York Times.

TRAGEDIES OF A GREAT CITY.

The report of the Coroner of Chicago for the twelve months ending November 30 reveals some of the tragedies of which a great city is so prolific a source. In the course of the official year the Coroner was called upon to investigate 4841 deaths, in 2419 of which inquests were found unnecessary. The leading causes and the number of sudden or violent deaths ascribed to each are shown in the following table:—

Suicides	385	Elevator accidents	27
Railroad accidents.....	290	Suffocation	29
Falls	206	Lockjaw	15
Homicides	103	Accidental and undetermined drownings	135
Street car accidents	72	Accidental shooting	11
Burned	98	Machinery accidents ...	20
Accidental and undetermined drownings	135	Lightning	12
Accidental and undetermined asphyxiation ..	60	Accidental shooting	11
Heat prostrations	38	Kicked by horses	10
		Scalds	43
		Hydrophobia	8

Correspondence.

LET THE BUYER BEWARE.

By HENRY LEFFMANN, M. D., of Philadelphia.

To the Editor of the Philadelphia Medical Journal:

The tendency toward paternalism in our government is shown pretty clearly in the laws against food adulteration. Not only are the texts of the acts specifically restrictive, but the interpretation put on these texts by commissioners and judges mostly inclines toward a stringency which the community at large neither asks for nor appreciates. It may be a question whether the promoters of such laws and rulings are not going too fast; in other words, whether a much higher responsibility should not be put upon the public, especially as to the importance of discretion in the matter of price. "*Caveat emptor*," "let the buyer beware," is an established maxim of law and a wise one; the person who pays the lowest price cannot complain if the lowest quality is furnished. Indeed a very large proportion of common food adulterations is brought about by the desire of the public for so called cheap products. In most cases these are cheap only in name. It is unfortunately true, that a high price is not necessarily a guarantee of high quality, but nevertheless the careful and discriminatory purchaser can avoid to a great extent deception and imposition.

We are led to make the above observations by the reading of a report of one of the State Experiment Stations, from which we learn that some of the cheap baking powders have been found to contain about twenty-five percent of ground rock (somewhat similar to soapstone). There can be no question of the dangerous character of the adulteration, yet its existence and continuance are dependent on the thoughtlessness or indifference of buyers. There are high class baking powders in the market made by responsible firms, and there is no reason why the inferior grades made to "raise the dough" only in the slang sense should meet with sale. Even when the ground rock is not present, almost all of the cheaper powders are found to be inferior in gas producing power upon which the value of the powder depends. Here is one point at least in which the cream of tartar powders surpass the alum and phosphate powders.

COLLECT YOUR FEES IN ADVANCE.

By G. G. WHITE, M. D., and W. A. MILLER, M. D., of Elkader, Iowa.

To the Editor of the Philadelphia Medical Journal:

A case just settled in the District Court, Clayton Co., Iowa, shows wantonness in forensic medicine. The plaintiffs had rendered medical services to the defendant who refused payment on the ground that the bill was ambiguous and that he was overcharged.

The defendant established as his defence that the services were of a confidential character and by statute found in Sec. 4608, Code of Iowa, plaintiff had no right to testify as to the nature of the malady until the defendant waived that right, which he refused to do.

As the services rendered were mostly for the treatment of venereal diseases, there was no way in which the doctors could have proven their bill or value of services. Attorneys for plaintiff advised settlement, whereby the physicians had to sacrifice part of their bill, the law not allowing the right to prove its valuation.

The above case is one to which we have been unable to find anything similar. We were ignorant as to the law not allowing us to prove our services. Our attorneys were unable to find a ruling in Court that would have given us this freedom, whereby we could have been allowed to testify as

to the valuation of our services in this case and collect our well earned fees.

We should be pleased to receive any light upon this point, or any knowledge relating to a similar case. Hereafter our fees for such services will be collected in advance.

NOTE ON A CASE OF TRUE EASTERN LEPROSY.

By MARION FREUND, M. D., of Itoselle, N. J.

To the Editor of the Philadelphia Medical Journal:

Some of the medical journals have had a good deal to say in one way or another about the hypothesis that the leprosy which is to be met with in Hawaii and elsewhere on the Pacific, is due to the eating of fish, more or less decomposed. May I say a word as to my own observations? They are not upon any extensive experience, but they are supported by those of others.

I do not believe the theory. I have had patients who had never tasted fish; and leprosy abounds in localities where fish is never eaten. More than this, it is seldom seen among certain tribes among whom fish is a staple of diet. Of course, I admit that some of the Hawaiian tribes are the most egregious liars, and as soon as a leper comes to understand that this malady is attributed to a fish dietary, he is none too slow to aver that he never has tasted of a morsel of the food. This is the syphilitic's plea over again! Still, I know that there are leprosy patients who have neither subsisted on fish, nor partaken of it to any extent; while there are others who seem to delight in decomposing fish, and who use ptomaines as a preferred condiment, who never have the disease.

I cannot believe the hypothesis, but if I may say it, I think that there is a bit of etiology to get hold of, though, perhaps, at the expense of broaching another hypothesis! At any rate, permit of a note on a case.

It was at Caygayan, P. I., April 1901. I had been treating more than one hundred and sixty cases of fever and ague among the natives, since February, and had had most excellent success, using sander eucalyptol in large doses. Quinia the patients stoutly refused, declaring that it was a poison. Before the American advent, Spanish practitioners, who had given quinia until the tinnitus aurium was manifest, had been assassinated on the plea that the peculiar ringing in the ears was "the making of insanity!" One morning a woman came to me to request a visit to her husband. She stated that he was "somewhere in," meaning that he was among the hills. I saw in a moment there was something odd about the case, and especially as she would not accompany me. She merely alleged that he had the fever and ague, and his business had kept him from home, "somewhere in," several months. She "wanted him cured, so that he might return." She was importunate, and I went. As I inquired my way, I was continually told that the man was known, and that he "had stinking feet." This was uttered in a significant way, but I gained no significance from it, even after I found the patient, and found that he had the intermittent very severely. He was in bed all alone in a hut, and after prescribing much the same as I had for others, I told him that if he would follow my treatment he would be out in a few days. "Then," I said, "come into the village and see me." On my return, I told the wife that she might expect him home inside of a week. For reply, she crossed herself, and fled.

It was hardly an hour before my man brought me in a ewer filled with water, and directed my attention to a sealed envelope, immersed in it. I took it out, shook off the water, and opened the soaking letter. It was from a priest, and begged that "even though I was so distinguished as to know that I could cure leprosy, to have mercy, and not let the cured man come to town." Leprosy? I sent for the woman. Yes, the man had it. He had been "somewhere in," banished for months; but—and O, the paths of

It!—she knew he had had the fever and ague before he was taken down, and—without any idea of treating leprosy—coveted the cure of the primary malady. The next two days were saints' days, and I did not travel; but on the third I journeyed to my patient's hut. I found that so far as the intermittent was concerned, he was "better than he had been in years." He continued the treatment, and was soon able to resume his wood-cutting. When I left the islands, though still isolated, he was hard at work, and it was said that his was the only case of leprosy that did not have the fever and ague complicating.

Contagious? I did not take it. I have my disbeliefs. But as for the hypothesis? In all cases of leprosy there are continued attacks of fever and ague. How far is this etiological? How far will the treatment of the intermittent overshadow the leprosy? And as for the Fish! Well, the leprosy patient, when isolated, is fed almost solely on fish and forbidden a vegetable diet!

Reviews.

A Text-Book of Surgery, by Dr. Hermann Tillmanns, Professor of Surgery in the University of Leipzig. Translated from the Seventh German Edition by Benjamin T. Tilton, M. D., Instructor of Surgery, Cornell University, and John Rogers, M. D., Instructor of Surgery, Cornell University. Volume 1, the Principles of Surgery and Surgical Pathology with 516 illustrations. D. Appleton & Co., New York, 1901.

The fact that Tillmanns' Surgery has passed through seven German editions indicates the popularity it has attained at home. It is already well known to, and valued by most American surgeons, as the third German edition was translated into English seven years ago. The text-book is issued in three volumes, the first of which, the subject of the present review, embraces not only the principles of surgery and surgical pathology, but contains chapters on diseases and injuries of special tissues, tumors, general surgical technique, and bandaging. Two sizes of type are used, the precise reason for which we are unable to discern, as many essential facts are given in the smaller, and much unimportant matter in the larger print. The subjects are treated in an unusually exhaustive manner, especially the chapter on anesthesia, from which we notice, however, the absence of medullary narcosis, but the effect of this completeness is marred by a promiscuous arrangement which resembles the construction of a German sentence. Hemorrhage is presented in four fragments, the control of bleeding during operations on page 53, the methods of arresting hemorrhage on page 92, hemophilia and bleeding under accidents during operations on page 62, and the varieties of hemorrhage together with its results on page 463 in the chapter on wounds of the soft parts; cellulitis separates inflammation of the veins from phlegmasia alba dolens; asepsis and antiseptics are discussed with the preparation of a patient for operation, and antiseptics are described together with the methods of applying dressings; and the subject of inflammation is sundered by injuries, healing, shock, and delirium tremens. The text is written in good clear English with only now and then a touch of Teutonicism. With a view to the American undergraduate certain words and phrases could be made clearer, such as sponges for "wipes," pyogenic membrane for "abscess membrane," non-jawed forceps for "forceps for holding bone," curetting for "scraping out," silicate of sodium for "water glass," contusions for "bloodless or subcutaneous injuries," and the strength of HgCl₂ should be expressed in parts instead of percentage. Many editorial notes could have been inserted, especially in the chapter on bandaging.

The work is copiously illustrated. Indeed, this profusion of pictures is excessive. Anthrax bacilli are depicted in 3 instances, anthrax threads in 3, anthrax spores in 2, anthrax cultures in 2, the microorganism of symptomatic

anthrax in 2, and tubercle bacilli in 4. Certain illustrations are used a second time; the following figures are identical: 255 and 335, 256 and 321, 260 and 299, 265 and 304, 351 and 379, 370 and 384, and 383 and 482. This does not detract from the value of the book, for the illustrations are all excellent, but it is sacrificing space to inflation.

Much that is obsolete has been eliminated from this edition, but we still find a detailed description of hospital gangrene, a full account of Lister's spray and his original dressing, and a reference to neurectasy for the cure of tetanus.

Tillmanns practices asepsis rather than antiseptics, operates by the dry method, does not use gloves or a mask, excises every chancre as early as possible, does not lay enough stress on the incision of punctured wounds, believes complete resection of tubercular joints in children should be given up, used dry dressings for skin grafting, and hardly gives Calmette's antivenine and the antitoxine of tetanus enough prominence.

The work infiltrates practical medicine more than American surgeries, teems with common sense, is fully flush with the times, and deserves a place on every surgeon's shelf.

[F. T. S.]

Pediatrics.—The Hygienic and Medical Treatment of Children. By Thomas Morgan Rotch, M. D., Professor of the Diseases of Children, Harvard University. Third Edition, Rearranged and Rewritten. Illustrated by Numerous Engravings in the Text and by Colored Plates. Philadelphia and London: J. B. Lippincott Company, 1901. Pp. xxi, 1021.

The third or "new edition, rearranged and rewritten," is, as the author remarks in the preface, practically a new book. The most striking changes, those which catch the eye first, are a judicious pruning of the illustrations and the adoption of the "text-book" rather than the "clinical lecture" style of writing; these are to be heartily commended. The most extensive chapter, as in the former edition, and the one to which the majority of those who consult the book will turn, is the one relating to feeding, and Dr. Rotch writes here with the authority of a teacher and the earnestness of a pioneer. He advocates strongly the use of the milk-laboratory, and while the subject of home-modification is thoroughly diseased, yet its difficulties are perhaps unduly emphasized. In the section on the use of whey in percentage feeding, it would have been fitting to give credit to Westcott for his original work in this line. Congenital heart disease is given space commensurate with the growing importance of the subject, and the section on diseases of the blood is well up to the present status of knowledge. The author has chosen the skin-diseases treated of with a common-sense appreciation of the varieties seen in pediatric practice. In the way of adverse criticism, which is perhaps superfluous to a third edition, the value of the book would be greatly increased by a more extended discussion of the diseases of the nervous system with greater detail of treatment. We regret also to see so eminent an authority favoring, even in a qualified way, the use of phenacetin in pneumonia. The changes in this edition are such as will insure for it quite as hearty a reception as that accorded to its predecessor. [A. H.]

A Text-Book on Diseases of the Ear, Nose and Throat. By Charles J. Burnett, M. D. E. Fletcher Ingals, M. D., James E. Newcomb, M. D. With numerous illustrations. Philadelphia and London: J. B. Lippincott Company, 1901.

This volume, beautifully bound and printed, contains 715 pages, 220 of which are devoted to the ear. It represents a modern condensation of the system, edited some years ago by Dr. Burnett, and it, too, will be regarded as a standard work.

The first six chapters on the anatomy and physiology of the ear are written in a technical way, discussing the

subject thoroughly and clearly. Some stress is laid upon the development of the organ in embryo. Under Instrumental Examination of the Ear, the author says of catheterization of the Eustachian tube, "This is not easily done; but fortunately it is an operation rarely, if ever, needed, and should never be performed except by an expert in aural surgery." Also, "Inflation by Politzer's air-bag, like inflation of the tympana by the Eustachian catheter, must be used with the greatest caution. It is rarely needed as a therapeutic means and should never be applied except by an expert." Preference is given to the use of Selgele's speculum, a modification of which Dr. Burnett has invented.

The chapter on "Tests of Hearing," on Catarrhal and Purulent Otitis Media, and on cerebral complications are all excellent. The pages devoted to the "Role of the Middle and Internal Ears in the Mechanism of Ear Vertigo," show the author at his best. The operation of Incision, devised by Dr. Burnett for the cure of this condition, has given markedly good results. Blake's blood-clot method of closing the incision in mastoid operations, is recommended. The parts devoted to the Nose and Throat are clear expositions of the views and methods of their several authors. Many of the points in technique have been elaborated from their own experience and are spoken of in detail. The treatment of tuberculosis of the larynx includes the best of the methods of recent years. The author believes that creosote is a most valuable drug in this affection. [W. G. B. H.]

A Laboratory Handbook of Urine Analysis and Physiological Chemistry. By Charles S. L. Wolf, M. D., 12mo, 195 pages and index. W. B. Saunders & Co., Philadelphia, 1901. \$1.25 net.

Books of this class are fairly abundant, and cover about the same ground, differing principally in the extent of the descriptions and the character of the industries. The present work is of the brief type, but contains a large amount of practical clinical chemistry, physiological chemistry proper receiving but little attention. Good accounts are given of all the important methods of examining blood, gastric juice and urine, the last mentioned topic taking over half the book. It is to be regretted that since the term "glucose" is applied to the dextrose of dietetic urine, no attention is called to the fact that it is not identical with commercial glucose; in fact, the word "dextrose" does not occur in the index. The illustrations are not all of merit, but a well executed uncolored plate of absorption spectra, and a plate of Vogel's color scale, add value to the book. The literary style is satisfactory and the typography well done, but the index is scanty. [H. L.]

Partial Ophthalmoplegia with Measles.—Simonin (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 27, 1901. No. 27.) reports the case of a soldier, aged 21, with measles, in whom partial external ophthalmoplegia, dissociated and transitory, of peripheral origin, appeared on the third day, with the eruption. Double convergent strabismus was marked, with ptosis of the upper left eye-lid, and left sided diplopia. After five days these symptoms began to fade, and had disappeared by the twentieth day. Paralyzes are more common in measles than in any other of the infectious fevers; but as a rule they occur during convalescence. Simonin reported this case on account of its rarity. [M. O.]

Symmetrical Adenolipomatosis in Women.—Launois and Bensaude state that symmetrical adenolipomatosis is generally seen in men. (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 27, 1901. No. 22.) In the three cases reported in women the disease is not typical. They then report a typical case of symmetrical cervical adenolipomatosis in a woman aged 34, who had been ill only six months. They also report three unpublished cases occurring in men. They believe that the condition is lymphatic in origin. The enlarged lymphatic glands undergo fatty degeneration, and adenolipomatosis results. The question whether it is tubercular or not remains unsolved. [M. O.]

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA NEWS.

University of Pennsylvania.—The University of Pennsylvania has been the recipient of several gifts in the last month; \$25,000 for the use of the new medical laboratories from Dr. Richard V. Mattison, '79 Medical, and Mr. Keasby, and \$5000 to the new Engineering Department from Dr. John S. Wentz, '64 Medical.

Society Meetings Next Week.—The following sections of the College of Physicians of Philadelphia will hold meetings next week, at 8.15 P. M. Tuesday evening, December 17, Section on Ophthalmology; Wednesday evening, December 18, Section on Otology, and Thursday evening, December 19, Pathological Society.

New Municipal Hospital.—It is rumored that the Council's sub-committee to which has been delegated the power of recommending a new site for the Municipal Hospital favors the lot of ground on the Asylum Pike, next to Second street, partly in the new forty-second ward, and partly in the old thirty-fifth ward. The plot contains forty and one-quarter acres of ground, and is well adapted for such an institution. The price asked for the ground is \$125,000. A mass meeting was held in Olney at which resolutions were adopted in opposition to the erection of a pest-house, or Municipal Hospital, on any of the proposed sites in that vicinity, instructing the ward's representative in Councils and in the City Committee to use every effort to prevent the same.

Scarlet Fever.—Owing to the prevalence of scarlet fever near Hazleton, Pa., it was necessary to close the public schools at Drums, a few miles west of Hazleton. Over 150 cases were reported last week.

Smallpox in Philadelphia.—Only seventy-two new cases of smallpox were reported for the past week. This is forty-one less than the week before, when 113 cases were reported. There was also a decrease in the death rate, only eight being reported, as compared with fourteen for last week. The total number of smallpox cases reported during the year is 840, and the deaths 119. There are now 285 cases under treatment in the city. House to house vaccination by a corps of physicians appointed by the Bureau of Health began December 7. The preliminary work was done in the Chinatown district the previous afternoon. Over forty physicians met at the Sixth District station house to make preliminary reports and to receive official badges and vaccine. Dr. W. M. Angney, who represents the Bureau of Health, explained the object of the meeting, and then made way for Hiram Porter, Director English's representative, who impressed upon the medical men the necessity of tact in their work, referring especially to the fact that although this vaccination was most necessary for the prevention of smallpox, it was by no means compulsory. The Board of Health has determined that all school children must be vaccinated, including those attending private, parochial, Sunday, or other schools. Visitors are no longer allowed in the hospitals or prisons of the city, nor are articles of food permitted to enter the institutions.

Children's Hospital.—At a meeting of the staff of the Children's Hospital, Philadelphia, held December 5, Dr. John H. Jopson was appointed visiting surgeon, replacing the late Dr. Samuel Ashhurst.

Scholarships Awarded.—Four students of the University of Pennsylvania have been awarded scholarships by the Institute for Medical Research, founded by John D. Rockefeller and endowed by him with \$200,000. Those receiving the scholarships were Dr. George H. Gildersleeve, of the hygienic laboratory; E. B. Vedder, C. M. Duval and Dr. F. P. Gray, all of the pathological laboratory. These scholarships were given in accordance with the plans adopted for the carrying on of the work of medical research, which called for the expenditure of \$20,000 a year, divided so as to provide for forty scholarships in different institutions of the country. Appointments are made for one year from candidates recommended by heads of laboratories of accredited standing, and only persons pursuing investigations on some important and specific subject in pathology, bacteriology or hygiene are to be chosen.

Allegheny County Medical Society.—Dr. A. C. Abbott, professor of hygiene in the University of Pennsylvania, will

deliver an address before the Allegheny County Medical Society December 17, upon hospital construction and management.

New Serum for Tetanus.—Dr. A. Leteve, of the Pathological Department of Mercy Hospital, Pittsburg, Pa., has discovered a successful serum treatment for tetanus. After a year of experimenting on lower animals he has tested his theory on human subjects, a middle aged man, a middle aged woman and a boy ten years of age, who were given injections of the serum. They were restored to health within five or six days.

Smallpox in Pennsylvania.—Smallpox has lately spread to Bangor and Downingtown, and five cases have been reported at Sellinsgrove. The Commissioners of Plymouth Township have ordered that no peddlers or collectors be allowed in the township. The Wilkesbarre street cars have ceased to run to Plymouth, the only communication still being maintained is for sending provisions to the smallpox-stricken town. Officers will be stationed on the bridges on all the roads, and no one will be allowed to pass unless carrying a special certificate, and these will be issued only in extremely important cases. This quarantine may cause considerable loss to Plymouth, as several hundred citizens of that town work in Wilkesbarre. Smallpox hospitals are being erected in Pottstown and West Chester. There are already eleven cases reported at Royersford, the latest victim being a physician.

Scarlet Fever at an Orphanage.—Thirty-seven cases of scarlet fever have appeared among the 200 inmates of the Methodist Episcopal Orphanage at Bala and the institution has been placed under quarantine. Investigation has failed to reveal how scarlet fever was brought into the institution, but thorough disinfection of the drainage system has been made and the disease is believed to be under control. No deaths have occurred.

NEW YORK AND NEW JERSEY.

Smallpox in New Jersey.—No new cases of smallpox have been reported in Camden. Thirteen patients are now in the hospital, which accommodates only twelve men. The Camden Board of Health is considering the advisability of enlarging the hospital. Although there is but one case of smallpox in Gloucester, a municipal hospital is to be erected. To avoid the possibility of an injunction, and spurred on by the constantly increasing list of smallpox cases, the authorities of Orange erected an isolation hospital in the middle of Heywood avenue, between Mosswood and Berkeley avenues, in that city, in the hours between midnight Saturday and Monday morning last. Ten patients are occupying cots there. Twelve cases of smallpox in the village of Sayerville have caused a rush to be vaccinated. There are two handkerchief factories in the neighboring village of South River, and many of the Sayerville people work there. On the recommendation of physicians the management of the factories served notice upon the employes from Sayerville that they must not return to work until the epidemic was under control. This order affects about three hundred hands, most of them the support of families.

Scarlatina in Millville, N. J.—Scarlatina is so prevalent and so severe in Millville that much alarm is felt. The Board of Health is making efforts to prevent the spread of the disease, and it will be necessary to close the schools. Two children died last week, and another is dangerously ill.

Smallpox Not Reported.—Assistant Sanitary Superintendent Black, of Brooklyn is investigating the failure of two physicians to report five cases of smallpox last week, one of which resulted fatally. On Friday, December 6, a woman 41 years old died of smallpox. Dr. John E. Walsh, of the Health Department, called at the house after the death and found three children ill with the disease. The house is an apartment house containing six families. On the first floor Dr. Walsh found a baby also suffering with the disease. This child was under the care of another physician. All the children were sent to North Brother Island.

A Bequest.—By the will of the late Dr. Henri Gullbault the Metropolitan Hospital and Dispensary will receive \$3000.

Health Boards to Meet.—The Associated Health Authorities will hold a meeting at Woodbury, N. J., on Tuesday, December 17. Dr. Benjamin Lee, secretary of the State

Board of Health of Pennsylvania, will discuss Smallpox, Dr. Charles W. Karsner will read a paper on Vaccination, and Dr. E. S. Cooke, Chief of the Bureau of Disinfection, Philadelphia, will speak on Fumigation and Prevention.

Dr. Henry Adjutant General.—On December 7th, Governor Odell appointed Dr. Nelson H. Henry Adjutant General of the State, to succeed the late Brigadier General Edward M. Hoffman, the appointment to take effect January 1, 1902.

Appointment of Dr. Pritchard.—Dr. Wm. B. Pritchard has been appointed consulting neurologist to the S. R. Smith Infirmary, Staten Island.

WESTERN STATES.

New Building for Contagious Diseases.—The St. Paul City and County Hospital intends erecting a new building for contagious diseases to cost approximately \$50,000. The building, which will be two stories high, will be so built that, to go from one floor to the other, one must go outside the building. Each story will contain four wards and a number of rooms. Each department has a room in which the doctor or visitor leaves his clothes, and then enters another room where the sterilized robes are kept. The first floor is for diphtheria, the second for scarlet fever. Disinfecting rooms, diet kitchens, baths, etc., will all be modern in construction. The building will hold 120 patients.

Tuberculosis.—It is stated that an average of one person dies each day from tuberculosis in Los Angeles, California.

Trinity Hospital, Milwaukee.—Four free beds have been established at Trinity Hospital for poor patients, and it is expected that two others soon will be provided. The free beds will be used by students of the Milwaukee Medical College for clinics. An effort will be made to claim exemption from taxation on the ground that free beds are maintained.

The Cincinnati Hospital Laboratory, under the direction of Dr. J. E. Greiwe, assisted by Drs. A. H. Friedländer, W. H. Crane, A. B. Devers, Frank Fee, J. W. Rowe, H. J. Whitacre, has recently started a post-graduate course in pathology and clinical microscopy.

A Heart Wound Sewed.—A negro was stabbed in the heart at Chester, Ill., and Dr. H. L. Nletert, Superintendent of the St. Louis City Hospital, where the patient was taken 24 hours after being cut, sewed up the wound, making several stitches. The patient is now well on the road to recovery.

SOUTHERN STATES.

A Reappointment.—Secretary Long has decided to reappoint Surg.-Gen. William K. Van Reyepen on the expiration of his term, December 18, and to postpone the promotion of Dr. P. M. Rixey. Dr. Van Reyepen is to succeed himself for a short time in order to secure the advantage of increased rank and pay which would be afforded him after serving 40 years in the navy. Dr. Van Reyepen, however, does not expect to serve until the retiring age next November, and will give way soon in order that the President's promise to Dr. Rixey may be fulfilled. Dr. Rixey will continue as White House physician until he is made surgeon-general.

Maryland Public Health Association.—The Maryland State Public Health Association held its fifth semi-annual meeting in Rockville, December 3 and 4. Papers were read by Drs. W. S. Thayer, L. Erich, J. Bosley, J. M. Klger, R. Stokes, E. M. White, J. S. Fulton and L. O. Howard.

Violets for Cancer.—A practical test of the efficacy of violet leaf infusion as a cure for cancer will shortly be made at the Baltimore University Hospital where a case of undoubted cancer of the breast in an advanced stage is under treatment. Many prominent Baltimore physicians and surgeons, when questioned as to their opinions of the virtues of violet leaves in cancer cases, ridiculed the idea. Others thought that if the patient was taken in an early stage of the disease, when the affection was purely local and the dreaded germs had not been absorbed into the system or affected the vital organs, a cure was possible. Exactly what the medicinal properties of violet leaves are could not be learned. Druggists and chemists, when asked, professed total ignorance of the subject. In the

backwoods of the South ponticles of violet leaves and the leaves of other flowers are used as a remedy for cancer, and, it is said, many cures are effected.

North Texas Medical Association.—The semi-annual meeting of the North Texas Medical Association was held at Greenville, December 10, 11 and 12.

Proposed Municipal Hospital, Washington.—Plans for the new Municipal Hospital have been issued by the District Commissioners. As planned, the institution will be of the most modern type and the group of structures contemplated will cost several million dollars. Congress has already provided for the site and appropriated \$5000 for the competition for plans. All competition sketches will have to be in the hands of the Commissioners by February 8, 1902. Three architects will be chosen through a preliminary unpaid competition as the competitors in the final paid competition. The unsuccessful architects in the final competition will each receive \$1000.

Typhoid Fever in Oysters.—Oyster shippers from Back River desire an investigation relative to an order promulgated by the commandant of Fortress Monroe prohibiting the sale of Back River oysters on government property. The claim made by the authorities is that they contain the germs of typhoid fever.

New Recreation Building.—A new recreation building for the use of the patients of the Sheppard and Enoch Pratt Hospital has been completed on the grounds of the hospital, near Towson, Baltimore County, Md. It is about 1000 feet distant from the main building, and is two stories high with a basement. The interior of the building is divided into two sections, one for the men and the other for the women patients. In the basement are bowling alleys, extending the entire length of the building, and a lounging room. Arrangements have been made for a shuffle-board, and the basement will also contain a storage-room, janitor's quarters and boiler and fuel apartments.

Suit for Libel.—In the Circuit Court of King George County, Va., suit for libel has been brought by Dr. F. F. Ninde against some citizens. Last winter Dr. Ninde was employed by the supervisors to vaccinate and attend small-pox cases. Later some of the citizens claimed that the disease was not smallpox and the newspapers criticised the doctor, charging him with a scheme to defraud the county. The jury failed to agree and another trial has been ordered.

To Treat Deformities.—A new department, that of orthopedic surgery, has recently been established at the hospital of the University of Maryland for the treatment of deformities, joint and bone diseases. The new department is equipped with the newest apparatus used in the treatment of such cases. Children and adults who are suffering from any deformity or have been crippled from birth or are crippled from any disease of the bones or joints, will be treated. This department will be under the direction of Dr. R. Tunstall Taylor.

Next Year the Medical Fraternity of the United States Army and Navy and National Guard will assemble in Washington. This organization of the military surgeons of the United States is a notable body. Surgeon General Blood, of Boston, is the first vice-president. Surgeon Sternberg, of the United States Army, was the original president. Within the last year it has mustered 61 new members from Massachusetts, and the Brigade and Regimental Staff is deeply interested. There were 500 members prior to the Spanish War, and while that number fell off slightly, there has been a reaction, till to-day the number approaches the maximum.

A National University.—Senator Depew introduced a bill in the Senate December 9th, to establish the University of the United States, for post-graduate work. It is reported that Andrew Carnegie will give \$10,000,000 to carry on the work, and a message from the President on the subject is expected shortly.

MISCELLANY.

The Statistics of Suicide.—Self-destruction is on the increase. An English alienist has investigated this subject, with discouraging results. Some forty years ago the average number of suicides was, in Sweden one to every 92,000 inhabitants; in Russia one to every 35,000 inhabitants; in the United States one to every 15,000 inhabitants; and in London and St. Petersburg one to every 21,

000 inhabitants. In France there were for every 100,000 inhabitants, from 1841 to 1845, 9 suicides; and from 1846 to 1850 10; from 1861 to 1870 13; from 1871 to 1875 15, from 1876 to 1880 17; in 1899 21; in 1893 22, and in 1894 26. From 1826 to 1890 the proportion of suicides in Belgium has augmented 72 per cent.; in Prussia 411 per cent.; in Austria 238 per cent.; in Sweden and Denmark 72 per cent. and 35 per cent. respectively, and in France 318 per cent. Recent figures show that suicide is more common in the French army than in any other European force. Out of 1000 soldiers fifty die by suicide, and of every 100,000 men in the army about twenty-seven commit suicide every year. In the United States the increase will probably reach 300 per cent. Two peculiarities are shown in the recently published figures of suicides in American cities, the recession of natives of Germany from the head of the list, and an increase in the number of suicides among colored people. In the last report published in New York City it was seen that there were more suicides by natives of the United States than by those of Germany, though the disparity was very small. The change is explained by the fact that while the number of German men who commit suicide is larger than that of male suicides of any other country, suicide by German women is comparatively rare. The suicides of colored people have been more conspicuous in the large cities of the South than in the Northern cities where the colored population is small. Colored residents of farms or small towns seldom commit or attempt suicide; it is in the large cities, where the struggle for existence is under conditions most unfavorable to colored men, that a few of them overcome their repugnance to such an act of violence. In proportion to the total population, suicides among Englishmen residing in the United States are much more frequent than among residents of Irish birth. Among male natives of France and Switzerland in the United States the rate of suicides is high; among women from France or Switzerland suicide is practically unknown. In respect to the total number of suicides compared with the population, Chicago and San Francisco rank highest among American cities. Baltimore and Richmond are low on the list.

Wind and Temper.—There is a close relation between wind and temper. While a cold breeze has a bracing effect, constant hot winds are regarded as a curse. In Egypt crimes are commonest when the hot khamseen blows, and the Arabs revolt in Algeria during the sirocco. The solano, which now and then rushes across the Mediterranean in fiery blasts from Africa, upsets everyone in Spain; and in Cuba the fierce hot wind is such a pest that a family living in Havana made it a rule not to speak while the wind was blowing, to avoid family quarrels.

Cigarettes in Iceland.—Cigarette-smoking has lately broken out with excessive virulence among boys and girls in Iceland. A proposal to cope with the nuisance is being considered by the municipal authorities of Reykjavik. It will, if adopted, empower any male or female adult to box the ears of a juvenile offender, annex his or her weed and impound the stock of cigarettes.

Smallpox in Cartagena.—Over 500 cases of smallpox were reported in Cartagena, Colombia, November 7th. While at first of a mild type, the epidemic has lately become more virulent. The U. S. Consul believes that many deaths ascribed to other causes were due to smallpox. A few cases of black smallpox have occurred.

Hemophilia.—When a female of the "bleeder" family is pregnant, the development of the malady in her offspring has been prevented by the administration of calcium chloride, 2.0 grams a day during the last three months of pregnancy.

Left-Handedness.—Lüddeckens claims that this is not a habit, but is always due to physiological causes, often an expression of the influence of heredity. Normally the blood pressure is greater in the left cerebral hemisphere than on the right side. When this pressure is stronger upon the right side, left-handedness results. In one case reported, in which the pressure was equal in both hemispheres, an alternating preponderance of one or the other side occurred, depending upon blood pressure variations. The term left-handedness is unsuitable, since phenomena are noted upon one entire side of the body, as Lüddeckens noticed in the case of his young son. He believes that all

attempts to overcome left-handedness should be stopped, since a high degree of efficiency upon that side may be acquired.—*Zeitschrift für Psychologie und Physiologie der Sinnesorgane*.

Mosquitoes and Malaria.—A communication from Algeria states that a careful watch was kept for the first appearance of anopheles, to determine if it coincided with the first cases of malaria. The mosquitoes began to arrive June 15, and between June 26 and July 10 seven soldiers, who had arrived during the winter, were received at the hospital affected with malarial fever, the first malarial patients of the year.

Chinese Death Rate.—Examination of statistics relating to the population of Hong Kong reveals an extraordinarily high mortality among the Chinese. It seems hardly possible to believe that out of every 1000 possible Chinese born in the colony, only 72 survive the first year of existence. However, the reports on statistics show this. The European infant mortality in Hong Kong is high, but that of the Chinese points to an absolutely criminal neglect. Definite sanitary regulations are gradually improving the condition of Hong Kong, but apparently it needs other steps also if the Chinese population is to be preserved.—*The Hospital*.

Obituary.—Dr. Patrick S. O'Reilly, at Bay St. Louis, Miss., November 19, aged 57 years—Dr. John Hammond Lovatt, at Florence, Kan., November 23, aged 60 years—Dr. Peter Faling, at Gasport, N. Y., Nov. 23, aged 62 years—Dr. Jefferson C. Cawood, at Knoxville, Tenn., November 28, aged 71 years—Dr. H. R. Bohn, at Biloxi, Miss., November 8—Dr. Henry Clarke, Houghton at New York City, December 2, aged 64 years—Dr. James E. Gibbons, at Baltimore, Md., December 2, aged 58 years—Dr. I. Newton Evans, at Hatboro, Pa., December 3, aged 74 years—Dr. David McDill, at Leavenworth, Kas., December 4, aged 41 years—Dr. James R. Deane, at Newton Highlands, Mass., December 6, aged 68 years—Dr. Rives Walker, at Bristol, Va., December 6, aged 45 years—Dr. John B. Norton, at Boston, Mass., December 8, aged 27 years—Dr. William White Harris, at Wilmington, N. C., December 9, aged 82 years.

GREAT BRITAIN.

The Cause of Cancer.—Dr. James Braithwaite, of London, advances the theory that excess of salt is one of the four factors which cause cancer. It is essential, but is inoperative without one or two of the others. Excess of salt may arise from too much meat. He considers that other factors are overnourishment, an impure condition of the body resulting, owing to the non-use and non-oxidation of food. Some local irritant or stimulant, such as friction from the stem of a pipe or irritation from some micro-organisms must always be present. Cancer is seldom seen among Jewesses, possibly from the difference of diet. Savages, so far as is known, are exempt from cancer, and they get no salt. All the domestic animals, except the pig, are subject to cancer, and salt is given to sheep, cows and horses, but never to pigs.

Guy's Hospital.—Mr. J. Pierpont Morgan, who has already given \$25,000 for the electric installation of St. Paul's Cathedral, has contributed the same amount to the renovation fund of Guy's Hospital.

Many Children Burned.—Dr. Wescott, Coroner of Hackney, a suburb of London has drawn attention to the yearly record of 600 children burned to death in London. The Government is considering the advisability of legislation which would enable Coroners to fine and imprison persons who leave children alone with fire, or with material for making a fire, if children are thereby burned to death.

A Bequest.—By the will of the late William Langlands, over \$50,000 was left to the institutions of Glasgow.

St. Thomas's Hospital.—Dr. C. J. Cullingworth, obstetric physician to St. Thomas's Hospital, who reached the age for retirement last June, was invited to continue in office for three years more. Dr. Walter Tate was elected additional obstetric physician in the hospital, in charge of 21 beds, thus diminishing the amount of Dr. Cullingworth's work. Dr. Cullingworth will retain charge of seven beds.

Hospital Sunday Fund, Melbourne.—Over \$30,000 has been collected and distributed throughout Australia in the past year by the Melbourne Hospital Sunday Fund, which recently held its 28th annual meeting.

A Donation.—The White Star Steamship Company has endowed the charities of Liverpool and Belfast to the extent of \$100,000 in memory of the late Thomas Henry Ismay, founder of the line, who died November 23, 1899.

English Notes.—Upward of seventy London physicians have expressed their approval of a society recently formed by women which holds periodical examinations in the theory and practice of massage and issues certificates.—Of the 552,000 yearly deaths in Great Britain 20,278 are due to violence.—The Middlesex County Council is calling a conference of district councils to consider the question of establishing a county small-pox hospital.—In every 1000 British men there are thirty-five widowers; in 1000 British women there are thirty-eight widows.—The census figures for all Great Britain show that, since 1821, 1041 people attained the age of 100 years and upwards. Of these 716 were women.—It is stated that the average height of English male subjects has increased one inch during the last fifty years.

New Hospital, Simla.—The new Walker Hospital at Simla, which is rapidly approaching completion, is a wooden building of very sombre appearance. In case of fire, but few bedridden patients could escape.

Whooping-Cough in British New Guinea.—An epidemic of whooping-cough is causing great ravages among the young population of British New Guinea. The high rate of mortality of the disease is attributed to the superstitious practices of the natives who consult the local sorcerer in preference to the doctor.

Sir William MacCormac.—Sir William MacCormac, Bart., president of the Royal College of Surgeons, died suddenly at Bath, December 4th. His health had caused anxiety for some time. He arose as usual but, feeling ill, returned to bed and died a quarter of an hour later, from heart disease. Sir William MacCormac was the most distinguished surgeon in the United Kingdom. Born in 1836, in Belfast, he was educated in that city, Dublin and Paris, taking many degrees in surgery. He was appointed a member of the Senate of Queen's University and Examiner in Surgery. Later he became surgeon and consulting surgeon to the Belfast Royal Hospital. As surgeon-in-chief of the Anglo-American Ambulance he saw much service in the Franco-German war of 1870, being present both at Metz and Sedan. He served, also, in a similar capacity in the Turko-Servian war of 1876. For twenty years he was one of the senior surgeons, and lecturer at St. Thomas's Hospital in London, and was consulting surgeon at other institutions, as well as examiner in surgery for the University of London, and the army and Indian medical services. He was the author of a great number of treatises on various subjects, most of which were contributed to different medical journals or societies. In 1899 he delivered the Hunterian oration before the Royal College of Surgeons. He was one of the few foreign honorary members of the St. Petersburg Academy of Medicine. At the time of his death Dr. MacCormac was serving his fifth term as president of the Royal College of Surgeons and his celebrity was world wide.

CONTINENTAL EUROPE.

VIENNA LETTER.

(From Our Special Correspondent).

At the meeting of the "Wiener Medicinisches Doctoren-Collegium" held November 4, Dr. Hochsinger discussed glandular fever, an infectious disease occurring in children from 5 to 8 years of age, causing unilateral, painful, swelling of the cervical and submaxillary glands rarely going on to suppuration. Constitutional symptoms are marked, and the outcome is usually favorable. When there is disease of the naso-pharynx, fever also occurs. He considers glandular fever a secondary disease, generally following some infection of the naso-pharynx. Glandular fever must be differentiated from tubercular adenitis. As treatment he advises ichthyol externally and antiseptics internally.

At the Gesellschaft der Aerzte in Wien, November 8, Professor Neumann presented a rare case of a dermatosis caused by moderate doses of Fowler's solution which was given for furunculosis. The patient was excited, eye-lids reddened, scrotum covered with crusts, and vesicles appeared on his thighs, hands and feet. After the arsenic

had been stopped for two weeks, only hyperkeratosis remained. Dr. Lang showed a case of lupus in which he was using the Röntgen and the Finson ultra-violet rays. Dr. Heibauer reported a severe case of ankylostomiasis in which thymol failed, while extract of felix mas cured the condition, the opposite of what generally occurs. Dr. Schiff presented patients with epithelioma and rodent ulcer which had resisted all treatment for seven years, cured by the Röntgen rays. Dr. Füchsig demonstrated a preparation showing a perforation from the esophagus into the trachea, following the ingestion of lye.

At the Wiener Medicinisches Doctoren-Collegium, November 11, Dr. Bum described the pathology and treatment of writer's and musician's cramp. The causes of these neurcises are neuropathic family history, uric acid diathesis, alcoholism, overwork, false technique, and injuries. He advises warm applications, massage, exercises, etc. Writing must be stopped. Bum believes the most favorable prognosis can be made when the spastic form occurs. Dr. Kornfeld discussed gonorrhea and marriage, commenting upon the frequency of blenorhea and its sequelae in women.

At the Gesellschaft für Innere Medizin, November 21, Dr. Schlesinger reported a most interesting case of myiasis intestinalis, a disease of the digestive tract caused by the larvae of flies. The condition was first described in 1806. A positive diagnosis was made late in the disease. The larvae are swallowed in water or upon food. The ordinary vermifuges are of service in the treatment, though surgical intervention may be necessary. Professor Weichselbaum demonstrated a specimen showing the changes produced by the larvae.

The Gesellschaft fuer Innere Medizin, formerly the Wiener Medicinische Club, held its first meeting November 7th with Prof. Nothnagel as president, and Professors Neusser and von Schrötter as vice-presidents.

Retirement of Prof. von Krafft-Ebing.—According to the *Hochschul Correspondenz*, Dr. von Krafft-Ebing, professor of psychiatry in the University of Vienna since 1889, will on April 1, 1902, return to Graz, where he formerly lived. Prof. Julius von Wagner-Jauregg is spoken of as his probable successor.

The Nobel Prizes.—The five Nobel Prizes, consisting of a little over \$40,000 each, which are awarded annually in accordance with the provisions of the will of the late Alfred Nobel, the inventor of dynamite, were awarded December 10. Mr. Nobel left an estate valued at almost \$9,000,000, and his will directed that the interest on the capital should be awarded as prizes to those persons who should have contributed most materially to benefit mankind during the year immediately preceding. The income from this amount, which was divided into five equal parts, was awarded as follows: To the person having made the most important discovery in the science of physics, to Prof. Röntgen; to the person having made the most important invention or discovery in the domain of chemistry, to Dr. Van Hoff; to the person having made the most important discovery in physiology and medicine, to Prof. Behring; to the person who had produced the most distinguished idealistic work in literature, to Armand Sully-Prudhomme; and to the person who has labored the most or best for the fraternizing of nations and for abolishing or diminishing standing armies, and for the formation of peace congresses, to Dr. Henri Dumant and Frédéric Passy, equally. The prizes were distributed by the Crown Prince of Sweden and Norway in Christiania, and all the winners were present except Sully-Prudhomme.

University Notes.—Lille: The widow of Dr. Morisson, former professor of pathology in the Lille Medical School, has bequeathed \$2,000 to the Lille Hospital.—Paris: Dr. Brouardel, professor of anatomy, has resigned as dean of the Medical School, a position which he has held for fifteen years. Dr. Debove, professor of clinical medicine, has been elected to take his place. The friends of Professor Brouardel will present him with a medallion which Roty is to engrave.—Berlin: Dr. Willibald Nagel, of Freiburg, has been appointed director of the physical department of the Physiological Institute, replacing the late Professor Arthur König.—It is also announced that the third medical clinic, under the leadership of Professor Senator, is soon to be housed in a large modern building next to the new

surgical clinic on Ziegelstrasse.—Professor M. Litten celebrated his 25th anniversary as a teacher on November 17th. The "Gesellschaft für Innere Medizin" has decided to admit female doctors of medicine as members.—Dr. Martin Lieker, of Leipzig, has been made custodian of the Museum of Hygiene.—Marburg: Dr. Ernst Romberg has recently been appointed professor of medicine.—Breslau: Dr. Richard Stern has been made professor of medicine and director of the medical polyclinic.—Munich: Dr. Max Stumpf has been made professor of gynecology and obstetrics, Dr. Karl Seydel professor of surgery, Dr. Gustav Klein professor of gynecology, and Dr. Richard Barlow professor of dermatology.—Bonn: On November 14th Professor von La-Valette St. Georges celebrated his 70th birthday.—Erlangen: Prof. Gustav Specht has become head of the medical department, with Prof. Ernst Graser as second assistant.—Leipzig: On October 25th Dr. Sattler, professor of ophthalmology, celebrated his 25th anniversary in practice.—Dr. Wilhelm His, Jr. has resigned his professorship, and has been appointed physician to the Municipal Hospital in Dresden.—Halle: Dr. Ziemke, of Berlin, has been appointed professor of medical jurisprudence.—Cologne: Dr. Lent celebrated his 70th birthday November 16th.—Kiel: The new insane asylum has just been opened with Dr. Siemering as its director.—Berne: In the middle of October Prof. Pfüger celebrated his 25th anniversary as professor.—Vienna: The City Council has decided to erect a monument to the late Professor Albert in the Centralfriedhof, near those of Hoffmann and Billroth.—An Institute for the treatment of skin diseases by the Finson light treatment will soon be founded under the leadership of Professor Lang.—Dr. Heinrich Albrecht has been made professor of pathological anatomy, as has also Dr. Richard Kretz.—Dr. Franz Kienast and Dr. S. Federn celebrated their 70th birthdays November 20.—On November 5th Professor von Reuss celebrated his 60th birthday. Addresses were made by Professor Monti and Dr. Jänner.—Graz: Dr. Otto Drasch has been made professor of histology and embryology.—Budapest: The Department of Hygiene, left vacant by the death of Dr. Josef Fodor, has been filled by the appointment of Prof. Leo Liebermann, with Drs. Gustav Riegler and Szekely as assistants.—Dr. Emanuel Herczel has been made professor of surgery.—St. Petersburg: A lady, Dr. N. Sieber-Schumow, has been temporarily appointed to fill the place of the late Professor Nencki as head of the department of biological chemistry in the Imperial Institute of Experimental Medicine, St. Petersburg.—Moscow: The Russian Government has decided to establish a Virchow Institute in Moscow.

Temperance in Turkey.—At the bottom of the wonderful physical vitality of the Turkish race is the universal abstinence of the common people. They are the most abstemious race on the earth and the healthiest. The soldiers, peasants, merchants, and members of the learned professions never touch alcohol, although the upper classes of Constantinople drink considerably.

A Special Electric Lamp.—It is stated that Dr. Sophus Bang, of Copenhagen, manager of the laboratory of Professor Finsen, the introducer of the light cure for lupus, has invented a special electric lamp, which gives but a feeble light, but is extremely rich in chemical rays. It is stated that the bacteriological power of this lamp is ten times as great as that of the ordinary arc lamp. Its cost is only about \$15.

Bees for Rheumatism.—Some years ago an Austrian physician advanced the theory that the virus of the bee sting is an infallible remedy for acute rheumatism, a fact which receives unquestionable confirmation from a custom of the country people in Malta. Bees are plentiful in this island, and their stings in such repute that resort to this primitive method of inoculation has been a common practice in severe cases of rheumatism, for generations, with most satisfactory results.—*Mediterranean Naturalist*.

Pneumonia at present leads all diseases in the number of deaths in the United States. Consumption and heart disease come next.

Obituary.—In Tübingen, Professor Carl von Liebermeister, chief of the medical clinic, died November 24, aged 69 years.—In Prague, November 17, Dr. Edlar von Jirus, professor of pharmacology in the Bohemian University, died, aged 61 years.—Dr. Ledresseur, professor at the University of Louvain, died recently, aged 55 years.

1.—In some obscure cases, the signs of pleurisy with effusion will often indicate the existence of perigastric abscess. In other cases, the appearance of a pleural friction over the base of the lung often points to tuberculosis, involving the pleura and the lung, secondarily to the peritoneum. Peritonitis associated with acute pleurisy and other complications within the chest is frequently the result of perityphlitis originating in appendicitis. Indeed, the chest is sometimes invaded in perityphlitis after successful surgical treatment of the primary disease, including removal of the appendix. In some instances of appendicitis, severe inflammation occurs within the thorax, characterized by a large serous effusion in the right pleural cavity. Purulent inflammation may occur, producing an abscess at the base of the right chest. This abscess may rupture into the bronchi with discharges of quantities of foul pus. In other intrathoracic complications of purulent perityphlitis, including septic endocarditis, the line of infection may be traced back through the liver and portal vein to the appendix. Secondary affections of the right pleura and lung occur in abscess of the liver. In inflammatory affections of the gall bladder and bile ducts, and in other morbid conditions. In all obscure diseases within the abdomen, particularly diseases of an inflammatory kind, let it be a clinical rule to examine the chest with especial care. Let such physical examination of the base of the chest in obscure and anxious abdominal cases be repeated as often as the examination of the abdomen itself. In the course of the investigation of a case of disease of the chest, such as a pleurisy or a basic cavity, we often discover evidence of disease within the abdomen. In such a case the disease below the diaphragm may prove to be the primary pathological condition. Let it be a rule of practice, therefore, in every instance of pleurisy and pulmonary disease, or of difficulty in connection with the interpretation of pulmonary symptoms, particularly at the base of the chest, to complete our examination with a careful inquiry into the condition of the stomach, the liver, the intestines, the other abdominal viscera, and the peritoneum, itself, remembering that affections of the chest often originate below the diaphragm. On the other hand we should never neglect to examine with particular care the state of the abdomen with respect to distension and pressure in every case of acute pulmonary disease. Invasion of the pleura and lung from the abdomen is simulated by secondary affections of the same parts in puerperal septicemia originating in the pelvis. Every patch of dulness and crepitus at the base of the chest is not, however, significant of invasion of the lung or pleura. Bruce cites many instances of the passage of infective materials from the abdomen into the pleura, and he asks: May not this be the usual route by which the pleura is invaded by the tubercle bacillus? [J. M. S.]

2.—Rosenbach expressed the opinion that iodides are of no value in the treatment of aneurysm, and that they are even harmful in arteriosclerosis, but the great bulk of medical opinion and experience is directly contrary to this. That iodides exercise a beneficial action in many of these cases seems to be proved by the experience of their almost universal use in practice. Stockman and Charteris have made systematic observations on the blood-tension and

pulse-rate of numerous patients who, for one reason or another, were taking potassium or sodium iodide. These observations were made with von Basch's sphygmomanometer and Gärtner's tonometer. They used only the iodides of sodium and potassium, generally in doses of 15 to 30 or 40 grs. per day, although a few patients had up to 180 grs. and one man was taking 300 grs. Some of these cases had healthy circulatory systems; others suffered from renal or cardiac disease, aneurysm, arteriosclerosis, and bronchitis. One of them had very severe iodism, others had it slightly. In no case did any fall in the blood pressure occur, or any change in the rate or the rhythm of the heart. Even the man who suffered so severely from iodism maintained his arterial tension unimpaired, although he said he felt very depressed and ill. In these cases the depression seems to be due to the coryza and partially to an action on the nervous system. Iodides neither directly weaken the heart nor dilate the arterioles. In animals iodine or the iodides, when given by the mouth, do not alter the dynamical conditions of the circulation. When given intravenously, potassium iodide exerts the marked depressing potassium action on the heart, whereas sodium iodide is practically without this effect. [J. M. S.]

3.—Rorie and Finlay report the case of a male, aged 58, who suffered from mania with delusions, for which he had been in an asylum for 40 years. He died suddenly without cause. At the necropsy a tear was found in the anterior wall of the left ventricle one inch in length, running in the line of the muscle fibres. The heart muscle was found to be in an advanced state of fatty degeneration, and also showed fatty infiltration. A second patient was a female, aged 58 years, who had been in an asylum for 8 years, suffering from alcoholic dementia. She died suddenly. At the necropsy, the heart was found to be fatty and on the anterior aspect of the left ventricle there was a small, irregular tear, about $\frac{1}{4}$ inch in length. A third patient was a man, aged 79 years, who was suffering from senile mania. He had a quarrel with another patient and died suddenly a short time after. At the necropsy a small fissure was found on the posterior aspect of the heart. It was exactly one-half inch in length. The heart as a whole was very fatty. [J. M. S.]

4.—Anderson reports the case of a man, aged 62 years, who had been suffering from pain in the chest and dyspnea for 5 days. There was no history of tubercle or syphilis. About a year previously he had an acute attack of pleurisy, to which he nearly succumbed. His urine at that time contained albumin, but that abnormal constituent subsequently disappeared. Temperature was 99.6°; pulse 104; respirations 31. The heart sounds were distinct, the first sound was prolonged at the apex, but no bruits were heard. The urine contained albumin. The patient died suddenly. At the necropsy the heart was found to be hypertrophied and dilated, with much fat on its outside. The coronary arteries were atheromatous. There was a perforation as big as a small crowquill on the posterior wall of the left ventricle, which corresponded with a ragged funnel-shaped ulcer, the size of a shilling, which had given way at its apex. About an inch lower down there was another, smaller ulcer, which extended as deeply as the visceral layer of the pericardium. The branches of the coronary artery near these ulcers were blocked for about $\frac{1}{3}$ inch by thrombi of an atheromatous nature. Evidently these had been the cause of the ulceration. The mitral valves showed old vegetations. The aortic valves were competent but contained small particles of chalky material. The aorta was dilated and very atheromatous. [J. M. S.]

5.—Kyle reports the case of a man, aged 32 years, who had rheumatic pain in the right wrist, both knees and right ankle. He was delirious and semiconscious and presented tremors. His temperature was 106.4°. The next day his temperature was 108°; and he was semiconscious and delirious, with tremors and twitching all over his body. The first sound of the heart was slightly muffled; but there was no friction or murmur. In spite of the hyperpyrexia, he recovered. [J. M. S.]

6.—Edlington reports a case of tortuosity of both internal carotid arteries. One of the bends of the vessel was situated external to the posterior pillar of the fauces at the level of the middle point of the tonsil. [J. M. S.]

7.—Thomas reports the case of an infant, aged 13

months, who sustained a tear of the lip from the upper jaw to the extent of an inch. Bleeding was severe and for the following 3 days at periods of 12 hours, the wound had to be cleaned of blood clot and redressed, owing to hemorrhage. The writer packed the wound with gauze impregnated with powdered **suprarenal extract** and ordered the administration of 1 gr. of the extract every 4 hours. No further hemorrhage occurred. A man, aged 23 years, had bled freely on receiving any slight wound, ever since he could remember. After a chisel wound, which bled freely every time it was dressed, freshly-powdered suprarenal extract was packed in the wound and 5 grains of the extract were administered every 4 hours. The hemostatic action was marked. [J. M. S.]

H. A. REEVES.

1.—Manson delivered the inaugural address "on the etiology of beri-beri" before the Epidemiological Society of London, on November 15, 1901. In his address he points out the prevalence of beri-beri in the tropics and states that in the search for the cause of this disease confusion must be avoided by a clear conception of the term beri-beri. He defines beri-beri as "a form of multiple peripheral neuritis which occurs epidemically and is specially characterized as compared with other forms of peripheral neuritis by proneness to edema and to implication of the neuro-muscular system of the central organ of circulation; by complete absence of the trophic skin lesions, of paresthesia of the muscles of the head and neck, of marked implication of the organs of sight, hearing, taste, and smell, and of the mental faculties." Immunity is not induced by an attack of this disease. Two sets of theories have been advanced as giving rise to the same: (1) The dietetic theory; (2) the microbe theory. Manson is inclined to the view that the disease is due to a germ whose nidus is located outside of the human body and that the disease is dependent upon the toxic products elaborated by these micro-organisms. He states that beri-beri resembles the intoxication resulting from alcoholism, the germ of which is the yeast plant, the solutions of sugar the nidus, alcohol the toxin, and the important pathological effect peripheral neuritis. He further states that there is a fair degree of proof that the germ producing beri-beri clings to people, as the disease is sometimes transported from one place to another, and he also states that it clings to places, as certain buildings and ships often remain infected for a long period. He also cites instances which support this view. [F. J. K.]

2.—In the second Harveian lecture Browne discusses the treatment of prostatic hypertrophy. Auto-catheterism should be advised in all cases unless this procedure is exceedingly difficult. In speaking of the cases of acute retention the lecturer says "there are no cases of prostatic disease in which it is impossible to pass a catheter into the bladder." Cases in which regular catheterism is impracticable are very rare; they should be subjected to suprapubic cystotomy, calculus removed if present, and any obstructing outgrowth from the prostate enucleated. Castration and vasectomy do no real good and are fraught with grave dangers. [F. T. S.]

3.—Pettigrew outlines his anatomical autobiography and describes how he won two prizes, one for a dissertation

on "The Arrangement of the Muscular Fibres in the Ventricles of the Vertebrate Heart, and the second for a thesis on "The Nerves and Ganglia of the Vertebrate Heart." To facilitate the dissection of the muscular fibres, the heart was stuffed with oatmeal and boiled for several hours to rid it of the cellular tissue, fat, etc. The cardiac nerves were traced by teasing the fat from them under hot water, and then boiling the heart in ether to remove any remaining portion of fat. (To be continued).

[F. T. S.]

4.—Cobbett discusses "Neisser's test for diphtheria bacilli." From facts at our command, he thinks it probable that diphtheria is spread by those who have come in contact with the sick and acquire the bacilli without becoming ill themselves. These individuals are not generally recognized as infections, but carry the disease. In the course of his bacteriological studies diphtheria bacilli would undoubtedly have been missed, had it not been for the employment of Neisser's stain. He found this staining method very valuable, but not infallible in distinguishing diphtheria from pseudo-diphtheria bacilli, and on the other hand, Hofmann's bacilli sometimes showed very minute polar bodies. He has devised a modification of Neisser's stain which consists in applying to one edge of a mounted cover slip a drop of 5% acetic acid, and by means of a small piece of filter paper the fluid passes under the glass. It is not necessary to move the slide from the stage of the microscope. It will be noticed that loose bacilli are swept under the cover slip with the current of fluid, then everything is blotted out for a second by a blue cloud, and finally the diphtheria bacilli, if they be present, are to be seen showing characteristic polar bodies giving the same reaction as Neisser's stain except that the bodies of the bacilli are not brown, but pale blue. Cobbett reaches the following conclusions regarding the diagnostic value of Neisser's stain: "Neisser's stain, therefore, fails to show polar bodies in a small proportion of true diphtheria bacilli; and it shows minute and doubtful polar bodies in a few Hofmann's bacilli. This fact detracts very little from the value of the stain as a differential test, because the exceptions to the rule are so few. We must, then, hold that a good positive reaction is positive evidence that the bacilli are diphtheria bacilli, that a definite negative reaction is valuable evidence, but not alone conclusive, while a poor or doubtful reaction is not of much value either way." [F. J. K.]

5.—Bond has seen several cases of fractured pelvis on the hunting field due to the horse rolling on the prostrate rider. When injured the bladder is usually ruptured in the anterior portion below the peritoneal fold by a projecting spicule of bone. When the urethra is crushed, it is generally due to the pubic rami being forced together like the blades of scissors, the horse falling on the side of the rider. When the bladder is ruptured, the seat should be sutured; when this is impracticable owing to the position of the wound, the bladder should be drained by a tube passing through the suprapubic wound, through an incision in the membranous portion of the urethra and emerging from the perineum. If the urethra be torn and suture be practicable, the bladder should be drained by a tube brought out behind the line of suture. In some cases in which the torn ends of the urethra are separated a great distance, the distal spongy portion with its supporting corpora cavernosa may be detached from the pubes and the gap thus closed. [F. T. S.]

6.—Richmond highly recommends sulphur in the treatment of dysentery, which he has had occasion to employ in a number of cases. Reports of five cases are mentioned which illustrate the efficiency of this drug. He thinks that sulphur is an ideal intestinal antiseptic because of its solidity and absorbability, and concludes that whatever may be the nature of this disease, this drug seems capable of controlling and curing dysentery. [F. J. K.]

7.—Reeves believes the open operation for congenital dislocation of the hip to be unjustifiable, the results are most unsatisfactory and the dangers to life and limb are real. He reduces the head of the femur into the rudimentary acetabulum and holds it there by an apparatus which makes extension on the lower extremity. The patient is allowed to go about with crutches. [F. T. S.]

MEDICAL RECORD.

December 7, 1901.

1. Some Observations on the Borderland Between Medicine and Surgery. GEORGE WOOLSEY.
2. The Expectant Treatment. ROBERT H. BAKEWELL.
3. The Psychic Half. J. ALLEN GILBERT.
4. Spasmodic Bronchostenosis. ALBERT ABRAMS.
5. The Hemorrhagic Diathesis in Relation to Operation on the Nose and Throat. E. HARRISON GRIFFIN.
6. The Treatment of Xanthoma of the Eyelids. FRED. J. LEVISEUR.

1.—George Woolsey presents some observations on the **borderland between medicine and surgery**. He mentions the condition of carcinoma of the stomach, and deals at length with its differential diagnosis. He then discusses the surgical means for its relief. It is not alone, he states, that surgery affords the best treatment in the malignant diseases, but also in perforating ulcer, and benign obstruction of the pylorus. The operations, gastroenterostomy and pyloroplasty are described. Appendicitis is considered a surgical disease, and the writer states that it is unfair to the surgeon to delay asking him to operate until the condition is so desperate that the result or even the expediency of the operation is very doubtful. He states that the leukocytosis which the blood count may afford may be an aid in the question of deciding upon operation, but he does not believe this is to be depended upon, for so many conditions may cause it to vary. The question of the mortality in cases of appendicitis is then considered, and means suggested to diminish, what the writer calls, an "unnecessary element of mortality." [T. L. C.]

2.—Robert H. Bakewell contributes a paper on the **expectant treatment**. He describes his experiences as medical physician of health in the Colony of Trinidad. He took charge of 111 cases suffering from a severe form of dysentery, and he lost only 4 out of the 111 cases treated with opium. He states his terror of the mortalities of some modern treatments in contrast with some of the older forms, especially dealing with the diseases typhoid fever and diphtheria. He says the effect of the teaching of the expectant treatment during his student days was to make him and his fellow students medical agnostics, who believed in nothing but the recuperative powers of nature, but he states that they were compelled to relieve pain and other urgent symptoms, and found that besides rest, food, and the simple applications of the expectant method, there were powerful drugs that unquestionably expedited a cure, when a cure was possible, and relieved suffering even when death was inevitable. But instead of using the enormous dose or their predecessors, they tried the minimum dose that would produce the desired effect, laying more emphasis on rest and sanitary measures, and urging preventive measures as far as possible. [T. L. C.]

4.—Albert Abrams discusses what he terms **spasmodic bronchostenosis**. He wishes to dissociate the condition of bronchostenosis as ordinarily interpreted, from the bronchostenosis which is a transitory condition, it being nothing else than asthma without paroxysms. In bronchospasm, associated with bronchitis, there are present all the symptoms of the latter affection plus a spasmodic cough which is exceedingly distressing to the patient and usually resists the conventional expectorants. If the spasmodic element predominates in bronchitis, the sputum is scanty and viscid. On auscultation of the chest of a patient with bronchitis in whom is associated bronchial spasm, there are in addition to the usual rales of bronchitis, dry, squeaking, and groaning sounds, which are chiefly expiratory with prolonged and accentuated respiration. In differentiating the rales of bronchial spasm from those of bronchitis, he administers a few drops of nitrate of amyl. Such inhalation will temporarily dispel rales due to bronchial spasm, while on the rales of bronchitis no effect is produced. In spasmodic bronchostenosis independent of bronchitis, iodide of

potassium is virtually a specific. He states that many of the so-called stomach coughs are due to bronchial spasm. He recommends the following formula for the treatment of spasmodic bronchostenosis:

R

Iodide of potassium	5 drachms.
Tincture of lobelia	10 drachms.
Spirits of glonoin (1 per cent.)	16 minims.
Elixir bromide of potassium	to 4 ounces.

Mix. A tablespoonful three times a day after meals. This dose may be gradually increased if necessary.

[T. L. C.]

5.—E. H. Griffin contributes a paper on the **hemorrhagic diathesis in relation to operation on the nose and throat**. He states that these cases will tax the ingenuity of the surgeon to the utmost, and will greatly shake his belief in all astringents after he has tried one after another to control this class of hemorrhage, and found them all to fail. Even the suprarenal extract he will discard in a true case of hemorrhagic diathesis as useless, and wonder where it received its reputation as a hemostatic. He states that in these cases it is so often impossible to obtain a history of bleeding until after an operation has been performed, and the surgeon is face to face with the fact that he has operated on a hemorrhagic case. A number of cases are on record in which the unfortunate possessor of this diathesis has lost his life through the error of not informing the surgeon that he bled, and bled profusely, after the slightest cut. He cites several cases which illustrate the difficulty of controlling such conditions. [T. L. C.]

6.—F. J. Levisur discusses the **treatment of xanthoma of the eyelids**. He regards the treatment of internal medication as useless. Excision is recommended by the majority of authors and is practiced exclusively. The galvanocautery is recommended in preference to the Paquelin cautery on account of the absence of radiating heat, but the destruction which is produced is too far-reaching, and, therefore, somewhat beyond the control of the operator. The same may be said of the caustics. He recommends **electrolysis** which possesses none of the disadvantages of other methods. Local anesthesia may be produced by the galvanic current on the negative pole. The intensity of this anesthesia is in direct proportion to the voltage of the current. A current of one-half milliamper and thirty volts will render a spot of the size of a pea anesthetic in two or three minutes. After that the amperage of the current may be increased without causing pain. [T. L. C.]

MEDICAL NEWS.

December 7, 1901. (Vol. LXXIX, No. 23.)

1. A Case of Suture of a Stab-Wound of the Heart, with Remarks on and a Table of Cases Previously Reported. GEORGE TULLY VAUGHAN.
2. When and How to Introduce the Stomach-Tube. MARK I. KNAPP.
3. The Pathology and Treatment of Bilocular Stomach, with a Report of Two Cases. CHARLES GREENE CUMSTON.
4. Some Unusual Localizations of Tuberculosis. FREDERICK A. BALDWIN.
5. Nephrectomy for Severe and Prolonged Mononephrous Hemorrhage. GILANVILLE MacGOWAN.

1.—G. I. Vaughan reports twenty-six cases of **sutured stab-wound of the heart** in which there were nine recoveries and seventeen deaths, a mortality of 65.38 per cent. The situations were as follows: 1, left auricle; 12, left ventricle; 8, right ventricle; and 5, not given. From the above it will be seen that the ventricles are more apt to be wounded than the auricles, and the left ventricles more frequently than the right. Of the recoveries, two were wounded in the right ventricle; two possibly non-penetrating and one in the apex. From the table appended to his article, the following conclusions are drawn: (1) The time has arrived when a wound of the heart should be operated on with as little hesitation as a wound of the brain, with the expectation under corresponding conditions

of getting equally good results. The mortality must inevitably be high—not from the operation, but from the injury—especially if all cases, including desperate ones, be undertaken. Selection of cases who have survived five or more hours after receiving the wound would give a good percentage of recoveries, but such selection is not to be recommended; (2) In all cases of wounds in the region of the heart, with symptoms threatening life, an exploratory operation should be done by making an osteoplastic flap, dividing the fourth and fifth costal cartilages at their attachments to the sternum and the ribs about one inch external to their attachment to the cartilage, somewhat according to the method of Roberts. This flap turned up as a door on a hinge, gives a good view of the pericardium and can easily be enlarged if more room is required; (3) while early and speedy operation is often essential to success, yet the importance of asepsis cannot be too strongly emphasized on account of the great danger of pericarditis and empyema. If there has been hemorrhage, a quantity of physiological salt solution, approximately equal in amount to the blood lost, should be injected into a vein while the surgeon is operating on the heart, if it has not been done sooner. [T. M. T.]

2.—M. I. Knapp does not think that such diseases as heart, lung and aortic diseases, general diseases, pregnancy, etc., contraindicate the use of the stomach tube, if properly handled. He advises the operator to stand at the right side of the patient, putting his left arm around the back of the patient's neck. This accomplishes two things: (1) the arm gives the patient an agreeable support to his neck; (2) with the arm around the back of the patient's neck, the operator has the most robust patient under his physioleal control. Then attempt to introduce the tube, which has previously been immersed in water—no other lubricant is necessary. With the left arm around the back of the patient's neck, the proximal end of the tube is held between the thumb and index of the left hand—the tube running through the palm of this hand and the opening of the tube away from the operator. This left hand is kept close to the patient's mouth. The tube, held this way, insures the operator against any of the stomach contents spurring upon him. The distal end of the tube—that part which goes into the stomach—is now taken between the thumb and index finger of the right hand, in the manner in which a pen is held, and introduced into the patient's mouth, which must not be opened any wider than is absolutely necessary letting the tube pass all the time between the flexed third and fourth fingers of the left hand. The object of this last procedure is to limit the side motions of the soft tube and prevent kinking; it gives a certain degree of stiffness to the soft tube. As soon as the tube appears to have reached the posterior pharyngeal wall, the patient is told to swallow and keep breathing deeply. The tube is now fed into the stomach, the end still passing between the third and fourth fingers of the left hand. It is not necessary to have the patient protrude his tongue, or for the operator to put his finger as a guide into the patient's mouth. The cyanosis of the patient need cause no alarm, as it is due only to a momentary cessation of breathing caused by the effort to expel the tube, in which the patient might succeed if the tube were not held with the right hand. [T. M. T.]

3.—C. G. Cumston divides bilocular stomach into two forms, congenital and acquired. The congenital form is distinguished from the latter in that it is usually free from adhesion with the neighboring organs and that the stricture is longer and is not formed of cicatricial tissue but of the normal structures forming the walls of the organ. This form resembles very closely the stomach of various rodents. The cardiac part of the stomach is usually larger than the pyloric. The strictured part connecting the two pouches is glossy white and longer than in the acquired form. Microscopically, no cicatricial formation can be discovered, and only atrophy of the gastric mucosa, more particularly of the glandular tubes, can be seen. Gastric ulcers have been found at stricture, always secondary, and probably produced by the pressure of the food passing through the narrow part of the organ. In the acquired condition symptoms arise which can be divided clinically into two groups. The first are simply those to which a gastric ulcer gives rise; after the lesion has existed for many years, or after several recurrences have taken place, the second group of symptoms appears and indicates bilocular stomach. In diagnosis very little can be ascertained by inspection,

but by palpation much can be learned. The epigastric and umbilical regions are often painful on pressure, and not infrequently a resisting mass can be made out, above which a high pitch percussion sound may be elicited, while on both sides of this high pitched area of percussion a tympanitic sound is obtained. Much importance has been attributed to the splashing sound which is frequently met with in the region of the umbilicus, but it is in no way characteristic of this condition. On percussion an interesting phenomenon is a tympanitic note over the pyloric pouch, while over the cardiac pouch there is elicited a dull note. In bilocular stomach the gastric contents show an absence of free hydrochloric acid or a trace. The acids of fermentation have been present in some cases. Where the gastric ulcer is recent, there is hyperacidity of the gastric contents. The absence of free hydrochloric acid and the fermentation are generally due to the existence of a chronic gastritis. An operation should be undertaken when a patient presents continued pain, repeated vomiting and other dyspeptic disturbances, or when symptoms, such as increasing emaciation and cachexia make their appearance. The author states that no operation can be decided upon before the abdomen is opened and the condition of affairs thoroughly ascertained, and it is only after the surgeon has become perfectly familiar with the anatomical conditions present that he can select the operation most applicable under the given circumstances. [T. M. T.]

4.—F. A. Baldwin gives some unusual localizations of tuberculosis which have come under his notice: (1) Tuberculosis of the hypophysis; (2) tuberculosis of the intercostal tissue near the sternum, with secondary tuberculosis of the axillary lymph glands; (3) primary tuberculosis of the Fallopian tube, with a large tuberculous abscess in the ovary; (4) tuberculosis of the thyroid gland; (5) tuberculosis of the uvula; (6) an adenomatous polyp of the cervix uteri showing tuberculosis. [T. M. T.]

JACOB SOBEL and CHARLES HERRMAN.

2. Appendicitis. JOHN B. DEEVER.
3. Report of a Case of Interstitial Pregnancy.
R. H. PIERSON.
4. The Daily Medical Inspection of Schools. D. S. LAMB.
5. On a New Principle in Nephropexy. CARL BECK.

1.—J. Sobel and C. Herrman report twelve cases of ulceromembranous angina in children under ten years of age. The situation of the ulceration was found in six cases on the right tonsil; in four on the left, and in two on both. In one case both tonsils were involved simultaneously, while in the other the left tonsil became affected two days after the right. Similar ulcerations, either independent of or in connection with the tonsillar ulceration, may occur on the tongue, cheeks, and gums. In the authors' cases the ulceration was limited to the tonsils excepting one case. Any portion of one or both tonsils may be affected. The size of this ulceration varies from that of a small finger nail to the greater part of the tonsil. The shape is irregularly circular or oval. As to its character, it appears to have a worm-eaten floor, the edges being on a level with or slightly elevated above the tonsillar surface. Tonsillar inflammation is usually very moderate; when more marked the ulcer appears somewhat deeper and the destruction of tissue greater than they really are. Within the first 24 to 48 hours it appears membranous. The color differs, being either a yellowish, greenish gray or a dirty light brown; but all have in common the sloughing base with the level or slightly raised edges. The depth varies from $\frac{1}{8}$ to $\frac{1}{2}$ inch, sometimes extending to the floor of the tonsil. There is some elevation of temperature—from 101° to 103.4° F. As a rule, there is no temperature. The submaxillary glands are generally enlarged, and always so on the side of the lesion. The symptoms are entirely local, fever, as a rule, rarely being so high as to produce constitutional disturbances. Generally the symp-

toms complained of are pain in the throat and difficulty in deglutition. The diagnosis, for convenience, is divided into (a) clinical; (b) microscopical; (c) bacteriological. Clinically, it must be distinguished from diphtheria, confluent follicular amygdalitis and other tonsillar inflammations. In distinguishing from diphtheria, for all practical purposes, it may be stated that the affection is ulcerative and not membranous; from confluent follicular amygdalitis, by the absence or mildness of constitutional symptoms, by the superficial character of the former, and by the presence, perhaps, of follicular spots on one or the other tonsil. A positive diagnosis can only be made by the microscopical appearances. The smears are stained with Ziehl's solution of carbol-fuchsin in the proportion of one to three of water. Microscopically will be seen the characteristic fusiform bacilli and spirilla in large numbers. The bacillus is about twice as long as the Klebs-Löffler bacillus and somewhat pointed at the ends. Some are bent in the shape of a crescent, others are arranged end to end, others at an acute angle, some arranged in pairs or groups and others scattered about without any particular order or grouping. The authors have found the bacillus distinctly motile. A bacteriological diagnosis is not reliable. The prognosis is invariably favorable. As to treatment, apply to the necrotic mass a solution of silver nitrate, three to five per cent. Lugol's solution is more efficient, but also more disagreeable. Siredey recommends chromic acid applied directly to the lesion. Alkaline mouth-washes, solutions of potassium permanganate, etc., should be given when necessary.

[T. M. T.]

2.—J. B. Deaver, in his article on **appendicitis**, states that if the three cardinal symptoms—pain, tenderness and rigidity—are kept in mind, the early diagnosis in nine cases out of ten is very easy. The sudden abdominal pain, general or localized to any part of the abdomen, is the first symptom—this after a short time localizing to either McBurney's point or to a point over the tip of the organ, which may be almost anywhere in the abdominal cavity. Tenderness is not that elicited by carelessly applied pressure or tight clothing, but a tenderness confined to a small area elicited by the pressure of a single finger. Pressure on other parts of the abdomen often causes pain under McBurney's point. Tenderness is more often localized to McBurney's point than is the pain. Rigidity is nearly always present from the onset, but this can sometimes only be demonstrated by the most gentle touch. He advocates early operation, and says the ideal time to operate is in the stage of appendicular colic before inflammation has taken possession of the vulnerable tissues composing the organ. [T. M. T.]

3.—R. H. Pierson reports a case of **interstitial pregnancy** in which the gestation originally occurred in that portion of the tube within the thickness of the uterine wall, the interstitial portion. As the ovum matured it forced open the uterine end of the tube and produced the above condition. To diagnose this condition prior to abortion and exploration is extremely difficult or impossible. In the case mentioned the careful digital exploration of the uterus, under suitable antiseptic precautions, did no harm and brought to light conditions least suspected. If placenta forceps had been used and the membranes simply twisted from their site, in all probability the tubal portion of the placenta would have remained to become a medium for the growth of septic germs. Two questions arise in considering this case: (1) what was the relation of the uterus to the tubal cavity while the fetus was in the uterus? (2) what would have been the result if the pregnancy had not been interrupted? From the condition of the tubal orifice, its distensibility, and the fact that the tubal cavity held so much placental tissue, when the uterus was distended by the presence of the fetus, the ring was much larger than at the time when first observed. Contractions of the uterus had contracted this ring. As gestation progressed and the uterus enlarged, it is possible, by the time the pregnancy was completed, the relations would have been nearly those found in the normally pregnant uterus, and the labor at full term would have occurred and a satisfactory result would have taken place without interference of any kind.

1. Hernia Epigastrica and Fatty Tumors in the Epigastrium. HOWARD A. LOTHROP.
2. One's Health in Egypt. F. GORDON MORRILL.
3. The Similarity of the Early Symptoms of Simple Abdominal Contusion and One Accompanied by Severe Intestinal Injury; the Need of Exploration Celiotomy as an Early Routine Measure.

JOHN T. BOTTOMLEY.

4. The Scope of Vaginal Section in the Treatment of Pus in the Pelvis, with a Report of Eighty-Two Abdominal Sections without Mortality; and Eighteen Vaginal Sections with One Death, Due to Accidental Causes. EDWARD REYNOLDS

and L. V. FRIEDMAN.

5. Prostatic Calculus Removed Through Perineal Section. CHARLES G. LEVISON.

1.—Embryological defect, weak abdominal parietes, trauma and the preperitoneal fat and the terminal vessels and nerves are the causative factors of **hernia in the epigastrium**. The abdominal wall becomes weakened and less able to withstand increased abdominal pressure at the points generally corresponding to the site of the passage of vessels through the anterior sheata of the rectus muscle or the immediate vicinity of the linea alba. It is probable that most epigastric herniae are preceded by a condition which, at one time, could be considered only as a fatty tumor, The tumor may give rise to no disturbance whatever. Symptoms may appear after trauma or they may be insidious and progressive. The symptoms are those of gastrointestinal disturbance, pain and intestinal indigestion. A fatty tumor or epigastric hernia will not disappear spontaneously; it may give rise to symptoms at any time. If symptoms are present, operation is indicated. [J. M. S.]

3.—We have no certain means of distinguishing between a **simple abdominal contusion** and one complicated by **severe intestinal injury**, except through an exploratory incision. This, to be of most avail, must be done within a very short time (3 to 5 hours) after the receipt of the injury. Having no other certain method of diagnosis, and the promptness of the operation being the feature necessary for its success, Bottomley believes that exploratory laparotomy, combining as it does opportunity for a certain diagnosis and the best possible treatment, if severe injury be present, should be a very early routine measure in all but the most trivial cases of contusion of the abdomen. [J. M. S.]

4.—Reynolds and Friedman were impressed with the considerable mortality necessarily incident to the abdominal extirpation of recently infected tubes and other collection of **pus in the abdomen**, and with the therapeutically good results of thorough **vaginal drainage** in such cases, that they adopted the rule that, in all cases of inflammatory masses in the pelvis which presented acute symptoms, and in which there had been a fairly continuous temperature, averaging 100° or more during the attack for which the patient sought treatment, they would confine operation to thorough drainage by the vagina, without attempting the removal of the affected viscus. [J. M. S.]

5.—Levison reports a case of **prostatic calculus removed through perineal section**. [J. M. S.]

11. Appendicectomy Surgical History. H. MERRILL RICKETTS.

1.—Billings discusses the "clinical observations in pericarditis." The constitutional disturbances of a primary general infection sometimes obscure the local manifestations of pericarditis and occasionally symptoms and signs of dry or plastic pericarditis are absent. He mentions that pericarditis with effusion may be accompanied by irregular remittent and intermittent types of fever. We are also informed that pericarditis with effusion is usually recognized in the post-mortem room and not clinically. Pericarditis occurring in the course of croupous pneumonia is, as a rule, more fatal than when it occurs during acute rheumatic fever. Rheumatic fever holds the first place in the etiology of pericarditis. Rheumatic pericarditis is sometimes characterized by sudden precordial pain or post sternal or epigastric distress and with dyspnea, and by an increase in the frequency of the pulse rate. At other times this condition may be ushered in by a few days of premonitory languor, anorexia, constipation, and slight disturbances of temperature and respiration. The onset of pericarditis in the course of rheumatic fever is difficult to recognize and requires the most careful daily scrutiny. The pericardial friction rub is usually the first sign of pericarditis. Endocarditis and myocarditis may accompany pericarditis in the course of rheumatic fever. The author reports a case of rheumatic pericarditis, also one of pyocarditis and a case of tuberculous pericarditis. The article is concluded by a discussion of the cardinal signs—the pericardial friction rub, the outline of precordial dullness, and the condition and position of the apex beat—and other signs. [F. J. K.]

2.—McFarland writes on "the pathology and pathogenesis of pericarditis." In this article he discusses this subject from the standpoint of the etiology, bacteriology, the morbid anatomy, and the prognosis. McFarland states that pericarditis is most common between the ages of 15 and 30, occurring more frequently in men than in women and affecting all classes of societies. Primary pericarditis is an extremely rare condition, while, on the other hand, secondary pericarditis is frequently a complication of the infectious diseases. Pericarditis may arise as the result of trauma or from lymphogenous or hematogenous metastasis. It has been known to occur in the course of rheumatic fever, pyemia, septicemia, pneumonia, chorea, endocarditis, tuberculosis, scurvy, blood diseases, malignant diseases, and in a few other infectious diseases. Streptococci, staphylococci, pneumococci, bacillus pyocyaneus, bacillus of Friedländer, and the bacillus tuberculosis, have been found in the purulent form. The tubercle bacillus is commonly associated with the hemorrhagic form. McFarland describes the morbid anatomy of the following varieties: Pericarditis sicca, sero-fibrinosa, purulenta, adhesive chronica, hemorrhagica, tuberculosa. The heart-muscle is always affected in pericarditis, the degree of this change depending upon the form of pericarditis. [F. J. K.]

3.—Preble discusses "the etiology of pericarditis." He carefully reviews the literature of this subject and reaches the following conclusions which we quote in substance: (1) Cases of acute pericarditis clinically primary occur, but are rare; (2) diseases to which pericarditis appears as a complication are in order of their frequency: pneumonia, 34%; rheumatism, 28.36%; chronic diffuse nephritis, 11.2%; tuberculosis, 10%; sepsis, 4.7%; aneurysm, 2.6%; typhoid, 1.7%; (3) the more extensive a pneumonia, the greater the danger of this complication; (4) the danger is somewhat greater with left than with right-sided pneumonia; (5) where only one lobe is involved the danger is least with a right upper-lobed pneumonia and greatest with a right middle or left upper-lobed pneumonia; (6) with an unilobar pneumonia the chances of a pericarditis are 1 in 40; with a bilobar or trilobar, 1 in 10; with quadrilobar, 1 in 5, and with a pneumonia of the entire left lung, 1 in 8; (7) the mortality of pneumonia with pericarditis is 92.4%; (8) rheumatic pericarditis is complicated by endocarditis in 60% of the cases, i. e., three to four times the normal rate of endocarditis; (9) the danger of pericarditis complicating rheumatism is the greater the younger the individ-

ual, and is somewhat greater with males than with females; (10) So far as acute pericarditis is concerned, the site and extent of endocarditis are apparently of no importance; (11) pericarditis appears as a complication of all forms of nephritis, but particularly the chronic diffuse with contraction; (12) It is an extremely ominous thing, for 22, i. e., 84.6% of the cases died; (13) It is still uncertain whether the pericarditis is toxic or infectious; (14) tuberculosis excites only one-tenth of the cases, and when one considers the extreme frequency of tuberculosis, pericarditis must be regarded as a rare complication; (15) pericarditis may be a part of a generalized acute tuberculosis, but is more often the result of a chronic tuberculosis of the lungs or mediastinal glands; (16) septicemia and pyemia contribute a very considerable number of cases of pericarditis. The primary focus may be remote or close to the pericardium; (17) aneurysm of the aorta causes 2.6% of all the cases, a very high figure when one recalls the comparative infrequency of aneurysm; (18) typhoid fever, which is rarely complicated by inflammation of the serous membranes, other than the peritoneum, contributed 4 cases, which is 1.7%; (19) the cases of obliteration of the pericardium are due to the following causes arranged in order of importance: Endocarditis, tuberculosis, chronic nephritis, aneurysm; (20) more than one-half of the cases in which the cause was clear, were due to endocarditis, or rather to some cause common to both the endocarditis and the pericarditis, and more than one-half of these cases showed a combined aortic and mitral endocarditis; (21) relatively six times as many cases of obliteration of the pericardium occur with aortic and mitral endocarditis than with either lesion singly; (22) tuberculosis causes but few cases of oblitative pericarditis; (23) pericarditis, accompanying nephritis, is not always fatal, but may apparently end in the formation of adhesions." [F. J. K.]

4.—See page 1140, Philadelphia Medical Journal, June 15, 1901.

6.—Dr. A. T. Mitchell, in his article on enucleation of the eye, comes to the following conclusion: (1) The method causes so much less traumatism than others that it is available where enucleation has to be done with least possible injury; (2) where grave reasons obtain against anesthesia, a quick operation is the only one that can be considered; (3) cosmetic considerations are met as well by other procedures; (4) an operation done quickly, with a few clean cuts, deserves comparison with the same thing most of us have seen the general practitioner take an hour of hacking and probing to do.

7.—LeCount believes that endothelial cells play an important role in inflammatory reactions. He concludes that proof is still lacking to show that fibrous tissue is developed from the endothelial lining of blood vessels.

[F. J. K.]

9.—Jones reports "10 cases of infectious multiple neuritis with two deaths" which occurred in the city of Minneapolis between the 15th of February and the 15th of March, 1901. He reminds us that influenza was epidemic at the time of the occurrence of these cases, and suggests that the influenza bacilli were responsible for the neuritis, especially as six of these cases occurred within one week. The majority of the cases was not typical, only one or two corresponding to the usual descriptions found in text books. Motor symptoms were prominent in some of the cases. There was also a minimum degree of muscular atrophy. Absences of trunk pain, tenderness, paresthesia, and anesthesia, were frequent. [F. J. K.]

7. On the Use of Gärtner's Tonometer.

LEROY CRUMMER.

1.—F. M. Crandall contributes a paper on: **A Century of Vaccination.** He summarizes lessons taught by the experience of more than a century as follows: 1. The first lesson cannot be better stated than in the words of the Berlin Board of Health: "Vaccination in infancy, renewed at the end of childhood, renders an individual practically as safe from death from smallpox as if the disease had been survived in childhood, and almost as safe from attack." 2. The duration of the immunity conferred by vaccination is variable. In many individuals vaccination in infancy, and revaccination in childhood is sufficient for life protection. In a limited number immunity is lost in five or six years. It is never possible to know with certainty to which class an individual belongs. In the face of an epidemic, therefore, vaccination of all who have not been vaccinated within five or six years, is giving what the lawyers call the benefit of a reasonable doubt. Every one who has been vaccinated in infancy and childhood, should be vaccinated not less than once in adult life. 3. The immunity conferred by vaccination is in direct proportion to the thoroughness with which it is performed, and this is shown with considerable accuracy by the character and number of the resulting scars. 4. Vaccination in infancy alone is not sufficient to wholly prevent smallpox among the adult population. 5. Optional vaccination has not proved sufficient to protect the community from smallpox. Compulsory vaccination is a measure warranted by more than a century of experience. 6. The mild compulsion enforced in this country, by requiring vaccination or evidence of its recent performance upon admission to the public schools, should have the hearty support of parents and physicians alike. [T. L. C.]

2.—Jay F. Schamberg discusses the **diagnosis of smallpox.** Five figures illustrating several degrees of severity of the eruption accompany the article. He deals with the prodromal symptoms, constitutional symptoms, distribution of eruption, character of the lesions, manner of eruption, course of eruption, as the question of differential diagnosis. The pustular syphilid, particularly that known as the varioliform syphilid, may resemble smallpox strikingly. The history and initial symptoms, and the fact that the syphilitic eruption comes out in successive crops; that the palms of the hands and soles of the feet, which are constantly beset with lesions in smallpox, are rarely attacked in the pustular form of syphilis, are points which will aid in the diagnosis. The confounding of smallpox with *impetigo contagiosa* can only rise from the misunderstanding of the nature of the latter disease, which is a purely local dermatosis resulting from inoculation of the skin with pyogenic microorganisms. The eruption is usually limited to the neck and face, although occasionally a few lesions may be present upon the hands. The trunk and lower extremities are, as a rule, entirely free, and the lesions do not ordinarily exceed a dozen in number. A diagnosis should not be based upon any one feature of the disease, but upon the entire picture presented. [T. L. C.]

3.—Robert N. Willson reports a case of **tetanus appearing in the course of vaccinia.** The patient was a girl baby of 11 months, who was vaccinated four weeks before she was seen by the writer. The vaccination was successful and ran a moderately severe course, and when last seen by the physician first in attendance, the ulcer was clean, still discharging serum, but free from any signs of secondary infection. Just four weeks after the first vaccination, symptoms of tetanus appeared. 10 cc. (= 500,000 units) of antitoxin were given and repeated the next evening. The child died the third day after the beginning of the tetanic symptoms. The curettings of the vaccine ulcer at the time of the first visit showed a profuse growth of *staphylococcus albus* in pure culture on blood serum, agar and bouillon. Of the latter there was no clouding but a mouldlike growth

on the top of the medium. No growth of the anaerobic bacilli was obtained, and none were discovered in cover-slip preparations made directly from the wound itself. Willson discusses several cases which have recently come to light of tetanus infection, and states that in every instance, and contrary to the rule of tetanus, the so-called secondary infection has appeared at a very late date, from the twentieth to the twenty-eighth day from the time of vaccination. All of these cases, including one reported still more recently from the Philadelphia Hospital, have been fatal, which is contrary to the rule, providing that the tetanus toxin was in fact introduced at the same time with the vaccine virus. In all cases the specific antitoxin was employed, and in Willson's case carbolic acid as well as chloral and the bromids by the rectum, but without permanently favorable result. In his own case a mixed infection was present in the vaccination wound when first the tetanus symptoms appeared. The cases observed up to this time point to the failure of the physicians regarding the danger of using the shield rather than a protective dressing, and the probability of secondary infection if the wound is left to the sleeve and atmosphere. [T. L. C.]

4.—George G. Groff discusses **vaccine production and vaccination.** He states that it was the experience of the army surgeons in Porto Rico during the Spanish-American war, that glycerinated virus, produced in one public laboratory, seemed absolutely inert. For 10 years he has been under the conviction that whenever epidemics of smallpox occur, the virus supplied to physicians is much more attenuated than when no epidemics exist. He also states that one of the questions of some difficulty to decide is the fact that when a sore arm exists, there may be a division of opinion as to whether or not it is a genuine vaccine vesicle. He inquires what percentage of such typical vesicles, scabs and scars is obtained from the numerous brands of virus now on the market. The epidemics in the State of Pennsylvania which have gained ground, he declares to have been due to the failure on the part of the physicians to diagnose the disease. In the 800,000 vaccinations made in Porto Rico by the military government, with virus produced on the ground, neither the scab, the lymph from the sore, nor the granulating tissue under the scab were used; only the product containing the virus. [T. L. C.]

6.—Mark I. Knapp concludes after a study upon the subject of **massage of the stomach**, that this treatment after the methods of *effleurage* and *tapotement* was a benefit in all six cases; each patient felt better, but he believes that this feeling of improvement was mostly psychic. The motility of the stomach was not only not increased by the massage but was actually delayed in every instance; and the influence on the secretion of hydrochloric acid certainly was not in accord with the theoretically accepted view, as the HCl. showed a tendency to diminish rather than to increase. He employed the form of massage known as *petrissage* once or twice and found that it could be employed only in patients with lax, thin abdominal walls, the stomach being either much dilated or in a very ptotic condition. He concludes by recommending stomach massage for its psychic effects only. [T. L. C.]

7.—Leroy Crummer presents a paper on the use of **Gärtner's tonometer.** He summarizes the value of the instrument as follows: In diagnosis.—In eliciting the tension in cases in which the mean blood-pressure is symptomatically changed—either increased or decreased. In prophylaxis.—In keeping track of the blood-pressure in those cases in which it is important to have the earliest possible knowledge of the break in the compensation, i. e., in the valvular lesions and in kidney diseases. In prognosis. In building our prognosis, in acute cases, on a maintenance of the power of the heart—read directly by means of this instrument. Therapeutically. As a measure of the effect of drugs or other treatment given for the production of changes of arterial tension. [T. L. C.]

1.—Grohé, after a careful review of the literature of the elastic fibres describes some experiments performed by himself upon young rabbits. He produced fractures in the bones, and then after healing had taken place, which was retarded as much as possible, the tissue was hardened, decalcified and sectioned. The results showed that ordinarily complete tear of the fibro elastic occurred, partly due to mechanical violence, partly to the extravasation of blood. Then the cells of the fibro elastic began to proliferate very rapidly, and in the callous these fibres were often found everywhere. In one case in which the radius and ulna had grown together, an extraordinary number of minute fibres were found between the connective tissue and the muscle. This proliferation of fibres occurred not only in external but also in the medullary callous. The origin of these fibres appeared to be from the old elastic tissue. [J. S.]

2.—Schiller describes the case of a man of 30, whose skull was deformed by several large protuberances. These had existed since his birth, and had formed an impediment to parturition. X-ray examination of these showed them to consist of bone. Up to his 19th year he had suffered severely from headaches, but after that time had had no further disturbance. There were no deformities in the bones of the face. This condition probably represented a congenital tumor-like hyperostosis of the bones of the skull. Although in these conditions the prognosis is usually bad, in view of the fact that no symptoms have occurred for 11 years, the patient may be regarded as likely to remain unaffected. [J. S.]

3.—Hölscher reports the following case. A boy of 14 with chronic otitis media of the right ear, severe pain in the right occipital region, and in the forehead. There was some fever and chills. The cause was supposed to be a polyp of the external meatus which was removed without relieving the symptoms. On the 5th day a radical operation was performed, opening the tympanic cavity of the ear, and examining the sinuses of the dura. These appeared to be normal; the condition of the patient, however, was very unfavorable and 2 days later, in addition to severe pains in the head, horizontal nystagmus was noticed and the following day slight paralysis of the left side of the face. On the 8th day a considerable amount of pus was discharged when the tampon was removed. The wound was enlarged and examination of the dura showed the presence of softening in the temporal lobe. The dura was therefore incised and a considerable amount of pus and necrotic brain matter was discharged. The patient rapidly improved after this and ultimately recovered. The interesting points in this case were the persistent absence of choked disk, the sudden increase in the rapidity of the pulse as soon as the abscess was evacuated and the brain pressure reduced. The case shows the importance of a thorough operation at the beginning. [J. S.]

4.—Klebs has discovered a form of micro-organism that is nearly always associated with tuberculous processes. It occurs in the form of a diplococcus and grows upon gly-

cerine agar as a very delicate, transparent brownish colony, then as these grow larger they become slightly darker in the centre. Microscopically it appears as 2 biscuit shaped microorganisms with the broad surfaces very close together, occasionally forming pseudo-tetrads. It is fairly large, the double form attaining a diameter of 3 micra. It is only found outside the cells; is best stained with 2% solution of safranin T, and only partially by Gram's method. If the growth is very luxuriant it forms chains. They have a very remarkable catalytic activity which can best be detected by pouring over the cultures a 2% solution of hydrogen peroxide. It is pathogenic for men and animals, causing a phlegmonous form of infiltration. He believes that its presence in tuberculosis is of grave significance, and reports a case in which in spite of energetic treatment with various bacillary extracts death ultimately occurred, because the diplococcus was present in considerable numbers. It is found not only in the sputum, and on the tonsils, but in tuberculous lymph glands and tuberculous joints. [J. S.]

5.—Marx reports the case of a woman, 42 years of age, who, with 2 previous pregnancies had had severe pains in the lumbar region. After the 3d she noticed that the pelvis was growing smaller, and on the occasion of the 4th parturition it was found that, as a result of osteomalacia, the true conjugate had been reduced to 5.1 cm. Cesarean section was therefore performed, a living child extracted and the incision in the uterus closed by sutures. The patient made an uninterrupted recovery. [J. S.]

6.—Gross reports the case of a boy of 9, who, at the age of 5, had inserted a shoe-button in the left nasal cavity. In the course of time a chronic and excessively fetid discharge appeared from the nose, excoriating the edges of the alae and of the upper lip. Examination was painful even under cocaine, but enough was discovered to recognize the presence of a large encrusted foreign body covering the septum and a part of the lower turbinated bone. In order to remove this it was necessary to chloroform the patient, when it was found that it was apparently a bony structure about the size of a hazel nut. When opened, the shoe-button was found in the interior fairly well preserved. After the removal Gross curetted energetically the surrounding structures, and the patient made a perfect recovery. [J. S.]

7.—Goldschmidt reports the case of a man infected with syphilis from his wet-nurse. At the age of 54 he developed glandular swellings in the neck and axilla. A diagnosis of pseudo-leukemia was made. In the course of the disease he developed on one occasion icterus. There was moderate enlargement and tenderness of the liver; there was an attack of erythema and the characteristic recurrent fever of Ebstein. The patient emaciated rapidly, and there was extreme tenderness of the legs. During this period he developed glycosuria which was not affected by the character of the food ingested; was not associated with increased quantity of urine, but seemed to cause considerable thirst. Four years after the first symptoms he had improved somewhat and the fever was still irregular. He developed ascites and moderate leukocytosis. Shortly before death the swelling in the glands disappeared. An autopsy was not made. On 2 occasions antistreptococcal serum was injected, but both times without result. [J. S.]

8.—Peters gives a brief description of several influenza epidemics that occurred in Petersthal and were studied by him and his colleagues. He also mentions some very interesting cases, one a man of 80, who had symptoms of complete intestinal obstruction cured by injections of atropine. Another, a case of pleurisy, which was relieved by drinking considerable quantities of Wernerer spring water; 2 cases of carcinoma of the pylorus which died under the manifestations of acute symptoms after having worked until a day or two before death, and a case of meningitis not relieved by lumbar puncture. [J. S.]

9.—Emmerich contributes a very violent diatribe against Wasmuth, who criticised his experiments with inhalation apparatus. He contends that the experiments were properly done and his results accurate. [J. S.]

10.—Buttersack gives a brief sympathetic and laudatory account of the career of Alvin von Coler, who had done so much to improve the organization of and to elevate the scientific work of the medical corps in the German army. [J. S.]

11.—Marcuse gives a brief account of the life of

Turneysser zum Thurn, a quack who followed in the footsteps of Paracelsus, and for a time succeeded admirably, amassing considerable wealth. Then as the result of an unhappy marriage he was brought to poverty and distress, which points the moral and adorns the tale. [J. S.]

1.—Weichselbaum reviews Virchow's life and works.

2.—Zappert examined about 200 spinal cords in embryos, new born infants, and children under two years of age. He found that hemorrhage into the posterior horns of the cervical cord, while not frequent after difficult labor, seems a characteristic condition. Simple hydromelia is not pathological, yet a complicated cavernous condition may develop in the spinal cord from simple hydromyelia. In one case, a child of 19 months, a progressive widening of the central canal occurred, combined with an increase of the neuroglial tissue, a distinctly pathological condition. In a case of anencephalus, congenital hydromelia occurred in the cervical region, as in syringomyelia. After reporting with histological detail several cases, Zappert concludes that a surely congenital neuroglial hyperplasia was not found in any case, but that there seems to be some relation between this infantile syringomyelia and other abnormalities of the cerebral nervous system. Thus it is seen that syringomyelia may be congenital and traumatic.

[M. O.]

3.—Landsteiner has studied the degenerative changes occurring in the kidney epithelium in the infections and intoxications. His methods of study are given in detail with several diagrams. He concludes that no parallel can be found between the deposition of fat in the renal epithelium and the destruction of the protoplasm of the kidney epithelium. Albuminous cloudiness may exist without fatty degeneration, but with outspoken fatty degeneration, the "little rods" of the kidney structure are not necessarily changed. Different types of fatty renal cells were observed. [M. O.]

4.—Störk examined the kidneys of 20 hereditary syphilitic embryos and children. After describing the fetal development of the kidney, he shows that neogenous zones should not be noted after the ninth month of fetal life. From his investigations, the kidneys of infants with congenital syphilis not only showed delayed development, neogenous zones being seen after birth, but also were abnormal in the form or arrangement of their component parts. In these cases the histological findings pointed to probable specific nephritis. He calls these abnormalities "secondary vegetative disturbances due to syphilis." [M. O.]

5.—After reviewing the literature of the subject fully, Stangl gives the histological findings in the pancreas of numerous cases, and reports his investigations in animals. He concludes that the fat droplets found in the pancreas

are noted first in the second half of embryonic development, and then only in very small numbers. After birth, however, with digestion, they rapidly increase in size and number, until the twentieth year of life, when they increase more slowly. They are distinctly visible in old age and are supposed to be the normal products of the cells. When they occur in excess in old age, they are the expression of the decreased vital energy of the cells.

[M. O.]

6.—Weichselbaum and Stangl describe the changes found in the pancreas in 18 cases of diabetes mellitus. The patients varied from 14 to 75 years in age, while the disease had existed from three weeks to 19 years. Atrophy of the parenchyma was noted macroscopically in 17 cases, many lobules being very small. The inter- and intra-lobular connective tissue had become lipomatous in 7 cases, while hyperplasia of the connective tissue was noted but once. In seven cases over 50 years of age the intima of the tiny pancreatic blood vessels was sclerotic. The islands of Langerhans were less in number and much smaller than normally. Fat droplets are seen in the normal pancreas. Only in these cases they are irregularly distributed in the tubular epithelium, while they appeared in large quantities, regularly arranged in the atrophied islands of Langerhans. They conclude from their researches that these changes are not due to pancreatitis or granular atrophy, but to a genuine atrophy from some unknown cause, especially affecting the islands of Langerhans. [M. O.]

7.—Kühls reports the autopsy upon the body of a man of 50, in whose stomach a cancer with ciliated epithelium was found, and this was noted in the metastases in the retroperitoneal lymph-glands, lungs, and suprarenal capsules. While this condition is very rare, Kühls explains it by referring to the embryonal gastric epithelium of the lower animals, where cilia are normally found.

[M. O.]

8.—From the examination of the neck of a case of total absence of the thyroid gland, Erdheim concludes that cysts are more apt to occur in the lower remnants of the branchial arches than in the upper; that it is still doubtful whether the cysts found in the reported cases of thyroid aplasia originated from the third or fourth branchial arch, that the cysts noted in Erdheim's case produced no thyroid tissue, since their origin was probably not the lateral branchial arch, but a remnant of the fourth median branchial arch; and that in cases of total thyroid aplasia, the lateral arch remnants are probably as plastic as the median. Besides, he concludes that while in the new-born infant these arches are solid, they form trabeculae by the second year; that large, light cells are only noted up to the third month, since they grow smaller after that; that the oxyphilic cells of Welsh only appear after the tenth year; that fat cells appear in the connective tissue in the fifth year, and increase gradually; that about the second year fatty droplets first appear in the epithelium; and that hemorrhages appear from time to time, well encapsulated. Finally, among the anomalies in the development of the thyroid gland, cystadenomata of the lingual duct are relatively frequent. [M. O.]

9.—Stravoskiadis has examined 28 specimens at different periods before pregnancy was completed and after parturition. Free decidual tissue was noted in the 18 cases of pregnancy, upon Douglas's pouch, the walls of the rectum, uterus, tubes, and broad ligament. The earliest was noted in the fourth month of pregnancy. It rises from the connective tissue of the serosa, not from the endothelium. Regressive changes are noted before parturition and for two months afterward, hyaline degeneration with cyst formation being seen. In some cases chalky bodies remain. Such findings are of great value in the diagnosis of a previous pregnancy, with abortion or parturition. [M. O.]

10.—Lindenthal studied a case of ruptured Fallopian tube in a young woman of 26, who died after laparotomy for ruptured tubal pregnancy. Pregnancy had taken place about 1 cm. from the uterine end of the tube. The growth of the embryo was stopped by hemorrhage, while the cells of Langerhans continued to proliferate and finally ruptured the tube, causing fatal hemorrhage. No decidual tissue was found. Excellent histological diagrams illustrate this article. [M. O.]

11.—Albrecht and Ghon describe the pathological con-

ditions found in cerebro-spinal meningitis. The micrococcus of Weichselbaum is generally noted in cases of true cerebro-spinal meningitis, the purulent exudate being seen in stripes or plaques, spread over the cerebellum, the convexity of the cerebrum, and the base of the brain. The meninges are thickened and shrunken, especially about the foramen of Magendie. The characteristics of the micrococcus of Weichselbaum are fully described and the literature of the subject is reviewed. Similar cocci have been found in the nose, throat, etc., of patients with meningitis, but they are not the true micrococcus of Weichselbaum. The micrococcus meningitis cerebro-spinalis is very rarely found in cases of mixed infection, though a few such cases have been reported. These seem to follow lumbar puncture. [M. O.]

12.—Wintersteiner reports a case of irido-cyclitis in a man of 26, suffering from cerebro-spinal meningitis. Thrombo-phlebitis of the retina followed, with optic neuro-retinitis. Such metastases as ophthalmia due to the micrococcus of Weichselbaum are very rare. [M. O.]

13.—Sachs reports a case of brain abscess in a man of 51, caused by the bacillus of Friedländer. This was confirmed by inoculation in mice, guinea pigs, and rabbits. Brain abscess is rarely due to the bacillus pneumoniae of Friedländer. [M. O.]

14.—Leiner reports eleven cases of diphtheria in which influenza bacilli were also found. Diphtheria with influenza seems more often fatal than is diphtheria alone, especially when that has been treated with antitoxin at once.

[M. O.]

15.—Bartel gives the autopsy reports in 23 cases of endocarditis. Five patients showed acute verrucose endocarditis with superficial bacteria; seven were subacute verrucose endocarditis with organized vegetations in which bacteria were embedded; five were old ulcerative endocarditis with deformity and calcification of the valve leaflets; and six were fresh endocarditis in tuberculous, cancerous, or old people. Bartel concludes that every verrucose endocarditis is mycotic in origin. The amount of vegetation found probably depends mainly upon the duration of the endocarditis and the resisting power of the individual.

[M. O.]

1. The Variation in the Course of the Pyramidal Tract. E. STRAUSSLER.
2. Pathohistological Examinations of the Central Nervous System in a Case of Sachs' Family Amaurotic Idiocy. E. FREY.
3. Further Contribution to the History of the Tay-Sachs Family Paralytic Amaurotic Idiocy.

II. HIGIER.

1.—The subject, a man of 66, died 58 days after an attack of apoplexy followed by left hemiplegia. There had been some improvement in the paralysis before death. By the Marchi method, degenerative changes were found in the lateral and anterior pyramidal tracts. The fibres in the anterior tract were atypical in the distribution, they left the periphery, then returned to it and spread themselves over the ventral surfaces of the cord. The fibres in the lateral columns involved a part of the cerebellar tract in the dorsal region. The specimen shows anomaly in the course of the pyramidal fibres.—[J. S.]

2.—The patient, a boy of 1½ years, had been born in the membranes. His teeth appeared at 11 months, but he never learned to speak nor to walk. At the age of one year he was, however, able to sit up and use his hands to feed himself. From that time he had emaciated and became completely idiotic, had never recognized his mother, and shortly before death there was some edema of the face. The physical signs indicated rachitis. There was profuse salivation and great difficulty in swallowing. The eye-grounds showed slight atrophy of the disk, and a marked disturbance in the region of the macula lutea. There were spastic contractures of the limbs. The patient was unable to sit up, and when the attempt was made, the head fell upon the chest and the chest upon the thigh. The reflexes were greatly exaggerated. The child turned toward light and seemed to be frightened by

noises. Just before death he developed opisthotonus, convergent strabismus, and, as a final symptom, eclampsia. Microscopically there was degeneration of the pyramidal column throughout the whole spinal cord. In the lower dorsal region there was degeneration of the posterior columns, and there was some degeneration of the anterior cornua, particularly pronounced in the cervical region. The columns of Clark were normal. In the medulla and pons the chief changes were in the fibres of the pyramidal tracts, which had lost their medullary sheaths to a considerable extent. In the brain the same thing was true of the fibres in the internal and external capsule, and in the median and lateral part of the cortex. There was also marked degeneration of the fibres from the cortex of the frontal lobes, and a slight degeneration of the fibres in the occipital lobes. In hematoxylin preparations, pronounced changes in the pyramidal cells could be detected; morphologically the brain was normal. By the Marchi method, with the addition of confirming the degeneration already described, considerable recent alterations were found in the cortex of the brain. Frey concludes the case indicates that the degeneration occurring in this form of idiocy is not congenital, but post natum, therefore it is not due to a defect of development—the normal arrangement of the convolutions in the brain excluding this—but to some condition that causes degeneration in the cortices of the hemispheres, and gives rise to the degeneration of the cells and fibers. [J. S.]

3.—Higier reports 2 additional families in which cases of the amaurotic type of family idiocy occurred. The first patient was one of 9 children, 2 of whom were dead; the six living children suffered with a lisp and stuttered. At the age of 4 months the child could sit up; at 6 months it could stand, and was able to recognize its mother. At 7 months the first tooth appeared. After this time the physical and psychical development of the child ceased; there was gradual cessation of spontaneous movement or interest in the surroundings, and, as a result of progressive weakness, inability to sit up. The muscles were weak but reacted normally; there were no contractures. The knee reflexes were variable. Babinski's toe reflex was always present on both sides. The child was easily frightened by noise and suffered from time to time with hunger. It could not fix any object; there was divergent strabismus, although apparently no interference with the muscles of the eyeballs. The optic nerves were pale; the macula lutea changed to an intensive bluish gray. This represents a case of the disease without distinctive hereditary influence. The second case, a girl of 12 months, was a child of first cousins; there was some neuropathic heredity, and of 5 older brothers and sisters, 2 suffered from exactly the same disease, both being blind and idiotic at death. The present disease commenced at the age of 7 months, at which time the child could stand up and feed itself. It then began to emaciate, became idiotic, lost the power of fixation and could not recognize its mother. There was slight contraction of the limbs, slight increase in the reflexes, and great weakness of the muscles. The eye-grounds could not be examined owing to withdrawal of the child from the clinic. The same family furnished the 3rd case, the 4th of that family affected. The patient when observed was 13½ months old, and was the child immediately succeeding the 2nd case. At the age of 8 months it seemed to be entirely normal. From this time it became weaker, and took less interest in its surroundings; it lay quietly most of the time, seldom crying, and frequently laughing without cause. Contractures were not present. The reflexes were normal; the child was easily frightened by noises; the pupils reacted to light; but there was no fixation. There was horizontal nystagmus. The region of the macula lutea was replaced by a white oval spot, and the optic nerves showed commencing atrophy. The disease appears to be degenerative and not inflammatory. There is no solution of the question why the child remained normal in all respects for 8 months. The changes in the eye were probably secondary to changes in the brain. A remarkable fact is that the disease seems to occur only among the Jews. Of the 26 families reported, all but one or two were Jewish. The same thing is true of intermittent claudication, of which Higier has seen 23 cases, 22 of them Jews.

A. HESSE.

5. Investigations Concerning the Digestive Properties of the Digestive Juice of the Small Intestine.

O. SIMON and ZERNER.

1.—The previous work concerning this question is first referred to, and the decision reached that there has been no thoroughly satisfactory proof of the absorption of albumins through the mucous membrane of the large intestine. The method undertaken to show that this does occur was the daily administration of an enema containing thymus gland; this was first boiled and then cut fine. Table salt and a little laudanum were given with the injections. The patient also received food by the mouth. The method of demonstrating that there had been actual absorption was to estimate the uric acid and phosphates in the urine; since it was shown that the uric acid and phosphates increase in the period during which the thymus was given. Mochizuchi decided that there had been absorption of the nucleo-proteids which had caused increase of the uric acid and phosphates in the urine. He also shows that there was increase in the nitrogen in the urine during the period in which enemata were given, hence he decided that there was also absorption of the proteid elements of the nucleo-proteids. He believes this demonstrates that certain albuminose bodies may be absorbed in this way, and that it is therefore possible to administer an important part of our nourishment by means of the bowel. [D. L. E.]

2.—Rencki in this portion of his paper discusses the changes in the hemoglobin and red blood cells occurring in new growths of the stomach, and in gastric ulcer. He uses the ordinary methods of studying the blood. In 15 cases of new growths in the stomach there was observed in 13 instances a decided increase in the red blood corpuscles. The lowest count was 2,680,000; the average was 3,875,000. In the early stages of the disease normal blood counts were observed in several instances; hence the count of the red blood corpuscles has no diagnostic importance, except that the statement that the red blood cells do not go as low as they do in pernicious anemia, is usually correct, but that this is not always true has been shown by cases of carcinoma of the stomach in which the blood count has been reported as low as 350,000. The hemoglobin in these cases of carcinoma varied between 90% in one case, and as low as 25% in other cases. The average was 65%. The hemoglobin, as others have observed, is usually decreased to a greater extent than the red blood corpuscles. In ulcer the average count of red cells was 4,539,000 in 14 cases. In one case, however, a count of 1,300,000 was obtained. The number of red cells depends upon the course which the ulcer runs. If there is frequent and severe hemorrhage of course the red cells sink very low. One important observation was the discovery of megoblasts in large numbers in one case of ulcer, a point which speaks strongly against the view that these are distinctive of pernicious anemia as against secondary anemia. The hemoglobin showed marked variation; from nearly 100% down to 19%. The conclusion concerning the red cells and the hemoglobin reached in this article is that there are no characteristic changes in either disease. Reduction of the hemoglobin below 60% is by no means characteristic of carcinoma, nor is the presence of nucleated red blood cells at all distinctive of ulcer. When, however, the red blood count is comparatively high and the hemoglobin is low, it speaks against anemia due to hemorrhage, and hence it speaks to a very slight extent in favor of carcinoma and against ulcer. [D. L. E.]

3.—Zweig gives an interesting discussion of Stiller's

sign, (movable 10th rib), which the last-mentioned author, as is well-known, considers a very characteristic sign of either existing or imminent neurasthenia. Zweig discusses the results obtained by those who have investigated cadavers, which speak strongly against this view of Stiller's, and which show its frequent presence in those who have had no signs of general neurasthenia, and, more particularly in those who have no signs of enteroptosis. His clinical results were also contrary to Stiller's view. He found that 49% of those persons who had movable 10th rib had evidence of nervous dyspepsia. Atony of the stomach was present in only a much smaller proportion of cases. This is contrary to Stiller's belief that atony is a certain accompaniment of enteroptosis and movable 10th rib. Movable 10th rib was found in exactly one-half of the 100 cases examined, these cases being examined in routine order, and not especially chosen. It was found almost as often in men as in women; in some cases it was found when the patient complained of absolutely no gastric symptoms. It does, however, seem to be to some extent a sign of the existence of nervous dyspepsia, but it is certainly not a definite sign of general neurasthenia.

[D. L. E.]

4.—Hesse gives an interesting discussion concerning the difficulty of making a diagnosis between gastric ulcer and disease of the gall bladder, basing his discussion chiefly upon the facts that have previously been presented by Naunyn, Kehr, Lindner and Kuttner. He believes that in a very considerable proportion of cases it may be entirely impossible to make a diagnosis between gastric ulcer and gall stones. If characteristic symptoms occur, they may be practically distinctive of one disease or the other, but the great difficulty is that in either condition characteristic symptoms may be almost entirely or entirely absent, and the symptoms which in earlier days were believed to be characteristic of one disease or the other, are now known to occur with some frequency in the disease in which they are comparatively unusual. He describes 2 cases: One of a woman of 30 who was said to have had icterus in childhood. After the birth of her second child she had gastric symptoms for some time, and then began to develop attacks associated with chilly feelings, pain in the back, and attacks of vomiting, and diarrhea. She had never had icterus after her childhood, never had any hemorrhage. The stomach was slightly enlarged, there were numerous tender points, the chief one being below the right border of the ribs, in the parasternal line, and a small tumor could be felt in that region. The diagnosis was relative stenosis of the pylorus, due to gastric ulcer. Operation confirmed this diagnosis. In the second case there had been for some years sudden attacks with nausea and vomiting, chilly feelings and violent pain in the gastric region. Icterus was said to have been present, but was never observed. One fact somewhat suggestive of gall-stone was that the pain usually appeared in the middle of the night. There was a tender point in the epigastrium slightly to the right of the middle line, and numerous hyperesthetic points. There was also a tender point in the back slightly to the right of the 12th dorsal vertebra. The test meal showed practically normal gastric conditions. The diagnosis was cholelithiasis and its consequences; other physicians who had seen the patient had, however, made a diagnosis of purely nervous disturbance or gastric ulcer. [D. L. E.]

5.—Simon and Zerner make an interesting report of the results which they obtained in working on a case of jejunal fistula. The patient had had a severe hemorrhage from gastric ulcer, and had at first been fed per rectum. It soon became impossible to feed her in this manner, and it was also impossible to feed her by the mouth, a fistula was therefore made to save her life, and she did well after the operation. The fluid which emptied itself through this fistula was golden-yellow in color, was alkaline to litmus, and acid to phenolphthalein. Its digestive properties were tested in a series of observations. It was found that it digested starches so long as the acetic acid was not added in quantities to make the total greater than 0.13%; it digested albumens rapidly, when moderately or strongly alkaline; it did not digest albumens when the reaction was about neutral or when it was acidulated with acetic acid. In other words the results show that in its native condition or when moderately acid it digested starches, when moder-

ately alkaline or strongly alkaline it digested albumens, but when acid or neutral, it did not digest albumens, and when alkaline it did not digest starches. This is compared with the fact that the contents of the upper part of the intestine are alkaline, while those of the lower part are acid. When remembering this fact, and considering the results here reported it seems not improbable that under normal circumstances the digestion of albumens and starches takes place, in chief part, at least, in different portions of the intestines, the albumens being chiefly digested in the upper part of the small intestine, and the starches in the lower. [D. L. E.]

LA PRESSE MEDICALE.

September 7, 1901. No. 72.

1. Phototherapy in the Treatment of Lupus and Dermatoses Limited to the Face. LEREDDE.
2. Phelps' Incision in the Operation for Club-foot.

COVILLE.

1.—In phototherapy, the action of the rays of light goes deep, forms perfect cicatrices, yet it destroys no tissue and causes no pain. After a detailed account of the apparatus employed, with explanatory diagrams, Leredde names the indications for the use of phototherapy. These are soft, superficial lupus; medium sized or large lupus; nasal lupus; orificial lupus; and lupus of the mucous membranes. Rarely it will be indicated in erythematous lupus; only occasionally in lupus of the body or extremities. It is also useful for skin diseases which remain rebellious to other treatment, such as naevi, acne rosacea, epithelioma, syphilis, etc. [M. O.]

2.—Coville, after discussing the utility of the Phelps incision in the operation for pes equino-varus, describes the operation as it is performed both by Lucas-Championnière, and by Kirrmisson. He believes that both are too radical, and that, in the treatment of such cases of club-foot, a large mediatarsal arthrotomy should be performed, with section of the anterior and posterior tendons of the leg and of the plantar aponeurosis. Then a cuneiform tarsectomy should follow, with resection or ablation of the astragalus, as may be necessary. Coville has recently performed two such operations successfully, which he reports.

[M. O.]

September 11, 1901. No. 73.

1. The Regulating Mechanism of the Composition of the Blood. CHARLES ACHARD.
2. The Treatment of Prostatic Calculi. R. TARNAUD.

1.—Histologically and physiologically the constitution of normal blood is always the same. When hemorrhage occurs and salts and liquids are injected into the organism, the normal equilibrium is soon re-established. This is due to the regulating mechanism of the composition of the blood. The kidneys, the glands of the skin and the alimentary tract, and the lungs, all excrete whatever excess of water, chlorides, urea, gases, etc., may be present in the blood. That this is true has been proved by many experiments. In disease the regulating mechanism works effectively as far as is possible under the existing conditions. It is only from this idea of a regulating mechanism of the composition of the blood that cryoscopy, antitoxins, edema, intoxications, crises in fevers, etc., are clearly understood. Therapeutically, injections may be given to raise or lower the concentration of blood. While his theory is by no means clearly expressed, nevertheless Achard believes that such a regulating mechanism must exist to keep the composition of the blood uniformly equal. [M. O.]

2.—Prostatic calculi may be found in the urethra or in the prostate gland itself. They may be ordinary urinary calculi which remain in the prostatic urethra or enter cavities in the prostate, communicating with the urethra; or they may form in the cavities of the prostate gland, and later enter the urethra. When an exploring instrument, sound or bougie, passes these calculi, a grating sound is heard and crepitation is felt. The treatment consists of the removal of the calculi through the rectum, urethra, or

perineum. The rectal operation should never be performed; the urethral operation is for small calculi only; while median perineal section is the operation to be preferred for large calculi. When the calculi are not in the cavities which communicate with the urethra, care must be taken not to open the urethra. Drainage should always be left in place after operation. [M. O.]

September 14, 1901. No. 74.

1. Gastroenterostomy in the Treatment of Dilatation of the Stomach. H. DEBOVE.
2. Tubercular Rheumatism. MAILLAND.

1.—Debove reports the case of a man of 41, who was inclined to obesity before marriage. At 26 he was married, and gastric troubles began almost at once. Since then he has kept thin. After the death of his two children he became worse, having marked hyperchlorhydria. Two years ago his wife died, since which time his gastric symptoms have been severe. Debove had diagnosed a gastric ulcer. Signs of stricture of the pylorus first appeared a year ago, with dilatation of the stomach. As much as 211% of hydrochloric acid was found after a test meal. Gastric lavage was instituted daily. As he did not improve, gastroenterostomy was performed. Since then his general condition has gradually improved, and no medicines are needed. Debove advises this operation when a gastric ulcer causes stricture of the pylorus and dilatation of the stomach. [M. O.]

2.—By tubercular rheumatism Mailland designates the articular symptoms which are probably due to the toxins produced by the tubercle bacilli, seen in tubercular individuals. The lesions found are irritative and fibro-plastic, like those found in rheumatism due to gonorrhea or the infectious diseases. These lesions may vary from a simple arthralgia to complete ankylosis. Mailland reports the case-histories of three such patients in full. In an acute case the shoulders were affected before a tubercular osteo-arthritis developed; in a chronic case, one shoulder, wrist and knee were affected, with final ankylosis, accompanying phthisis. The diagnosis of this condition is often difficult. The treatment remains that of tuberculosis elsewhere. [M. O.]

September 18, 1901. No. 75.

1. Deformities of the Pupils in the Insane. E. MARANDON de MONTYEL.
2. Cystic Degeneration of the Fetal Kidney. LENOBLE, CARAES, and LE BOT.

1.—Deformity of the pupil has hitherto been supposed to occur but rarely among the insane, excepting in general paralysis. Pupillary disturbance has been noted in alcoholic dementia, organic dementia, periodic mania, and in insanity of toxic or infectious origin. But Mignon's thesis shows how commonly these occur. Marandon de Montyel found deformities of the pupil in 83% of the 77 insane patients examined. In 37% the pupils were unequal; in 12% myotic; in 15% mydriatic; and deformed in 41%. In 44% there was some trouble in the reaction to light; in 29% some trouble in the reaction to accommodation, and in 27% Argyll-Robertson pupils. He concludes that pupillary disturbances are excessively frequent among the insane, especially inequality of the pupils; and that while slight in most, they are severe in some cases. [M. O.]

2.—Lenoble, Caraes, and Le Bot report a case of polycystic kidney in the fetus. A woman of 32, in whom fetal movements had ceased two weeks before labor, had a very difficult labor, until a sac adherent to the dead fetus had been evacuated. The labor terminated successfully, and the woman recovered quickly. In the fetus, a normal sized female, the kidneys were large and cystic, the right kidney weighing almost a pound. After discussing this rare condition, with a description of the microscopical lesions seen, they state that the cystic degeneration of the kidneys probably began in the tubules, about the third

month of intrauterine life, and increased rapidly; for the membrane of the cysts is probably the remains of the tubular epithelium. [M. O.]

JOURNAL DE MEDECINE DE BORDEAUX.

September 7, 1901. (31me. Année, No. 36).

1. Two Cases of Osteosarcoma of the Leg.
CHAVANNAZ.
2. The Alterations in the Leukocytes in Animals Bitten by Venomous Serpents.
B. AUCHÉ and L. VAILLANT.

1.—Chavannaz reports two cases of **osteosarcoma of the leg**, the one upon the fibula of a man of 50, the other on the tibia of a man aged 65. In both cases amputation was performed at the hip-joint, with perfect operative recovery. Now, almost two years after the operation, the former shows only pulmonary symptoms. The second case died with marked cachexia and pulmonary congestion a year after the operation. [M. O.]

2.—Auché and Vaillant report the results of their experiments upon the **white blood corpuscles of animals bitten by venomous snakes**. Leukocytosis occurs in all cases, immediately. This reaches its maximum in from eight to twenty-four hours. The **hyperleukocytosis** persists till death in those cases, which are rapidly fatal. In other cases it diminishes gradually. The polynuclear leukocytes are especially increased in number, while the lymphocytes diminish. The eosinophiles are decreased during the time that the hyperleukocytosis persists. When an animal has received an injection of Calmette's antivenomous serum just before, or a few days before being bitten, the same changes occur, only with greater rapidity and intensity, especially in those cases which recover. When an animal has received an injection of antivenomous serum alone, hyperleukocytosis, much less marked in intensity, occurs. [M. O.]

September 15, 1901. (31me. Année, No. 37).

1. The Histology of Amyloid Disease of the Liver.
B. AUCHÉ.

1. **Amyloid disease of the liver** is localized to the tiny blood vessels at first, to the walls of the trabecular capillaries; later, of the intralobular capillaries. Amyloid matter forms a solid cylinder of the former arterial walls, with almost total obliteration of the lumen of the vessel. When the liver cells show changes, these begin near the affected capillaries. Thus it is that specimens may show three layers in a lobule, a narrow periphery of fatty degeneration, normal liver cells in the center, and between them the intermediate layer showing the changes of amyloid degeneration. The cell granulations are gradually replaced by this material. Others claim that the hepatic cells never become amyloid, the changes found in them being due to mechanical forces alone. Auché gives a detailed description of the histological findings in two cases of amyloid disease of the liver. His investigations show that amyloid degeneration is not seen in the liver cells at all, the changes there found being those of compression, deformity and atrophy, always secondary and mechanical. [M. O.]

September 22, 1901. (31me. Année No. 38).

1. Syphilitic Hydrocephalus. ROCAZ.

1.—Rocaz reports a case of **syphilitic hydrocephalus** in an infant of six months. The mother, a woman of 20, had become infected after marriage, having a specific laryngitis, pharyngitis, and syphilides. Her hair also fell out in large quantities. One miscarriage occurred before this child was born. The infant was small, had a constant coryza, macular syphilides, an anal mucous patch, and a marked increase in the size of its head, which measured 48 cm. in circumference. Both fontanelles were open and fluctuated. There had never been any convulsions. Upon mixed treatment, continued for one year, all symptoms disappeared. The head remains large, but the child is growing up to it. [M. O.]

Society Reports.

THE NEW YORK OBSTETRICAL SOCIETY.

Meeting held November 12, 1901, Dr. Malcom McLean in the Chair.

Dr. W. S. Stone presented a specimen of **cancer of the ovary** in a woman of 47 years whose last labor occurred 23 years before. Menstruation began at twelve years, and was normal until a year ago, when profuse menorrhagia, lasting twelve to fifteen days, began, accompanied by pains in the lower abdomen. She was pale and somewhat emaciated, the cervix was large, hard and nodular, and the uterine body felt enlarged, and retroverted. Behind and to the right was a hard, globular mass about the size of a grape fruit, apparently adherent to the uterus. The diagnosis was made of **cancer of the uterus** with a tumor of the right broad ligament. The uterus and tumor were removed, the patient making an uneventful recovery. The uterus was large and hard, and in the left horn was found a small ragged adenoma or adeno-carcinoma. The tumor was a solid growth of the right ovary, measuring 8 by 9 cm., firmly adherent to the rectum. There were some softened areas of necrotic tissue, but it presented the typical picture of carcinoma. Such a combination of cancer of the uterus and ovary is rare, while the limited involvement of the uterus would suggest that it was secondary. Dr. H. J. Boldt advised that the ovaries be removed always when performing the radical operation for uterine cancer. Dr. J. Riddle Goffe thought that there existed two spontaneous, unrelated, foci in the case reported.

Dr. Dougal Blissell presented a **new operation for retroversion of the uterus**, with a patient. His procedure follows. The abdomen is opened by median incision, pelvic adhesions are broken up, attached organs freed, and ovaries and tubes, if diseased, are removed. The uterus is then pulled upward. In order to form an exact idea of the relaxation of the round ligament, a suture is passed through it about one-half inch from its attachment to the uterus; the same suture is again passed in an opposite direction through the round ligament at a point about one inch from its first insertion. This is done on the other side. When these sutures are tied, the round ligaments become looped, and the amount of round ligament to be resected shows. If the tension is too great, the section is made inside the loop; if not sufficiently taut, it is made outside. Another suture is passed under the round ligament, which, when tied, completely encircles the round ligament, preventing its retraction when cut. This is also done on the other side of the loop, one-quarter of an inch from the uterus. The temporary suture is cut, and dissection from the broad ligament follows. Permanent sutures are inserted and the raw surfaces adjusted. The first patient operated upon in this manner was a woman of 30 with pain in the pelvis which prevented walking or standing with ease, and some vesical tenesmus. Menstruation had lasted at times 20 days. After curettage, abdominal section showed the uterus completely retroverted. Two and a half months after operation the uterus was in perfect position, menstruation had occurred twice, lasting eight days, and all pain and discomfort had vanished. Dr. W. Wylie preferred this operation to ventrofixation except in women past the menopause. He considered Alexander's operation the best.

Dr. W. R. Pryor, who opened the discussion upon **dysmenorrhea in nulliparae**, believed that many cases were due to errors of development and the changes which occur with advancing years. He usually found irregularities in development of other parts of the body, changes associated with various distortions of the uterus. The endometrium may be hypertrophied or atrophied. If the cervix is hypertrophied, he advises either amputation or incision. He obtained good results from gelsemium and cannabis indica, if the flow was too free, or with hyoseyamus, when marked hys-

terical symptoms existed. The radical cure is conception. Dr. Florian Kling believed that anteflexion, with stenosis at the internal os, caused dysmenorrhea. In these cases dilatation and curettage will give permanent relief, while sterility is cured in the same manner. In many cases of dysmenorrhea due to ovarian trouble, he used the curette. Dr. H. C. Coe, who had performed abdominal section on the previous day on a multipara, whose uterus was divulsed and curetted four months before to relieve obstructive dysmenorrhea, had found both ovaries adherent and one tube so diseased that he removed it. Neither dysmenorrhea nor sterility can be cured by dilatation and curetting alone. Dr. Wyllie believed that the real cause was imperfect development; that the membrane was not nourished sufficiently to become a normal living membrane; that its blood supply was deficient; and that it could not perform its menstrual functions properly. If active disease be excluded, anteflexion may exist. Mere mechanical opening the canal does not overcome the difficulty. In patients with dysmenorrhea, a silver probe introduced in the Sim's position, will cause pain when the probe reaches the internal os, a condition which is almost pathognomonic. He advised thorough divulsion and dilatation. After dilatation he passes over the surface of the endometrium with the curette, leaving in place a hard rubber drainage tube. Keeping the os internum open for a week, or more will cure many cases. The tube may be left in through one menstruation and should then be taken out. In obstructive cases the tube can be left in, and the patient can go about. The trouble will return in three, four, or six months, and the procedure may have to be repeated. He has treated hundreds of cases without serious consequences from the use of the tube, which is kept in place with a hard rubber Albert Smith pessary. The same treatment is of value in sterility. Dr. Goffe considered an imperfectly developed uterus the principal cause of dysmenorrhea. In women who are free from pain in the early menstrual life, but develop dysmenorrhea later, some pathological lesion is found, endometritis, salpingitis, or ovaritis. With undeveloped uterus, treatment with carbolic acid applications after dilatation must be continued over a long period. After six months the patient is often pregnant. If the treatment is without benefit, he dilated the internal os, curetted and packed the uterus with gauze, which acting as a foreign body, stimulated contraction, and the uterus develops with exercise. Improvement in the circulation of the uterus, ovaries and tubes follows. Dr. A. H. Ely believed the pathological condition to be hyperplastic endometritis in an undeveloped uterus. Dr. J. N. West referred to other causes, chronic salpingitis, retroversion, and tumors, but used dilatation in obstructive dysmenorrhea. Dr. E. E. Porter thought that the form of the drainage used after dilatation should depend upon each individual case. Dr. H. N. Vineberg agreed that in the slighter degrees of arrest of development, with long narrow cervix and sharp anteflexion, dilatation and curettage were of benefit. Dr. Joseph Brettauer used dilatation when stenosis existed, and considered general hygienic treatment necessary. Two years ago he had seen a book by Fliess, in which were reported a number of cases of dysmenorrhea cured temporarily and permanently, by the application of cocaine to certain parts of the nose. His personal experience, so far limited, has not been uniformly satisfactory.

CINCINNATI RESEARCH SOCIETY.

Regular Meeting Held November 14, 1901.

Dr. Arthur Knight presented a specimen of psammoma of the brain which sprang from the dura in the centre of the orbital plate and extended upward and backward directly into the frontal lobe. It resembled a large solitary tubercle $1\frac{1}{2}$ inches in diameter and $1\frac{3}{4}$ inches long. He reviewed the literature carefully, demonstrated microscopical sections, and showed that the whorls seemed formed by groups of cells which had undergone hyaline and calcareous

degeneration; and that the spindle was called to the normal production of brain sand. The possibility of a blood vessel origin was also pointed out. The paper was discussed by Drs. Griewe, Bettmann, Heldingsfeld, Whitacre, Allen and Muhlberg.

Dr. Muhlberg then read a paper on spinal respiration. When the cord is severed from the bulb by a transverse section opposite the first cervical vertebra, respiratory movements of the diaphragm cease. That this is not due to a shock or inhibition of the phrenic nuclei was demonstrated by W. T. Porter, who, experimenting on rabbits, showed that when a hemisection in the above locality is made and thereby the half of the diaphragm on the homogenous side stopped, the movements can again be started on the hemisectioned side by dividing the opposite phrenic nerve. This is due to a crossing of the impulse from the opposite side, as it descends from the respiratory centre. The crossing probably occurs in the dendritic processes of the phrenic nuclei. The object of the present research was to ascertain whether the crossing occurred through the direct pyramidal tracts, i. e., through the anterior columns of the cord. Rabbits were used in the experiment. The method adopted was identical with Dr. Porter's with the exception that, besides the hemisection, the anterior column on the opposite side was divided. In every case, the results were the same as in Porter's experiment, namely, the diaphragm on the hemisectioned side resumed its respiratory movements on cutting the opposite phrenic, showing that the crossing took place from the lateral columns. When the entire cord with the exception of the anterior columns was divided, the result was the same as total section, the diaphragm did not again contract even after prolonged artificial respiration. The latter experiment proves that no respiratory impulses descend the anterior columns.

Painful Exostosis of the Internal Table of Occipital Bone.

—L. Galliard reported an interesting case diagnosed cerebellar tumor, but shown at autopsy to have been an exostosis of the inner plate of the occipital bone in the right cerebellar fossa. (*Bulletins et Mémoires de la Société Médicale des Hôpitaux de Paris*, July 4, 1901, No. 23). This exostosis was situated at the point where the patient's intense neuralgia occurred. The patient was a rachitic woman of 36. Besides the neuralgia, which was paroxysmal in character, she had vertigo, vomiting, and outspoken phthisis. Galliard asks what should have been the treatment of this case. For trephining would probably have failed to discover the exostosis. [M. O.]

Genital Pain, a Gynecological Study.—The female genitalia are so richly innervated that pain is easily felt. The nerves come from the hypogastric and lumbo-aortic plexuses. Pain of genital origin is both physical and moral. It often happens that a woman with a grave genital lesion will complain of but slight pain, while one with little wrong will have many severe pains. This is due somewhat to the reflexes being weakened when the lesion is severe. Dr. L. Leon Archambault discusses this subject in *L'Indépendance Médicale*, (June 5, 1901, No. 23). He says that the pain is spontaneous, or provoked, by examination, etc. It may be continued, or intermittent, and may change its position. Pain is more frequent in affections of the adnexa than in those of the uterus; it is most intense in acute disease; both physical and moral pain co-exist; finally the pain described is generally inversely proportional to the pain existing. [M. O.]

Siberian Butter.—Siberia has long been sending butter to England, but the opening of the Trans-siberian Railway has made it a far more formidable competitor than it formerly was. Last year the imports of Siberian butter were valued at £1,400,000, and this year it is estimated that they will reach the value of £2,500,000. The supply of butter which Siberia can furnish is said to be practically unlimited, and it is possible that the opening up of Siberia may affect the dairy industry of these countries as disastrously as the opening up of America affected the wheat-growing industry. It is also expected that Siberia will shortly flood the English market with poultry, game and meat.—*London News*.

PENETRATING WOUNDS OF THE HEART WITH
SUTURING OF THE WOUNDS.—REPORT OF A
CASE.*

By H. L. NIETERT, M. D.,

of St. Louis.

Superintendent and Surgeon in charge, St. Louis City
Hospital.

Wounds of the heart, penetrating into one of the cavities where hemorrhage was checked by suturing, are extremely rare. They are rare by reason of the fact that patients usually bleed to death before surgical aid can be rendered, and also because of the hesitancy on the part of the surgeon in deciding upon the operation, this class of wounds being looked upon as almost universally fatal. From the best information obtainable there are twenty-two of such cases on record. The history and descriptions in some instances, however, are so incomplete that it is a question whether all belong to this class of cases.

In reviewing these reports it is noticed that the suturing is usually performed several hours after the injury, showing that there must have been present some condition which retarded the flow of blood sufficiently to allow time for the surgeon to act. It is this condition, to my mind, that makes these wounds most interesting and not so much surgical skill required in suturing them.

The case which came under my observation, and a report of which follows, entered the hospital at 6.00 P. M. on April 20, 1901, with a history of having been stabbed two hours prior to admission. The patient was a young man, 22 years of age, well developed and weighing about 180 pounds. He was in an unconscious condition and all information had to be obtained from an officer who accompanied him. According to the officer's statement, patient, during an altercation with another man, had been stabbed in the chest with a knife. It was also learned that after the injury patient ran a distance of 100 feet, when he fell exhausted and unconscious. After the infliction of the wound and up to the time of admission, friends of the patient made repeated attempts at reviving him and falling in this had him forwarded to the hospital.

General inspection showed the skin and lips very pale, breathing shallow but regular, and patient lying quietly and senseless on the operating table. A knife wound was noticed $\frac{3}{4}$ in. in length and situated at a point corresponding to the fifth intercostal space on the right border of the sternum. Wound was filled with small clots of blood and the bleeding from it amounted to about as much as one would expect from a small superficial skin wound and did not impress one as being connected in any way with the heart.

The physical examination, however, revealed the true nature and depth of the wound and that an internal hemorrhage was taking place. The pulse was imperceptible. No apex beat could be found. Examination of the femoral arteries elicited a slight pulsation of those vessels. A feeble pulsation could also be detected in the carotids.

Percussion showed an area of heart dulness bounded on the right by the right border of the sternum, above the third rib and on the left by the nipple. The increased area of dulness indicated, to my mind, that a hemorrhage was taking place into the pericardial sac. The question arose whether the right pleural cavity had been opened, and if so how much bleeding was taking place into that cavity.

Percussion over the right chest, however, outlined the lung in its normal area.

Auscultation showed a muffled sound over the heart area and the heart beat barely audible. The sounds made the impression that the heart was farther from the ear than normal. The contractions at this time were irregular and numbered about 120 per minute. Careful auscultation did not make it possible to hear any splashing or whizzing sound, indicating again that there was no air present and therefore no connection with the pleural cavity or lung. No abnormal signs were audible over any portion of the lungs.

An immediate operation was decided upon and after the usual preparations a semi-circular incision was made in the skin over the sternum with the base of the flap toward the left side. The cut was made through the stab wound and laid bare the bony wall to the extent of about 3 in. in diameter. The patient being unconscious, no anesthetic was necessary. On raising the flap it was found that the knife had penetrated between the fifth and sixth ribs immediately to the right edge of the sternum. It was decided to follow the recommendation of E. Giardano in his surgery (*La Chirurgie del Pericardio e del Cuore*) where he advises, first, to follow canal of wound to pericardium and heart rather than make an osteoplastic flap, as it might be sufficient to stop hemorrhage through a small opening in this way. The cartilages of the fifth and sixth ribs on the right side were severed near the sternum, then by means of the rongeur a sufficient portion of the sternum was removed to bring the cut in pericardium plainly into view. A cut $\frac{3}{4}$ in. in length was found in pericardium from which very little blood flowed, as a large clot was lying immediately behind, preventing the escape of any liquid blood. With the finger introduced into the pericardium, I could feel the cut in the heart. In order to be able to approach this wound, it was thought necessary to enlarge the opening in the sternum, which was done so that it measured 2 in. in diameter, the pleura being left intact. The edges of the cut in the pericardium were then seized with forceps and the wound enlarged, making it 2 in. in length. That a high pressure existed in the pericardium was shown by the fact that the blood spurted from the cut, carrying with it large coagula. The heart, which had hitherto acted feebly, was now becoming more forcible and began to press the blood clots forward.

It was noticed that the thickest layer of coagulated blood was found against the posterior surface of the heart and was removed partly by means of the finger hooked around the heart and partly by a stream of physiological salt solution poured into the sac. After removal of all the clots the heart beat was 100 per minute, regular and forcible.

The hemorrhage from the heart during all this time was controlled by pressing the tip of the finger into the cut. Before suturing the edges of the wound, the bleeding from the wound was carefully observed and it was noticed that it occurred mostly during diastole and almost ceased during systole. The wound in the heart measured $\frac{1}{2}$ in. in length, the line of the cut running parallel to the longest diameter of the heart and was situated in the center of the wall of the right ventricle. The blade seemed to have penetrated it obliquely.

In order to facilitate the suturing of the heart, the edges of the cut were seized by two narrow Kocher forceps and the organ drawn forward into the opening in the sternum and held there until the first suture could be introduced, after which forceps were removed and the heart was held by the suture. Three interrupted silk sutures were required to stop the bleeding, care being taken on introducing the needle not to include the endocardium. The knots were drawn together and tied during diastole. The patient was then heavily stimulated by injections of whiskey, strychnine and physiological salt solution.

While suturing the heart, patient became conscious and conversed in a perfectly rational manner, he discussed the injury and, on inquiry, stated that he felt no pain, nor was any perceptible shock noticed while the heart was being manipulated.

The pericardium was partly closed and a small drain of plain gauze introduced. The flap of skin was

* Published synchronously with the *Interstate Medical Journal*.

stitched back with the exception of a small opening for drain

POST OPERATIVE COURSE.

Immediately after the operation patient's temperature was 98°, pulse 110, respiration 30.

At 6.00 o'clock the next morning patient had a temperature of 98°, pulse 120, respiration 30 and was resting fairly well, was most comfortable with chest elevated to almost sitting posture.

During the entire course of treatment patient was regularly stimulated with whiskey and strychnine. Hypodermic injections of physiological salt solution were administered every three hours.

Patient had a complete suppression of urine, as repeated catheterization of bladder did not furnish enough to enable us to make a urinalysis. In order to favor the action of the kidneys, hot applications were made to the body and enteroclyses of hot water were given every three hours, but without any results. About 32 hours after the operation the patient's condition gradually grew worse. Temperature rose to 104°, pulse became very rapid. Patient died 33 hours after operation, having remained conscious up to the last moment.

POST-MORTEM EXAMINATION.

This was made under the direction of Dr. Funkhauser, the Coroner of St. Louis, and showed all the organs, excepting the heart and pericardium, in a normal condition. I am extremely sorry that no report could be obtained as to the condition of the kidneys, as I feel satisfied that abnormalities would have been found in that organ.

The pericardial sac was found to be completely obliterated and a fibrinous exudate covered the entire heart. Removal of the lymph exposed a highly injected pericardium which was very cloudy in appearance. The edges of the wound in the heart were agglutinated and the sutures, three in number, were intact and were covered with a layer of lymph.

The right ventricle was then opened by a V-shaped incision, so that the entire wall was left intact, with wound in the center, as shown in the cut.

FIG. 1.—A Case of Suturing the Heart.

The endocardium was found to be smooth and retained its normal lustre. The heart muscles appeared soft and flabby. The cut in the endocardium was about $\frac{1}{2}$ in. in length, was parallel to and situated between two columnar carneae, which were lying close together in the anterior wall of the ventricle, so that the wound on the inside could not be seen until these masses of flesh were drawn apart. The edges of the wound were noticed to have become agglutinated and showed no inflammatory changes.

The cause of death, from post mortem findings, was given as shock and pericarditis.

The case, although terminating fatally, presented numerous points of interest. In the first place our patient was unconscious, not from shock or loss

of blood, but from the circulatory disturbance, caused by the compression of the heart. The unconsciousness was to the extent that permitted of operation without anesthetic. The moment the pressure was removed, consciousness was restored completely.

It was the first case operated upon in which no injury existed to the pleura, and hence no communication between the pleural cavity and the pericardial sac. In the other 22 cases reported, the pleural cavity had been opened on the left side in 21 cases, on the right side in one case. There was therefore in all those cases a direct flow of blood from the heart, through the opening in the pericardium into the pleural cavity. In the present case the blood being unable to escape, caused a gradual increase of intra-pericardial pressure and a steadily growing weakness of the heart, hence the patient was pulseless and the heart beat barely audible; and yet the pressure was not sufficient to cause a stasis and cyanosis, which so often precedes death in similar wounds. Cohnheim demonstrated in his experiments on animals, that hemorrhage of this kind caused a compression mainly of the auricles and large vessels, damming back the blood and preventing its flow into the ventricle, thus producing a marked cyanosis. This was not visible in our case and was perhaps due to the fact that bleeding took place chiefly during diastole and very little blood flowed directly from the cavity during systole.

Although pressure was increased somewhat, it was not to the extent of complete compression of the auricles. There was an absence of that splashing sound in the region of the heart, which is so frequently described by surgeons in connection with the reports of their cases.

I should like to suggest the following explanation for this striking fact: I have observed and operated upon four cases of penetrating wounds of the pericardium in which there was a bleeding into the pericardial sac. In these four cases there was a communication of the sac with the pleural cavity, and in each instance the splashing sound was audible. I conclude therefore that the absence of the sound is due to an increased intra-pericardial pressure, produced by an accumulation of blood. This accumulation is due to the absence of an avenue of escape, there being no communication with the pleural cavity. Therefore, the splashing sound, audible over the region of the heart in injuries of this kind, seems to be an important sign in connection with the diagnosis, as it determines whether the pericardial sac communicates with the pleural cavity or not.

The whizzing sound described by surgeons in connection with these cases, which indicates the presence of air in the pericardium, was also absent in our case.

The fact that the wound in our case was extra-pleural made it advisable to perform the suturing through the extra-pleural route. In all other cases reported, either the right or left pleura was injured and the operations were performed through the intra-pleural route. The avenue of suturing was therefore different from any heretofore. It was performed through an opening two inches in diameter without any difficulty, the heart being held with

forceps and drawn up to the opening while the first suture was being applied. Not the slightest tearing was produced, nor did any shock follow the application of the instruments.

Another point of interest was the fact that the knife penetrated on the right side of the sternum. With the exception of the case reported by Watten in *Deutsche med. Wochenschrift* (Leipzig), September 5, 1901, all the wounds were found on the left side of the sternum.

The direction and position of the wound in the heart was also an extremely interesting feature in the case and was such as permitted of the least amount of hemorrhage. The knife had penetrated the heart muscle obliquely, the direction being that of the staff, as shown in Fig. 1. Elsberg, in the *Journal of Experimental Medicine*, September, 1899, reports the result of his experiments on animals and showed conclusively that oblique wounds bled far less than perpendicular ones, as in this form the canal of the wound is longer and favors the formation of small clots. "Then, too, in oblique wounds the surfaces are more tightly pressed against each other during the systolic contraction of the part." But this was not the only favorable circumstance in our patient's wound. The main factor and which, in my opinion, prevented our patient from rapidly bleeding to death, was the position of the cut in the endocardium. As stated above, it was about $\frac{1}{2}$ inch in length and situated between and parallel to two columnæ carneæ, and in order to see the wound it was necessary to draw apart the columnæ. It was observed during the operation that only a small hemorrhage took place during systole, which was undoubtedly due to the pressing together of the columnæ, acting as valves to the opening. Since the hemorrhage occurred mainly during diastole, it must necessarily decrease as the pressure in the pericardium increased. In this way the wound was pressed against from both sides and it is likely that this condition served to keep our patient alive for over two hours.

The experiments of N. Napolkaw,⁸ Delorme, Elsberg and others¹ were also borne out in this case in regard to the size and position of the clot of blood in the pericardium, namely that the thickest portion of it was found back of the heart. The front of the heart was covered with a layer not thicker than $\frac{1}{4}$ of an inch, while that lying against the posterior portion of the heart was at least $\frac{3}{4}$ of an inch in thickness.

METHODS OF OPERATION.

Different methods have been devised for suturing the heart, and surgeons have divided them into two classes, one the extra-pleural, in which an osteoplastic flap is made of the sternum; the second the intra-pleural method with osteoplastic flaps, laying back one or more ribs. In the first method the pleura is left intact, while in the second the pleural cavity is always open. The first method has been described and advocated by von Rydygier² and Giordano.³ The method of von Rydygier consists of an osteoplastic flap made as follows:

The first incision made transversely across the sternum on a level with the lower border of the second rib, extends from the right to the left bor-

der. A second cut is made parallel to the first on a level with the fifth rib, the two are united by a third incision, running parallel to the left border of the sternum. The cartilages of the third and fourth ribs on the left side are then divided, as is also the sternum, and the entire flap forcibly pulled toward the right side.

The one by Giordano consists of an osteoplastic flap with a hinge on the left side of the sternum and includes a section of the sternum extending from the attachment of the second rib down to the fourth.

Statistics gathered by Fischer and Loison⁴ have shown that the large majority of wounds of the heart have occurred in the ventricle. I have been able to find only one case, that reported by E. Giordano in 1898, in which the auricle was injured.

With a view to obtaining a flap which would lay bare a large portion of the heart, and especially the ventricles, and thus cover the large majority of cases, I have in some twenty sections on the cadaver, outlined a flap which seems to answer all purposes. It includes that portion of the sternum extending from a point on a level with the lower border of the cartilage of the third ribs down to the articulation of the gladiolus with the ensiform cartilage. An incision is made from the right border of the sternum transversely across on a level with the lower border of the third rib to a point about 1 inch to the left of the sternum. A second cut is made from the right border of the sternum across to a point one inch to the left of the sternum and on a level of the articulation of gladiolus with the ensiform. The left extremities of the two cuts are united by a perpendicular incision. The cartilages of the fourth, fifth and sixth ribs are divided, care being taken to remain close to the cartilages, particularly that of the fourth, as the pleura usually lies closely attached to that rib. It is an easy matter then to loosen with an elevator the tissues from the posterior surface of the sternum as the pericardium is only loosely attached and there is at no time any danger of injuring the pericardium.

With a cartilage saw and the costotome the sternum is readily divided. However, care should always be taken not to allow the instrument to pass beyond the right border of the sternum, as there is great danger of injuring the right pleura, which lies immediately back and comes up to the right border of the sternum. I have found it safest after the sternum had partly been divided, to pass the finger back of sternum and push away the right pleura before dividing the entire sternum. After dividing these bony structures the entire flap is forcibly turned toward the right side and the cartilages on the right side partly broken. As shown in Fig. 11, by this method a good view can be obtained of the heart with the exception of the upper portion of the auricles and the beginning of the great vessels. It exposes the anterior surface fairly well and that is usually all that is desired in the extra-pleural method, since in those cases where the side of the heart is injured the pleura will be found to be penetrated also, in which case the intra-pleural method will be the more advisable operation.

FIG. 2.—A Case of Suturing the Heart.

For the intra-pleural method, the one devised by Rotter,⁵ seems to me to be the best, as it lays bare the greater portion of the heart, is the most rapidly performed with the least amount of hemorrhage. It consists of an incision extending from the left border of the sternum, parallel to the third rib outward about 2 inches. A second incision is made on a level with the sixth rib and extending from the left border of the sternum to a point 2 inches toward the left side. A third incision connects the outer ends of the two incisions. The third, fourth and fifth ribs are then divided in the line of incision, as are also the muscles and pleura. The entire flap is then forcibly turned toward the right side and the cartilages broken near the sternum. In this way the right ventricle and a large portion of the left can be brought clearly into view. The hand can readily be passed into the chest cavity and the heart grasped or pressed forward to facilitate the suturing.

Since out of the 22 cases reported 21 wounds were inflicted on the left side of the sternum, all injuring the pleura, it seems to me to be the operation that would cover the large majority of cases. I had occasion to perform the operation a number of times on the cadaver and recently performed a slight modification of it on a patient whose left ventricle had been penetrated by a knife. In this case the suturing was performed with little difficulty. The operation was performed four weeks ago and as the patient is still under observation and not completely recovered at this writing, the case is not included in this report.

Other operations of the intra-pleural method have been devised by Pamoni and Parozzani,² but differ only slightly from Rotter's operation.

Although it is advisable for the surgeon to be familiar with all the methods in use, it seems to me that a thorough knowledge of the anatomical relation is of the most importance. Thus, Watten, who had to deal with a stab wound on the right side of the sternum in the fourth intercostal space, in which the pleura was injured, made a flap including the third and fourth ribs on right side and turned them outward. He claimed that this opening gave him ample room to suture the wound, which

was located in the right ventricle. It is therefore impossible to lay down any definite rule for exposing of the heart and each operator should be guided by the position and direction of the wound.

I have been able, as mentioned above, to collect from various records, twenty-three cases of penetrating wounds of the heart, where suturing was performed. This number includes my own case. The following are brief reports of the names of the operators, year of operation, position of the wound and result:

No. 1.—Cappellen,⁶ operation performed in 1896, wound located in the fourth intercostal space on left side of the sternum; patient died.

No. 2.—Farina,⁶ operation performed in 1896, wound located in fifth intercostal space, left side of sternum, penetrating left ventricle; patient died.

No. 3.—Rehn,⁶ operation performed in 1897, wound located on left side of sternum in fourth intercostal space, injuring the right ventricle; patient recovered.

No. 4.—Parrozzani,⁶ operation performed in 1897, wound located in seventh intercostal space, left side injuring left ventricle; patient recovered.

No. 5.—Parrozzani,⁶ operation performed in 1897, wound located in third intercostal space, left side, injuring left ventricle; patient died.

No. 6.—Parlaveccchio,⁶ operation performed in 1899, wound located in fifth intercostal space, left side of sternum, injuring left ventricle; patient recovered.

No. 7.—Ninni,⁶ operation performed in 1898, wound located in fifth intercostal space, left side of sternum, injuring the left ventricle; patient died.

No. 8.—Giordano,² operation performed in 1898, wound located in second intercostal space on left side of sternum, injuring left auricle; patient died.

No. 9.—Pagenstecher,² operation performed in 1899, wound located in fourth intercostal space on left side of sternum, injuring the left ventricle; patient recovered.

Cases Nos. 10, 11 and 12, reported by W. Hordynski and W. Maleszewski in *Medycyna*, 1899, and operated upon by Kosniski, are as follows:

No. 10.—Wound located in third intercostal space, left side of sternum, injuring the left ventricle; patient died.

No. 11.—Wound located in third intercostal space on left side, injuring the right ventricle; patient died.

No. 12.—Wound located in fifth intercostal space on left side, injuring left ventricle; patient died.

No. 13.—Nicolai,⁶ operation performed in 1899, wound located in fourth intercostal space on left side of sternum, injuring right ventricle; patient died.

No. 14.—Tuzzi,⁶ wound located in fourth intercostal space on the left side, injuring left ventricle; patient died.

No. 15.—Lango,⁶ wound located in third intercostal space on left side of sternum, injuring left ventricle; patient died.

No. 16.—Ramoni,⁶ wound located in third intercostal space on left side of sternum, injuring left ventricle; patient recovered.

No. 17.—Rosa,⁶ operation performed in 1899, wound located in fifth intercostal space on left side, injuring left ventricle; patient recovered.

No. 18.—Marion⁷ (*Presse Med.*, 1899, No. 2), wound located in fifth intercostal space on left side, injuring right ventricle; patient died.

No. 19.—Maselli,⁸ operation performed in 1900, wound located in sixth intercostal space on left side, injuring left ventricle; patient died.

No. 20.—Nanu¹⁰ (Bukarest), operation performed in 1900, wound located in third intercostal space, left side, injuring left ventricle; patient died.

No. 21.—Watten,² reported in *Deutsche med. Wochenschrift* (Leipzig), September 5, 1901, stab wound of right ventricle, penetrating fourth intercostal space on right side, which he sutured on March 25, 1900; patient recovered.

No. 22.—Case reported above, operated upon April 20, 1901, wound located in fifth intercostal space on right side, injuring the right ventricle; patient died.

No. 23.—Dr. George Tully Vaughn, operation performed October 12, 1901, wound located on left side in fifth intercostal space, injuring left ventricle; patient died. (A report of this case was read before the Virginia State Medical Society, November 5, 1901.)

From the above report it is seen that out of 23 cases, 16 died and 7 recovered. Wound was located on right side of sternum in 2 cases, on the left side in 21 cases. Pleura was injured in 22 cases and uninjured in 1 case. Left auricle was penetrated in 1 case, right ventricle in 6 cases, left ventricle in 15 cases; in one case the report does not state what part of the heart was injured.

It is my firm belief that, in the future, operations on the heart, for penetrating wounds, will be more frequently performed. The idea that the surgeon is powerless when it comes to treating wounds of that organ, must necessarily lose ground in view of the good results obtained in some of the cases operated upon.

Statistics show that more than 90 per cent. of all heart wounds not operated upon prove fatal. The mortality in the above reported cases, although they must be classed among the most serious of heart wounds, is only 70 per cent.

Many years ago Billroth is reported to have said that no surgeon should attempt to suture the heart if he wished to retain the respect of his fellow-physicians. Surgery of the heart has advanced far since the time that remark was made. It is beyond doubt that the same authority would consider operative interference advisable in a great number of cases were he still with us. I believe the surgeon is justified in attempting to stop a dangerous hemorrhage from the heart by suturing the wound, just as he would stop a hemorrhage from a vessel by ligation. All wounds of the chest where life is endangered from internal hemorrhage should be explored to the bottom if, in the judgment of the surgeon, the parts are accessible. That the greater portion of the heart is accessible has been clearly demonstrated.

JOURNAL DES SCIENCES MEDICALES DE LILLE.

September 14, 1901. (No. 37.)

1. The Employment of Suprarenal Extract in Ophthalmology. L. THILLIEZ.

1.—Thilliez who has used suprarenal extract in the treatment of diseases of the eyes reports excellent results. He states the procedure is not absolutely new as Dor, in 1895, and Bates, in 1896, showed the vasoconstrictive action of the aqueous extract of the drug. He describes the material as being of a brownish color, which can be preserved indefinitely as long as the bottle is kept closed; but it alters rapidly when exposed. By means of a single instillation a conjunctiva which previously had been remarkably injected immediately becomes the seat of a local anemia. The duration of this transformation varies from a quarter of an hour to two hours. This vasoconstrictive action of the suprarenal extract is not only confined to the conjunctival vessels, but also extends to the subconjunctival and episcleral vessels and even a little upon the deeper vessels. The drug has the advantage of rendering more prominent for purposes of examination and treatment granulations and follicles. Several interesting cases are appended. The author claims that there is a decided advantage to be derived by employing the suprarenal extracts in operations such as removal of chalazions, and in operating for strabismus; the author has twice excised lachrymal glands with a marked diminution of hemorrhage, something which he considers worth estimating in such difficult dissections. He quotes Darrier, who employed the drug in a case of glaucoma where the vision continued to decrease in spite of a performed iridectomy, and reports a rapid diminution in tension and an improvement in the visual acuity. While iridectomy will always remain the operation of choice in glaucoma, the "antiglaucomatous" action of this drug should not be ignored.

Double Perinephritic Abscess.—Edgar Hirtz reports a unique case of double perinephritic abscess. (*Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, June 27, 1901. No. 22.) A woman of 42, after an angina which lasted two weeks, had chills and fever. There was tenderness over the right renal region with some swelling on palpation. Five days later tenderness was noted over the left renal region. A diagnosis of perinephritic abscess was made and operation decided upon. On the left side over a liter of pus was evacuated. Two weeks later, the same operation was performed on the right side, when even more pus was evacuated. Both abscesses had formed about the same time, and both healed after about two months' drainage. Hirtz considers the angina to have been due to the same streptococcus which was found in the pus from the perinephritic abscesses. Dupré suggested that there might have been in this woman one horse-shoe kidney, so that one abscess really had been opened upon both sides. [M. O.]

THE DIVISION OF THE SENSORY ROOT OF THE TRIGEMINUS FOR THE RELIEF OF TIC DOULOUREUX; AN EXPERIMENTAL, PATHOLOGICAL AND CLINICAL STUDY, WITH A PRELIMINARY REPORT OF ONE SURGICALLY SUCCESSFUL CASE.*

By WILLIAM G. SPILLER, M. D.,
of Philadelphia.

Assistant Clinical Professor of Nervous Diseases, University of Pennsylvania,

and CHARLES H. FRAZIER, M. D.,
of Philadelphia.

Professor of Clinical Surgery, University of Pennsylvania.

PART I.

By WILLIAM G. SPILLER, M. D.,

From the William Pepper Laboratory of Clinical Medicine
(Phoebe A. Hearst Foundation.)

In a paper published in the November, 1898, number of the *American Journal of the Medical Sciences*, p. 532, I made use of these words: "If it could be shown that the sensory root of the Gasserian ganglion does not unite after its fibres are divided, we should have a fact of great importance. Division of this root would probably be a less serious operation than the removal of the entire ganglion, and might have the same effect in the relief of pain,

*Published synchronously with the University of Pennsylvania Medical Bulletin.

but the surgical difficulties might be insurmountable. Experiments on animals to determine whether or not the sensory root of the Gasserian ganglion unites after section of its fibres might result in a lessening of the great mortality now existing in operations on the ganglion." Dr. C. H. Frazier has shown that the division of the sensory root may be performed in man, and probably with less danger than the removal of the Gasserian ganglion, as hemorrhage is not so likely to be severe. I should like to lay particular emphasis on the fact that in proposing this operation I did so with much caution. I believe that Horsley is the only one who before Dr. Frazier has divided the roots of the trigeminal nerve without removing the ganglion. Horsley avulsed them at their attachment to the pons, and his patient died seven hours after the operation.¹

Frazier has cut the sensory root of the trigeminal nerve in a large number of dogs. Seven of these lived sufficiently long for a study of the nervous system by the method of Marchi. The results of my microscopical examination of the nervous systems from these seven dogs are as follows:

Dog No. 4.—Distinct degeneration by the Marchi method is found in the sensory root at its entrance

1. Horsley: British Medical Journal, 1891, Vol. II, p. 1249.

FIGURE 1.—Section of the medulla oblongata from dog 4, showing the descending spinal root. The dorsal portion of this root (D) is much more degenerated than the ventral portion (V), because only the lateral portion of the sensory root was completely divided between the pons and the Gasserian ganglion, as shown in Figure 2. The black dots represent the degenerated fibres.

into the pons, and this degeneration is much more intense in the external portion of the root than in the medial portion, although distinct degeneration is detected also in the latter. The motor root in its intracerebral portion shows slight degeneration. A few black dots are present in the mesencephalic root of the trigeminal nerve. In sections from the medulla oblongata the degeneration is especially intense in the dorsal portion of the spinal root, while comparatively few black masses are found in the ventral portion (see Fig. 1). The Gasserian ganglion and the nerve fibres at each end of this ganglion seem to be normal.

are much degenerated, while those at the peripheral end are not degenerated. This degeneration at the central end is probably the result of purulent meningitis.

Dog No. 11.—The degeneration of the sensory root of the trigeminal nerve in this case is present, but unimportant.

Dog No. 12.—The degeneration of the sensory root of the trigeminal nerve in this case is slight. Slight degeneration is detected in some of the fibres at one end of the Gasserian ganglion.

Dog No. 13.—Degeneration of the sensory root of the trigeminal nerve in this case is not distinct.

FIGURE 2. The sensory root at its entrance into the pons, from dog 5. The lateral portion (P) is intensely degenerated, while the medial portion (G) is only slightly degenerated. The degenerated portion indicates the extent of the division of the sensory root. By comparing Figures 4 and 5 it will be seen that the fibres of the lateral portion of the sensory root at its entrance into the pons, in their further course occupy the dorsal part of the descending spinal root.

Dog No. 5.—The degeneration of the trigeminal nerve is similar to that in dog 4, only it is more intense in dog 5 (see Fig. 2). Both anterior pyramids show slight degeneration. Much degeneration is found in some of the fibres at one end of the Gasserian ganglion, while those at the other end of the ganglion are normal.

Dog No. 6.—The degeneration of the sensory root of the trigeminal nerve in this case is distinct, but is not very intense.

Dog No. 10.—The degeneration of the intracerebral portion of the sensory root of the trigeminal nerve in this case is very indistinct. The nerve fibres at the central end of the Gasserian ganglion

Two of these cases, dogs four and five, were especially satisfactory for microscopical study, while the others presented too little degeneration to permit valuable conclusions to be drawn. In dogs four and five it is evident that the lateral portion of the extracerebral sensory root of the trigeminal nerve was cut, while the median portion was only partially injured. In these cases the dorsal portion of the spinal root of the trigeminal nerve also was more degenerated than the ventral. I have not been able in these two cases to detect any attempt at regeneration of the sensory root of the trigeminal nerve, but these cases do not disprove the possibility of such a regeneration. The difficulties of tech-

nique in determining by microscopical examination a regeneration of the cut sensory root of the trigeminal nerve are considerable. In removing the brains in dogs four and five the slight connection by means of the motor root between the Gasserian ganglion and the pons was destroyed.

It is important to determine whether regeneration of the central nervous system is possible, and with this object in view an examination of the literature is desirable.

Baer, Dawson and Marshall² state that, on the clinical side, so far as they were able to ascertain, no satisfactory cases are reported for man of regeneration and return of function after lesions causing the destruction of any part of the central nervous system. These authors do not discuss the histological evidence of regeneration. They conclude from a few experiments cited from the literature that in the lower vertebrates a certain amount of return of function seems to follow a lesion in the central nervous system, while it is not yet decided certainly whether any such return is possible among higher animals. They experimented on dogs by ligation of the roots of the second cervical nerve between the spinal ganglion and the cord, and from physiological results they conclude that after severance of the fibres of the dorsal roots of the spinal nerves between the ganglion and the cord, regeneration of the fibres into the cord will take place under proper conditions, so that normal reflexes through the respiratory, cardiac and vasomotor centres may be obtained. They do not venture to express a positive opinion as to the completeness of the regeneration and the average time necessary for the restoration of function, but their seven experiments showed that great individual differences existed in the rapidity of regeneration. In some cases the return of functional activity in the dorsal root fibres seemed to be nearly complete at the end of ninety days, while in one case the return was far from complete after an interval of 151 days. They conclude that if the posterior root fibres can thus be regenerated in the posterior columns of the cord, there seems reason to hope that the fibres in other tracts may possess the same property, and that therefore it is not impossible that with the proper technique a severed spinal cord might be made to regenerate its broken tracts, both the ascending and the descending. It is much to be regretted that the histological evidence of regeneration of the central nervous system obtained by these investigations of Baer, Dawson and Marshall has not been published.

I hesitate to criticise these carefully performed experiments, but it should be remembered that they do not afford satisfactory evidence that restoration of function after destruction of a part of the central nervous system in man will be complete.

It is presumable that if such restoration occurs in the dog it occurs also in man under similar conditions, but it is only presumable. In these experiments posterior roots were ligated; it would have been better if they had been resected. The divided ends would then have retracted from one another,

and the bridge of degenerated tissue caused by ligation of the roots would not have existed. It is possible that such a bridge of tissue may guide the young nerve fibres to the spinal cord.

We know that where only a few sensory fibres exist these may be sufficient to convey impulses coming from the periphery of the body to the central nervous system. Fickler³ states that in a case of his own, sensation was at one period fully lost but returned after a time to such a degree that almost all qualities became normal, only that warmth and cold sensations were somewhat impaired, and yet very few nerve fibres were found in the posterior and antero-lateral columns of the spinal cord at one level. These few fibres must have been sufficient for the restoration of sensation. The motor tracts of the cord in this case contained more nerve fibres than the sensory tracts, but very little return of motion had occurred. It appears that more normal fibres are requisite for motor function than for sensory.

Fickler also states that Schiefferdecker, Kahler, Stroebe and others have not found any regeneration of nerve fibres worthy of the name after division of the spinal cord in vertebrates. He concludes that the nerve fibres he found within the pia of the spinal cord were regenerated fibres. This conclusion is hardly warranted. Dr. Dercum and I⁴ have shown that such fibres may be present in the spinal pia when there is no reason for believing that they are regenerated fibres, and Bielschowsky⁵ later has demonstrated the same fact. Bielschowsky also makes the statement that experiments have shown that the spinal cord is not capable of regeneration after it has been divided.

Stroebe's⁶ article on regeneration of the spinal cord is especially praiseworthy. After a careful review of the literature on this subject he shows that the opinions of the investigators differ concerning the possibility of regeneration of the cord. Stroebe found from his experiments on rabbits that the nerve fibres of posterior roots that were injured at the level of the lesion in the cord, grow out again from the spinal ganglion toward the spinal cord, and push in a certain distance between the tissue of the scar formation. It was therefore evident that an attempt was made by the posterior roots to penetrate the scar tissue of the cord, but the attempt was not very successful.

The evidence of restoration of the spinal cord being so doubtful, it has seemed to me equally uncertain whether the normal relation of posterior roots to the spinal cord is re-established after these roots have been cut in man. The posterior columns of the spinal cord are largely composed of nerve fibres from the posterior roots, and if these fibres within the cord are not restored after they are divided, it seems probable that the portion outside of the cord, *i. e.*, within the posterior roots, is not

restored after these roots are divided. The chief difference between the structure of the intramedullary and extramedullary portions of these fibres, that I am aware of, is that sheaths of Schwann exist on the latter and not on the former, and yet this may possibly be an important difference.

The recent investigations of Bethe⁷ may cause us to modify greatly our views regarding the regeneration of nerve fibres. Some investigators in the past have held that the nuclei of the sheath of Schwann have an important rôle in regeneration, but most authorities have taught that regeneration occurs by the outgrowth of axones from the old axones of the central stump of the divided nerve. Bethe has resected the sciatic nerve of the dog, and sewed the peripheral stump within the muscle to prevent union of the two ends. The peripheral end of the nerve degenerated below the point of division of the nerve, but later full regeneration of this peripheral portion occurred from the nuclei of the sheaths of Schwann. The nerve terminated at its proximal end blindly. Irritation of the newly formed nerve caused contraction of the muscles supplied by it, and the regenerated nerve differed in no way from a normal one, and yet it was not in continuity with nerve cell-bodies. If this regenerated nerve were cut, its peripheral portion below the line of division degenerated but the more central portion persisted, even though it were not in connection with nerve cell-bodies. These investigations of Bethe may possibly show that the presence of a sheath of Schwann is necessary for regeneration of a nerve fibre, and may compel us to accept the possibility of regeneration of posterior roots which are provided with sheaths of Schwann, and to deny the existence of regeneration of nerve fibres within the cord which have no sheaths of Schwann, even though they may be the continuation of posterior root fibres. These very experiments make it doubtful however whether the posterior roots would be restored beyond the point where the sheath of Schwann ceases, that is, at the entrance of the root into the spinal cord; they may possibly explain why peripheral nerves regenerate so readily while the spinal cord does not.

The nerve fibre of the posterior spinal root has apparently the same structure as the sensory fibre of the peripheral nerve, and yet the reaction of the cell-body in the spinal ganglion is very different according as its central or peripheral process is divided. Investigators (Lugaro, Mering, Fleming, van Gehuchten, Cassirer) have shown that division of the peripheral process of a spinal ganglion cell-body causes very distinct degeneration of this cell-body, or even complete destruction of the cell-body, while Lugaro⁸ has demonstrated that the cell-bodies of the spinal ganglia belonging to the sciatic nerve undergo no distinct change when the posterior columns of the cord or the posterior roots belonging to these ganglia are divided. In advanced tabes dorsalis the posterior roots are intensely degenerat-

ed even close up to the spinal ganglia, and yet Schaffer, a very careful investigator, has found the cell-bodies of the spinal ganglia normal in tabes by the Nissl method, and I have confirmed his observations. These findings seem to show that the peripheral process of the cell-body of the spinal ganglion has a different importance from that of the central process, and that although a peripheral nerve may be restored after it has been divided, it does not necessarily follow that the nerve fibres of the posterior root will also be restored after they have been divided. What is true of the spinal ganglion cell-body and its processes is probably true of the Gasserian ganglion cell-body and its processes.

We must, therefore, conclude that further study is necessary before we can be convinced that regeneration of sensory nerve roots in man occurs, and that full restoration of function is possible after division of sensory nerve roots. Even if a partial regeneration of these roots were possible, it does not follow that pain would return after division of the sensory root of the trigeminal nerve. There might be a partial return of sensation without pain. We must acknowledge that some evidence of partial return of function in injured posterior roots in animals exists, but no evidence of return of function in the trigeminus after the division of its sensory root is to be found in literature. It is a question whether the fibres of this root could penetrate through the thick bands of the middle cerebellar peduncle and pyramidal tract to the sensory terminal nucleus of the nerve within the pons.

In view of the uncertainty of regeneration of the sensory root of the trigeminal nerve, and of the great mortality in removal of the Gasserian ganglion, the division of the sensory root for the relief of tic douloureux is a justifiable procedure, and I trust we may be able to keep under observation for at least two or three years the patient on whom Dr. Frazier has performed this operation. We are not urging that division of the sensory root should at once replace removal of the Gasserian ganglion, and distinctly recognize that the former operation is on trial.

Frazier has shown by experimentation that the motor root of the trigeminus in the dog may be spared. The possibility of saving this root was present in my mind when I urged that this operation should be tried. The motor root has never been left intact when the Gasserian ganglion has been entirely removed, and it probably never can be. It seems to me a fortunate occurrence that in this first successful operation on the sensory root of the trigeminus Frazier divided the motor root as well as the sensory. All communication between the Gasserian ganglion and the pons was in this way fully destroyed and the best possible conditions were obtained for testing the possibility of regeneration of the sensory root. If this case should be as successful clinically⁹ as it has been surgically we may be able hereafter to relieve the pain of tic douloureux without paralyzing the muscles of mastication, for Dr. Frazier's operation seems to indicate

7. Bethe: Abstract in *Centralblatt fuer Nervenheilkunde und Psychiatrie*, July, 1901, p. 449.

8. Lugaro, cited by Flatau: *Fortschritte der Medizin*, 1897 No. 15.

9. Sufficient time to determine this has not yet elapsed; so far the case has been very successful clinically.

that he is able to save the motor root; and we may also be able to lessen the danger of loss of vision, inasmuch as by division of the sensory root the nerve cell-bodies of the Gasserian ganglion are left in normal relation with the peripheral distribution of the trigeminus, and changes in the cornea may be less likely to occur. It is not improbable that these cell-bodies exert a trophic influence on the peripheral branches of this nerve. If this operation should be done again, it would be well to resect the sensory and motor roots, instead of merely dividing them. If it should be fully established that the sensory root will not regenerate after it is cut, the motor root should be spared.

There are some other conclusions to be drawn from the microscopical study of the nervous system of the dogs operated on by Frazier.

Bregman¹⁰ has obtained results from experiments on the rabbit very similar to my results obtained from the dog. In his cases, where the descending spinal root of the fifth nerve was fully degenerated, the sensory root at its outward entrance into the pons was also completely degenerated; but where only the ventral portion of the spinal root was degenerated, only the medial portion of the sensory root at its entrance into the pons was degenerated; and where only the dorsal portion of the spinal root was degenerated, only the lateral portion of the sensory root at its entrance into the pons was degenerated. Bregman also found degeneration in the intracerebral portion of the motor root of the fifth nerve after this root was divided, and this was an ascending degeneration in motor fibres. He found also the mesencephalic root of the fifth nerve degenerated.

From the results obtained by Bregman and from mine, we may conclude that the nerve fibres of the sensory root of the fifth nerve, in both its intracerebral and extracerebral portions, maintain the same relative positions throughout the course of this root. This is an important fact, because we may conclude that if the nerve fibres of the sensory root do not mingle freely without regard to order, the nerve fibres of the Gasserian ganglion also probably preserve a definite order of arrangement. The nerve fibres passing distally from the ganglion separate into three distinct divisions at the peripheral end of the ganglion. We can hardly suppose that the nerve fibres within the ganglion are arranged without definite order if in both the sensory root and the peripheral divisions a very definite arrangement exists. Tiffany's suggestion to spare the inner third of the ganglion in order to preserve vision seems, therefore, to have an anatomical basis, although it is not improbable that if this inner third of the ganglion were removed, the relief of pain would not be permanent.

PART II.

By CHARLES H. FRAZIER, M. D.

The surgery of the Gasserian ganglion has received a great impetus during the past few years, largely through the efforts of those who by the most

careful study of the anatomical relationship of the structures in and about the field of operation have been successful in surmounting many of the operative difficulties. All the improvements in technique, for a practical consideration of the subject, may be grouped under two headings: (1) those which render the ganglion easier of approach, and (2) those which suggest means, not of controlling, but of preventing hemorrhage. The pterygoid route of Rose and the temporosphenoidal route of Doyen have practically been abandoned in favor of the temporal route first advocated independently by Hartley and Krause. In order to lessen the risk of injuring the middle meningeal vessel and to facilitate the exposure of the ganglion Cushing suggested a modification of the Hartley-Krause operation, which he has called the infra-arterial route. The base of the flap corresponds to the level of the zygoma and the trephining opening is sufficiently low to escape the sulcus arteriosus in the anterior inferior angle of the parietal bone, which lodges the middle meningeal vessel, and to give the maximum exposure with the minimum of cerebral compression. Sapejko (*Revue de Chirurgie*, September, 1901) goes so far as to recommend the removal of the great wing of the sphenoid up to and including the foramina rotundum and ovale.

No matter what the method of approach, each of these operations has for its object the removal or avulsion of the Gasserian ganglion and the adjacent portions of its first, second and third divisions. I am about to describe an operation for the relief of tic douloureux which depends for its success not upon the removal of all or part of the ganglion, but solely upon the division of its sensory root. This plan of operation, so radically different, was suggested to me by Dr. William G. Spiller almost three years ago. Granting for the time that from the operator's standpoint this measure could claim many points of advantage over those procedures which entail the removal of the ganglion itself, I withheld my endorsement until I was convinced that regeneration of the nerve fibres at the point of division was doubtful, and that in view of this uncertainty, therefore, this operation might be justified. In order to demonstrate experimentally that regeneration would not take place, I conducted, in connection with my colleague, Dr. Spiller, a series of experiments in which the proposed operation was practiced upon dogs. The interpretation of the results of these experiments and their significance from the standpoint of the neuropathologist is carefully considered in Dr. Spiller's contribution in this paper. Suffice it to say here that Dr. Spiller is of the opinion that the burden of evidence is still with those who would prove that regeneration of fibres with restoration of function does follow division of these sensory roots.

Operation.

The following are the steps of the operation:

1. Reflection of a horseshoe-shaped flap of skin and subcutaneous tissue. The flap corresponds in width to the length of the zygoma; its base is on a

10. E. Bregman. Obersteiner's "Arbeiten," vol. 1, 1892, p. 73.

level with the lower border of the zygoma, its convexity reaching a point 6 cm. above.

2. Division of the zygomatic processes of the malar and temporal bones. After reflection of the superficial flap of skin and subcutaneous tissue an incision is made in the periosteum over the middle of the zygoma throughout its length and the periosteum elevated sufficiently to allow of the introduction of the bone-cutting forceps and the division of the zygomatic processes of the malar and temporal bone.

In my operations upon dogs, where the field of operation was so much smaller than that of the human subject, and where the bellies of the temporal and masseter muscles were proportionally so much larger, I found it absolutely necessary to resect the zygoma in order to be able to retract the temporal muscle sufficiently to allow of a proper exposure of the field of operation and I determined to introduce this step into the technique of my next operation upon the human subject. It is better to practise a temporary rather than a permanent resection of the zygoma. At first thought one might think it inadvisable to replace the segment on the grounds that the bone might not become united owing to the difficulty of keeping it at rest. One will realize how unlikely it is that this will occur if one takes into consideration that the most likely cause of displacement, viz., muscular action, is not operative because the muscles attached to the fragment of bone and concerned in the act of mastication will have been deprived of their motor nervous supply, which is derived from the inframaxillary branch of the trigeminus, before the operation has been completed. (This assertion is based upon the assumption that the integrity of the motor root of the ganglion has in but very few instances been preserved.) One or two sutures introduced at either end of the fragment through the periosteum will suffice to insure fixation until union occurs. Necrosis of this fragment has been recorded as a possible unfavorable complication of temporary resection, but this can be avoided if one bears in mind that the bone receives a liberal blood supply through the periosteum and avoids stripping this structure from the bone except at the points where the bone-cutting forceps have to be applied.

3. Reflection of a horseshoe-shaped flap, composed of temporal fascia, muscle, zygoma and pericranium, corresponding in shape to the superficial one but of somewhat smaller dimensions. This flap is reflected sufficiently to expose to view the temporal fossa; during the operation it will be subjected to considerable traumatism consequent to the constant traction and pressure and will be swollen and tender for a short time. Owing to the contractile character of the tissues of which it is composed the flap will shrink at least one-third before the operation is completed, so that some little traction will have to be made in order to approximate the edges upon closure of the wound.

4. Removal with the trephine of a button of bone

at a point corresponding to the middle of area exposed and enlargement of the opening with the rongeur forceps until its diameter measures three to four centimetres. The usual precaution must be taken in trephining here, as in any portion of the calvarium where the bone is of such variable thickness, in order to avoid injuring the dura; and additional precautions are necessary in this region owing to the fact that the middle meningeal artery lies immediately beneath the button of bone to be removed. With the rongeur forceps the trephine opening is enlarged about equally in all directions and should extend downwards to the level of the crista infratemporalis.

5. Separation of the dura and exposure of the ganglion and its sensory root. The adherent dura is separated by blunt dissection (the handle of a scalpel enveloped in a single layer of gauze will meet all indications) inwards and forwards until the foramen ovale or rotundum comes into view, either of which serve as a guide to the site of the ganglion. This is the most tedious stage of the operation and one which taxes the patience of the operator to the utmost. Hemorrhage now constitutes the great bugbear. Protracted and persistent oozing follows the separation of the dura from every point at which it is adherent to the skull; the older the patient the firmer the adhesion and the freer the hemorrhage. Hemostasis can be effected only by pressure and heat; small pledgets of gauze saturated with a hot saline solution are cautiously applied to the bleeding point and allowed to remain for periods of two to five minutes. In my series of operations upon dogs I tested the efficiency of gelatin in 5 per cent. solution as a hemostat in intracranial operations with practically negative results. The solution had no apparent effect. The dura is most adherent to the skull at the margins of the foramina so that the most troublesome bleeding is not experienced until one has arrived almost at the site of the ganglion. Second only to hemorrhage as a troublesome feature of this stage of the operation is the presence of large bony eminences on the floor of the middle fossa. As pointed out by Amyx these eminences are more commonly met with in heads not having a great transverse diameter between the ears, but whose external bony prominences are well marked rather than in those skulls with a large transverse width; these prominences are situated usually external to the foramina ovale and rotundum and, if very large, will have to be chiselled off in order to expose the foramina to view and remove the ganglion. In some cases the ganglion itself lies beneath a bony roof as though it were a continuation of the petrous portion of the temporal bone. While this is an anomaly in men, it is not so in the dog. Almost without exception in the series of dog's skulls which I had an opportunity to examine while carrying on the experimental work, the ganglion was covered by a thin shell of bone which had to be removed in order to bring to view the ganglion and its sensory root.

FIGURE 3.—Illustrating the final step of the operation. The sensory root is picked up on a blunt hook preparatory to its division. (This drawing made directly from a dissection upon the cadaver, shows the reflected dura propria and the relationship of the foramina rotundum, ovale and spinosum and the middle meningeal artery to the Gasserian ganglion and its sensory root).

With hemorrhage well enough under control to enable one to recognize the anatomical landmarks, the operator makes an incision into the dura and dura propria between the foramen ovale and spinosum and with a blunt dissector separates the dural envelope from the upper surface of the ganglion as far back as may be necessary to expose to view

the sensory root. Up to this point the method of procedure has not differed essentially from those operations which have in view the extirpation of the ganglion. From now on the courses diverge; in the one the operator proceeds to liberate and extract the ganglion and its branches, in the other to liberate and divide the sensory root. The divi-

sion of the root is not a difficult performance. When fully exposed it is picked up on a blunt hook which is passed around the nerve from without inwards. The nerve is divided either by making traction with the hook or cutting directly upon the hook with knife or scissors. It would be a better plan, however, and I will carry it out in future cases, after elevation of the nerve upon the hook to grasp it with a pair of forceps, hemostatic or dissecting, and remove a small section with knife or scissors. This slight modification will add nothing to the dangers and little to the difficulties of the operation and will serve a two-fold purpose, on the one hand furnishing a specimen for a pathologic examination, and on the other leaving a defect in the continuity of the nerve which would render regeneration a possibility still more remote.

In connection with this step of the operation, there is one point which will naturally come up for discussion. Can the sensory root be isolated from the motor root so that the integrity of the latter may be preserved? This question may be answered in the affirmative if certain reservations be made. That it is possible upon the living subject to separate the motor from the sensory root was proven by my own case. I had practically concluded the operation and was about to close the wound; in order to assure myself that none of the fibres of the sensory root had been left undivided, I repeated the last step of the operation and in so doing picked up the motor root which up to this time had remained intact, and unintentionally divided it. It is *possible*, therefore, to divide the sensory without the motor root; whether we can attain sufficient dexterity to avoid the accident which happened in my case is a matter to be settled by future repeated observations.

6. Closure of the wound.—The section of zygoma is returned to its normal situation and secured in place by one periosteal suture at either end. While there is no danger of displacement as a result of muscular action, the fragment may be dislodged during the application, or the changing, or the pressure of the dressing and for this reason the introduction of a suture at either end is recommended. A narrow strip of gauze enveloped as it passes by the scalp in a cuff of rubber tissue is introduced for drainage. If the bleeding is free at the conclusion of the operation, it must be controlled by pressure with strips of gauze. The rubber tissue, by preventing the edges of the scalp wound adhering one to the other, will insure perfect drainage. The wound in the temporal muscle and fascia is closed with buried interrupted catgut sutures, and the superficial wound with interrupted silk-worm gut sutures.

A special protective dressing is applied to the eye in order to prevent corneal ulceration.

Remarks.

Whether this operation for the relief of tic douloureux will receive the endorsement of the surgical profession and take the place of the operation now in vogue, will depend altogether upon the acceptance without reservation of the facts embodied in the following two assertions: (1) Regeneration of the sensory root will not take place after its division, and (2) (a) Liberation and division of the

sensory root, obviating many of the operative difficulties associated with the liberation and extraction of the ganglia, is easier of execution; (b) the integrity of the structures of the cavernous sinus is not endangered; (c) the operation should be attended with a lower mortality.

I will not enter into the discussion of the subject of the regeneration of the sensory roots of the cranial ganglion, as this is a problem which should be left to the neuropathologist for solution and in this paper has been very carefully and exhaustively treated by Spiller. It remains for me to substantiate the claims which have been advanced from the surgical aspect.

Every surgeon will frankly admit that hemorrhage is the greatest bugbear in operations upon the Gasserian ganglion and holds it accountable for many failures and many fatal issues. The bleeding that takes place during the operation in this field might be said to be either troublesome or alarming: troublesome when it follows division of the middle meningeal artery, the emissary veins; alarming when due to laceration of the cavernous sinus. Let us consider the various sources of hemorrhage separately. Hemorrhage from the middle meningeal artery, since the adoption of the infra-arterial route, will occur infrequently and when it does, may be controlled by plugging the foramen spinosum with gauze or, as Krause has suggested, with the end of a blunt hook (Krause has had constructed a series of hooks of various sizes which he keeps on hand to meet this emergency). If, in enlarging the opening in the skull, the operator should resect that portion of the skull containing the sulcus arteriosus, he runs the risk in the removal of that segment of bone of wounding the vessel. As it is not necessary, in order to expose the ganglion, to carry the resection so high, injury to the vessel at this stage of the operation should be regarded as a blunder. The vessel will most likely be injured at its other fixed point, namely the foramen spinosum. If too great traction be made upon the vessel at this point in elevating the brain, or if too great force be applied in separating the dura in the neighborhood of the foramina where the attachments are firmest, the vessel is in imminent danger of being lacerated. Experience alone teaches one how much force can be applied to these structures without endangering their integrity. In so far as the middle meningeal artery is concerned, neither of the two operations under discussion can claim an advantage over the other. Hemorrhage will follow the separation of the dura from the various places at which it is attached to the skull: it is very variable in quantity, the degree of hemorrhage seeming to be in proportion to the number and firmness of the dural attachments. From this source bleeding is, to say the least, annoying but can always be controlled by pressure. The nearer one approaches the ganglion, the firmer the adherence of the dura, the correspondingly freer the bleeding. Inasmuch as the ganglion receives its largest blood supply from below, surgeons are advised in performing those operations which are designed to remove the ganglion, to put off the elevation of the ganglion till the latest moment in order, as Cushing says, to postpone what

degree of hemorrhage is unavoidable as long as possible. In this particular, therefore, one can justly claim for the operation, which leaves undisturbed the attachments of the ganglion to its unyielding base, an advantage over one the execution of which invades this source of free and troublesome hemorrhage. The time required to separate the ganglion from its base and the additional time required to control or check the flow of blood before the operation can be proceeded with, must be taken into consideration and given due weight in the estimation of the relative merits of the operation under discussion.

The third source of hemorrhage is the cavernous sinus, and, as has been already said, should any injury happen this sinus bleeding may be so profuse as to give cause for alarm. The sinus is exposed to danger once the operator begins to free the internal aspect of the ganglion, and in this connection Cushing says "that it is well to conduct these manipulations *as near as possible to the sensory root, since that is the safest point*, and one at which there is less likelihood of injuring the cavernous sinus and sixth nerve." Therefore, in limiting our field of operation to the posterior aspect of the ganglion and its sensory root, we confine our manipulations to the point of greatest safety. So much stress would not be laid upon the superiority of one operation which is associated with less bleeding than another, because the amount of blood lost in either is not a menace to life and will not materially affect the ultimate results, but because the control of hemorrhage necessary to the continuance of the operative maneuvers is only effected after repeated application of pressure for various periods of time, which in the aggregate may rightly be considered as a factor unfavorably influencing the results. Patients of advanced years, and most of the sufferers of trifacial neuralgia that come to us for operation have reached that period of life, are not good subjects for prolonged general anesthesia, therefore any measure which will economize time should, other things being equal, carry some weight with it. Thus far I have aimed in drawing a comparison to throw the balance in favor of the operation requiring less time for its completion and attended with less hemorrhage. I now call your attention to the operative difficulties and dangers that are avoided by stopping short of the extraction of the ganglion. It goes without saying that the exposure of the ganglion is less difficult by far than its extraction. The ganglion and its three divisions are so firmly bound down to the base of the skull that the liberation of the structures is the step of the operation which, above all others, tests the skill, dexterity and patience of the operator. For the completion of this step of the operation one begins by exposing the superior surface (to quote Cushing again) "of the stellate structures well back on to the sensory root." Without going a step further, without exciting one whit more hemorrhage, without running any further risk of injuring adjacent structures, we have made all the preparation necessary for division of the sensory root. Thus one operation is practically complete before those difficulties, both serious and troublesome, common to the other operation

have been encountered. Not only then do we obviate certain operative difficulties, but we are able as well to eliminate certain dangers to adjacent structures. In practically every operation in which the ganglion has been removed the motor root has been destroyed, but from what has already been said in discussing the last steps of the operation we not only believe it possible to divide the sensory without the motor root, but were able to demonstrate this on the living subject. Too much importance, it seems, has been attached to the question of the preservation of the motor root, since its division causes only the little annoyance to the patient that follows paralysis of the muscles of mastication on one side. The patient can chew his food only on the unaffected side. However, if it is possible to save the nerve, we are not justified in deliberately sacrificing it, and if the neuralgia involve both the right and left trigemini, what is only an annoyance in a unilateral case becomes in the bilateral a serious complication.

As the motor root, so the sixth nerve is almost always injured during the extraction of the ganglion; its proximity to the ophthalmic division is such that division of one without the other is practically impossible.

Although a positive assertion cannot be made, there are some grounds for believing that trophic disturbances in the cornea, secondary to division of the first root of the ganglion itself, may not follow the division of sensory root because of the probable presence in the ganglion of trophic centres presiding over the peripheral nerve. In the case, which is reported in this paper, there was not a suspicion of a keratitis, although a very simple dressing, consisting of a compress saturated with boracic acid, was applied to the eye, and this for only one week following the operation.

On the assumption that we are recommending an operative procedure which obviates many difficulties and some dangers, which is easier of execution, comparatively speaking, and economical as to time, it is reasonable, at least, to prophesy a greater reduction in the mortality than that which has resulted from the improvements in technique which have within the past two years been suggested.

Conclusions.

As a substitute for all operations which depend for their success upon removal of all or a part of the ganglion, I recommend an operation which depends for its success solely upon the division of the sensory root of the ganglion. Granting it will effect a radical and permanent cure, the advantages of this operation are the following:

1. It should be attended with a lower mortality.
2. It obviates a number of difficulties.
3. Its execution is, comparatively speaking, simple.
4. It is practically complete when the posterior aspect of the ganglion and its sensory root have been exposed; that is, it is practically complete before the difficulties most serious and troublesome common to other operations have been encountered.

5. The integrity of the cavernous sinus is never in danger.

6. The risk of injuring the sixth nerve is avoided. The following is a brief history of the case upon which I performed this operation:

J. L., aged sixty-eight, was referred to my service in the University Hospital by Dr. D. J. McCarthy.

Family History.—Father and mother died from

orbital nerve, beginning at the supraorbital notch and extending up over the forehead as far back as the anterior edge of the parietal bone. These attacks were provoked by exposure to cold, dampness or wind. Four years ago a neurectomy of the supra-orbital nerve was performed, after which he enjoyed a period of relief. Within a year of this operation the pains recurred with their former severity, when

FIGURE 4.—Showing area of anesthesia one week after division of the sensory root of the trigemini.

typhoid fever, one brother and sister living and well, two brothers died from unknown causes. His wife, four sons and one daughter are living. One son and one daughter are subject to attacks of supraorbital neuralgia, one son died from phthisis.

Previous History.—Had the usual diseases of childhood. About ten years ago had an attack of sciatica which lasted for some seven months, but did not confine him to bed.

Social History.—The patient was born in Ireland and came to the United States thirty-four years ago. Has been a hard worker ever since ten years of age. His occupation formerly was that of fireman, at present he is a watchman. Has never used alcohol excessively, occasionally taking a glass of liquor, which he found increased his neuralgic pains. No venereal history.

History of Present Illness.—About five years ago he first began to have sharp shooting pains referred to the course and distribution of the right supra-

the second peripheral operation was performed. The latter afforded him relief for about six months; and since that time a third and fourth operation have been performed. Each succeeding operation seemed to afford him relief for a shorter period of time. The administration of large doses of salicylates had beneficial results for a while.

Condition on Admission.—Examination of the thoracic and abdominal organs negative.

Examination of the Head.—The area of tenderness extends on the right side of the head backward from the supraorbital margin a distance of 13 cm., and from the median line a distance of 8 cm. The area of anesthesia is 2 cm. wide anteriorly and 5 cm. wide posteriorly, and its inner margin is 1.5 cm. to the right of the median line.

Examination of the Eye.—Hypermetropia and astigmatism; no coarse changes.

Urine Analysis.—Clear, amber, acid, light floccu-

lent precipitate, specific gravity 1019, urates and mucus, no albumin or sugar.

October 12, 1901. Operation. Division of sensory root of Gasserian ganglion.

October 17, 1901. Examination of patient under this date reveals complete anesthesia over the area corresponding to the distribution of the trifacial nerve (see Fig. 4).

November 2, 1901. Patient was discharged from the hospital to-day. During the post-operative period nothing occurred worthy of note.

Examination under present date reveals absence of the supraorbital reflex on the affected side. The area of anesthesia extends back from the supra-orbital margin 18.5 cm. and 3.5 cm. to the right of the median line at this level. The zygoma has become firmly united. There are no corneal ulcers of the eye of the affected side.

THE OPERATIVE TREATMENT OF INTERCOSTAL NEURALGIA OCCURRING IN THE DEFORMITIES OF THE CHEST FOLLOWING POTT'S DISEASE AND SCOLIOSIS.

By CHARLES F. PAINTER, M. D.,
of Boston, Mass.

In a considerable number of cases of bad thoracic deformity, the result of Pott's disease or scoliosis, one not infrequently meets with cases where pain is a conspicuous feature, referred commonly to the lower ribs on one side, or to the costo-vertebral articulation or its immediate neighborhood. On examination, one frequently can demonstrate the overlapping of the lower ribs by the iliac crests in such a way that the soft parts are pressed between these bones. In other cases it can be shown that the ribs are crowded together, causing the intercostal nerves to be similarly compressed. A further confirmation of the pressure theory is found in the fact that a supine position relieves the pain almost at once, and even in the erect position, if the extension of the trunk can be accomplished, either temporarily or permanently, cessation of the pain is secured.

That, anatomically, conditions of this sort exist in the case of bad scoliotics and healed Pott's disease can be very readily demonstrated by the X-Ray. Reference to Redards' recent X-ray atlas will show several cases of both diseases in which the ribs are in contact or actually overlapping.

(Photographs made from these plates would not reproduce well and are therefore not shown in this article.) Three photographs are shown of most severe grades of deformity, because they represent fairly well the type in which these neuralgic symptoms occur.

In the Pott's cases the manner in which the deformity is developed is of course very evident. The destruction of the bodies of several vertebrae allows the ribs to crowd together, and the shortened trunks of these patients are sufficiently familiar. These cases are more likely than the scoliotics to have bilateral symptoms, though even in them this is unusual because of the fact that an absolutely symmetrical destruction of the vertebral bodies by the tuberculous process is not likely to occur; more

destruction takes place on one side than on the other. In the scoliotics the pain is almost always unilateral, because on the convex side of the rotation there is a separation of the ribs, whereas the concave side is the one where compression occurs and where pain is commonly referred. It must be remembered that the X-rays are taken with the patients supine, a position in which it is well known scoliotics are taller than when standing and that therefore the conditions are not at their worst. Indeed, clinically that is the position when such cases have no pain because the ribs then are the widest separated.

The problem which one has to face in these cases is a purely mechanical one, and sometimes can be wholly met by mechanical means; by the use of a swathe or a brace. Many times, however, more radical procedures are necessary, and under these circumstances excision of a rib is usually effective in bringing about a permanent cure. There is no account of operative interference in these cases which I have been able to find in the literature covered by the Index Medicus. So far as I know, the operation was first done by Dr. J. E. Goldthwait in 95, and the following reported cases were operated at the Carney orthopedic clinic upon patients who were not relieved by the less radical procedures.

The technique is simply that of an excision of the rib and the point of election at which to operate is not chosen with a view of finding the particular nerve which is pressed upon, but to remove sufficient bone to give the other ribs more room. It may be of course that one of the ribs is chosen which is causing the pressure upon the intercostal.

The following cases are reported:

CASE 1.—Boy, 20 years of age. Pott's disease since he was an infant; a bad deformity, as shown in photograph. Complained of a great deal of pain in region of lower left ribs. Ribs were closely crowded together and the lower ones covered by the iliac crest; when lying

FIGURE 1.

* Read by title before the American Orthopedic Association, in June, 1901.

down free from pain. In January, 1900, Dr. J. S. Stone, to whom I am indebted for this case, excised the tenth left rib through the incision shown in the photograph. Relief from pain on the left side was immediate. Later, symptoms developed on the other side in a similar situation, but have now (August, 1901) let up, probably due to a tuberculous process in the right hip which has developed of late.

CASE II.—In 1895 a woman came to the clinic, aged 25, a bad thoracic deformity from Pott's; pain referred to the lower right ribs. A light swathe was tried for a time, but no effect, and later still a back brace, also to no purpose. The pain was wholly relieved by recumbency. Dr. Goldthwait removed about $4\frac{1}{2}$ inches of the tenth rib on the right in January, 1896. This gave entire and permanent relief to the pain and she was enabled to resume her work, which she had been obliged to give up on account of the pain. She was last heard from in 1899.

CASE III.—Male, 50 years, laborer for the street cleaning department. When 28 years of age, sustained a fracture and dislocation of the left shoulder. As a result of this he has never been able to raise the left arm but a few

FIGURE II.

degrees from his side. For the past 20 years he has used the heavy broom used by crossing sweepers, and has gradually developed a right dorsal rotary curve of the spine. For 2 years before coming to the clinic in 1898 he had been able to work only very short hours because of pain in the left lower ribs. This was partially relieved by a tight plaster swathe applied as in fractured ribs, but yet he was unable to do his work as crossing sweeper. In December, 1900, four inches of the eleventh rib on the left was excised, with very considerable relief of pain, so that he has been at work since, but there is still some soreness in that same region. He was a much older patient than the others, and had some osteo-arthritis changes going on which doubtless complicated matters.

CASE 4.—N. H. Female, 23. Had Pott's disease at 6 years of age, which left her a very much shortened trunk, due to a knuckle in the back, involving 5 or 6 of the mid-dorsal vertebrae. This caused her no trouble until 2 years ago, when she began to have pains referred to the lower ribs on both sides, especially the left, where the ribs were pressed down inside the iliac crests. Pain entirely relieved by recumbency and not affected by tight swathes. The discomfort was severe enough to keep her from doing her work as a mill operative. In November, 1900, the left 10th rib was excised back to the angle. This gave immediate relief, but since then she has had so much

pain on the right side that she has had to resort to the use of a swathe, which partially relieves that side.

CASE 5.—M. K. Male, 25. As an infant had Pott's and hip disease, leaving him with an ankylosed right hip in position of right angled flexion and a very marked knuckle in the spine, as shown in the photograph (fig. 3); the ribs are very much compressed and crowded down inside the iliac crests. A subtrochanteric osteotomy was done in 1898

FIGURE III.

upon the hip. In the early part of 1900 he began to complain of a great deal of pain in the left back, beginning at the spine below the scapula, protruding around to the front. A brace, with heavy pad, giving compression over the painful ribs, served for a while to give some relief, but it was not possible to work all the time. After a few months trial the left eleventh rib was excised with immediate and permanent relief. Has had no trouble since.

CASE 6.—C. D. Male, 21. This patient is one of the most extreme grades of scoliosis that I have ever seen. The deformity was noticed first when he was 13 years old and steadily increased in spite of braces, jackets, exercises and 3 months in bed. When lying in bed he was nearly three inches taller than when standing. During the past year and a half he has complained of considerable pain when standing or sitting, referred to the mid-thoracic region on both sides. This is relieved by recumbency. His general condition has rather contraindicated operation and a swathe tightly applied has kept him fairly comfortable.

Case 7.—M. D. Female 23. This young woman had Pott's disease 12 years ago. The process was a rapidly destructive one and the knuckle, composed of 3 or 4 dorsal vertebrae, is quite sharp. Four years ago she first began to complain of pain referred to the right lower ribs. A back brace which tended to hyperextend the trunk with a leather swathe attachment gave her entire relief for 3 years. The pain returned coincident with the wearing out of the brace, and has again been relieved by putting the brace into condition again.

This case, as the others, was perfectly comfortable while she remained recumbent.

CASE 8.—E. G. Female. This patient had a very sim-

ilar condition to case 4 of this series, viz.: a right-angled flexion of the left hip from hip disease, and an extreme deformity from Pott's in the dorsal region. She complained a great deal of pain in the lower thoracic region on both sides, especially the left. $3\frac{1}{2}$ inches of the 10th rib was excised with marked relief of symptoms in the left side. A light canvas swathe reinforced with whale bone has partially relieved the right side.

These cases represent only the most striking ones of this condition coming to the clinic in the last six years. There have been several others with similar symptoms, but relief has been secured by the less radical procedures.

SPLANCHNOPTOSIS.

Factors: A. Relaxed Abdominal Walls (including Pelvic and thoracic diaphragm);

B. With Consequent Distalward Moving of Viscera;

C. Gastro-Duodenal Dilatation, (with report of two operations for its relief and a rubber air pad as a supporter).

By BYRON ROBINSON, B. S., M. D.,
of Chicago.

(Continued from page 999.)

Horizontal Position.

A dominant factor in splanchnoptosis is venous congestion during erect attitude, hence the patient should assume especially the horizontal position. When a patient with established splanchnoptosis assumes the erect attitude, the viscera in general pass distalward, the veins immediately enlarge, the abdominal wall is put on a stretch, and it projects or bulges over the symphysis pubis sufficient to hide the genitals from view. The patient in the erect attitude assumes a position of lordosis as in advanced pregnancy, in order to secure a compensatory weight balance.

In the horizontal position the patient with splanchnoptosis should lie on the side and not on the back. All patients with established splanchnoptosis suffer from gastro-duodenal dilatation, due to pressure on the superior mesenteric artery, vein and nerve on the transverse segment of the duodenum. I experimented with dead subjects who had been afflicted with splanchnoptosis, and when such subjects were placed on the back, the viscera, especially the enteronic loops, passed distinctly more and more into the lesser pelvis, dragging and tugging on the superior mesentery artery, vein and nerve, which compressed more and more the transverse segment of the duodenum. When the subject of splanchnoptosis lies on the back, the enteronic loops glide into the lesser pelvis, which makes the superior mesenteric artery, vein and nerve approach closer and closer to the vertebral column and thus lessen the superior mesenteric vertebral angle.

I have personally observed splanchnoptosis and gastro-duodenal dilatation progress until the stomach filled the abdomen like an ovarian cyst. The more acute the superior mesenterico-vertebral angle, the more the transverse duodenal segment is compressed. If the subject lies on the side, the (superior) mesenterico vertebral angle is made larger, releasing the transverse duodenum from compression. Pregnancy increases the (superior) mesenterico vertebral angle, forcing proximalward

the enteronic loops and thus releasing the transverse duodenum from pressure. A great benefit in the wearing of an abdominal binder is to increase the (superior) mesenterico-vertebral angle, releasing the duodenum from compression and preventing further gastro-duodenal dilatation. Lying on the abdominal surface of the body, with a pillow under the thorax, the symphysis pubis would have the ideal position to make the largest (superior) mesenterico-vertebral angle (as it exists in quadrupeds). Hence the splanchnoptotic should lie in the horizontal lateral position as much as is convenient to increase the (superior) mesenterico-vertebral angle, to avoid venous congestion and to prevent the viscera from passing distalward, producing stenosis and kinking of the lumen of the vessels, ducts and viscera. Lying on the back, or standing, increases the compression of the duodenum by the mesenteric vessels and nerve.

FIG. 17 represents the uretero-venous triangles drawn from a female about 50 years of age. Left uretero-venous triangle a, apex; b, base (renal veins); c, ovarian vein; d, ureter. Right uretero-venous triangle. a, apex; d, ureter; c and d, ovarian vein and vena cava; b, base (renal vein); a, points also to the uretero-venous crossing and besides it points to the proximal ureteral spindle. 2 points to the pelvic segment of the ureter coursing through its veins, and also it is the distal ureteral spindle. The uretero-venous triangles are always more or less distorted in splanchnoptosis.

The Cold Douche.

The cold douche is of limited value even when applied with the physician's direction. It can be applied to the abdomen in the vagina or rectum.

Resection of Segments of Abdominal Wall.

In 1885, Prof. Schröder, of Berlin, employed this method while I was a pupil of his department, and he distinctly concluded it was unsatisfactory, and sufficiently a failure to justify its abandonment. He proved that the abdominal wall again stretched.

The Union of the Two Recti Abdominales in a Single Sheath.

My attention was first called to the subject of lax abdominal walls by Prof. Karl Schröder, whose pupil I was for a year. In that year (1884-1885) Prof. Schröder, the greatest gynecologic teacher of his age, was at his zenith of fame, and his clinic was vast. In fact, he tapped the whole of Europe for his material. He discussed in his clear style the misfortune of lax abdominal walls, and he resected the large oval segments of the abdominal wall lying between the diastatic recti abdominales. He then united the sheaths of the recti in the median line. But Prof. Schröder said then to his pupils that he was not fully satisfied it was the best surgery that he knew at that time. Later German surgeons improved on Schröder's ideas by splitting the sheath of the recti and enclosing both the recti abdominales in one sheath by uniting the recti sheaths anterior and posterior to the recti muscles.

In 1895, Dr. Orville W. MacKellar and I operated on a woman pregnant four or five months, where the diastasis of the recti abdominales was very marked, and the uterus, on coughing or extra-intra-abdominal pressure, would project between the recti abdominales. We united the split sheaths of the recti anterior and posterior, enclosing the two musculi recti abdominales in one sheath. Dr. MacKellar reports to me at present that his patient is perfectly well, and the operation was a success. Dr. MacKellar was at the delivery and the recti sheaths remained perfectly intact. For the post-operative hernia, for years past at the Mary Thompson Hospital, I have split the recti and enclosed them in a single sheath. Every one with sufficient experience knows that the post-operative hernia of any considerable size, in women over 40, is in every case accompanied by splanchnoptosis. Dr. MacKellar and I have records to show that 6 years after enclosing of the two recti abdominales in a single sheath, for splanchnoptosis, the operation is a success. The mesenteries are not to suspend the viscera, but to act as a neuro-vascular visceral pedicle, and to prevent the entanglement with other viscera. It is the abdominal wall that holds the viscera in position.

Besides, I showed in 420 detailed records of personal autopsic abdominal inspection, that in 96 per cent. of the subjects the enteron has a mesenteron sufficiently long to herniate through the inguinal, femoral or umbilical rings. Hence the mesenteries must be looked upon as neuro-vascular visceral pedicles, and not as suspensory organs, while the abdominal walls are the great supporters and retainers of the viscera. And as every anatomist knows, the recti abdominales are among the chief regulators or governors of visceral poise, at least

FIG. 18.—Front view of gastro-duodenal dilatation from compression of the transverse segment of the duodenum by the superior mesenteric vein, artery and nerve. 1, 2 and 3, colored portion showing dilatation of stomach and duodenum; 4, stomach; 5, superior mesenteric artery, vein and nerve bound in a strong bundle and compressing the duodenum against the vertebral column; 6, jejunum (note how its natural size is retained, while on the opposite side the duodenum is dilated). 7, Enteronic loops in the pelvis dragging under and more on the structure compressing the duodenum.

they retain the viscera in their first delicate normal balance.

In uniting the two recti abdominales into a single sheath the operation may be performed without entering the peritoneal cavity. I think this operation has a large field of usefulness, for it can be performed without entering the peritoneal cavity and after any laparotomy.

For Gastro-Duodenal Dilatation—Gastro-Enterostomy.

In all cases of advanced splanchnoptosis gastro-duodenal dilatation exists, due to compression of the transverse duodenal segment by the superior mesenteric artery, vein and nerve. I have carefully tested this matter in abdominal autopsies for nine years.

Gastro-jejunostomy.—This I consider one of the best surgical methods to overcome extreme gastro-duodenal dilatation. I proved in gastro-jejunostomy in dogs, ten years ago, that it will enable the stomach to contract, because the food does not tarry in the stomach, but passes immediately into jejunum and ileum, the business portion of the tractus intestinalis. Any segment of the

tractus intestinalis containing no contents, or over which no food travels, will remain contracted.

Any one can prove this by excluding a segment of the bowel from fecal circulation; it soon contracts and remains in that condition. In 1894, Dr. Lucy Waite and I made an abdominal autopsy on a man aged about seventy years, in which the stomach rested on the pelvic floor, presenting enormous gastro-duodenal dilatation. But the duodenum transversum practically remained in its original location and relation.

This illustrates that, since the duodenum cannot pass distalward with other viscera, on account of its attachments, that it can be relieved only by turning the fecal current over another route. Gastro-enterostomy has, in the operation for relief of gastro-duodenal, a much wider and more useful range than for malignancy or stricture of the pylorus.

My first case of gastro-enterostomy for gastro-duodenal dilatation in 1894 was performed on a patient of Dr. C. Henry of Fostoria, Ohio. This patient vomited for nearly two years. At the operation the stomach and duodenum were found enormously dilated due to compression of the transverse segment of the duodenum by the superior mesenteric artery, vein and nerve. The stomach occupied

the pelvis. I performed gastro-enterostomy with my segmented rubber plates. In 1901, seven years subsequent to the gastro-enterostomy, Dr. Henry informs me that she is perfectly well.

A Resume of Splanchnoptosis.

In splanchnoptosis, in general, canalization is compromised, nerve periphery traumatized, motion, secretion, respiration, visceral function, circulation and muscular contraction are disordered—ending in malnutrition and neurosis.

1. There are three conditions to consider in splanchnoptosis, viz.: (a) relaxed abdominal walls, thoracic and pelvic diaphragms; (b) splanchnoptosis, and (c) gastro-duodenal dilatation. The disease is remarkably common especially in females.

2. The general effect of splanchnoptosis is compromising of circulation (blood and lymph) and respiration, traumatizing nerve periphery, impairing elastic and muscular tone of the abdominal walls and deranging secretions and muscular co-ordinations. Its results are malassimilation and neurosis.

3. Splanchnoptosis stenoses or kinks the lumen of ducts, vessels and viscera.

4. Splanchnoptosis is dislocation of the abdominal viscera. A viscus is dislocated when it is fixed permanently out of its place. More adults have dislocated viscera (from local peritoneal adhesions) than normal ones.

5. Splanchnoptosis appears to be to a large extent of congenital predisposition, as its subjects are generally feeble, slender, atonic, highly neurotic, ill nourished, deficient in vital force with weak physiologic functions and anatomic structures, with apparently a hard struggle to battle for life and against its forces. It seems sufficiently difficult for the splanchnoptotic merely to live—without attempting to work or reproduce children. They are consequently physically and mentally weak.

6. The symptoms of the splanchnoptotic are complex and numerous. Each cause in splanchnoptosis produces a vicious circle of pathologic effects—on the viscera, circulation, respiration, nervous system and nourishment. Splanchnoptosis is often mistaken and wrongly diagnosed as neurasthenia, nervous exhaustion, hysteria, spinal anemia, menopause, etc., nervous dyspepsia and neurosis.

7. The large and complex groups of symptoms produced by splanchnoptosis must be considered independent of inflammatory processes.

8. Large numbers of so-called dyspeptics are splanchnoptotics.

9. Stellar's costal stigma of floating tenth rib I have not studied sufficiently to make a report.

10. The splanchnoptotic appears neurotic, slender, and delicate, poorly nourished, pale, non-energetic, tired, and as a sad, helpless picture. Splanchnoptotics form a distinct class, with peculiar characteristics like the class of tubercular subjects to which they are related.

11. Splanchnoptosis is a general disease of all the abdominal viscera; the tractus intestinalis, urinaris and genitalis are equally affected, but from anatomic mechanism the tractus intestinalis suffers

FIG. 19 illustrates nephroptosis dextra. 1, the nephroptotic kidney; 2, the elongated right renal artery; 3, the curled and dislocated ureter. The left kidney and ureter is represented as normal. A and B represents the apex of the uretero-venous triangles. The right one is distorted from right nephroptosis. Right nephroptosis is due, in man, to the erect attitude. In dogs and pigs the right kidney lies proximal to the left. The erect attitude reverses these anatomic data because the anchorage of the right kidney, the right renal artery, is longer than the left

FIG. 20 (author) is a cut to illustrate the position of the duodenum and the superior mesenteric artery, vein and nerve. 1, the superior mesenteric vein; 2, superior mesenteric artery, the nerve not represented in the cut; 3, distal end of duodenum; 4 and 5, stomach; 6, hepatic artery; 7, splenic artery; 8, gastric artery, the hepatic and gastric arteries making what I shall term the gastro-hepatic circle; 9, the esophagus; 10, the gall-bladder; 11, the pylorus; 12, the duodenum; 13 and 16, gastro-epiploea sinistra et dextra; 17, spleen; 15, part of liver. This cut shows that the duodenum in the acute mesenterico-aortic angle is the acute mesenterico-vertebral—however, the real angle of strangulation.

the most. All splanchnoptotics have genital ptosis and nephroptosis.

12. In diagnosis it is well to palpate every abdominal viscus, first in the horizontal position and second in the erect position. The liver, spleen and kidney may appear dislocated only when standing erect. Frequently the muscoli recti abdominales are so diastatic that one can palpate every abdominal viscus through the fascia of the linea alba, thinned by the elongation and separation of its fascial fibres.

14. Since my clinic and private practice has consisted of 90 per cent. of women, I cannot estimate the percentage of splanchnoptosis as regards sex.

15. Gestation plays an influential role in increasing splanchnoptosis, as when the fascial and muscular fibre of some abdominal walls are once well elongated and separated they do not return to normal.

16. The 2d, 3d, 4th and 5th decades of life are the chief ages of suffering in splanchnoptosis.

17. The symptoms which predominate in splanchnoptosis are from the side of the nervous system, as depression, melancholy, excitability, irritability and the stigmata of hysteria. The patients complain much of disturbed circulation causing cardiac palpitation and vigorous aortic pulsation or rhythm. It is a beating tumor and some physicians mistake it for aortic aneurysm, because the aorta is so much uncovered by viscera and only covered by the abdominal wall.

18. Two characteristic groups of symptoms of the splanchnoptotic exist, viz.: On the one side neurasthenia and sick headache, and on the other indigestion, poor appetite and constipation.

19. I cannot agree with Meinert in attempting to establish an etiologic relation between chlorosis and splanchnoptosis. I found no such relation in my series of observation.

20. The large number of women who had not

borne children, who have not laced tight, had no wasting disease, but having splanchnoptosis, indicates a congenital predisposing factor.

21. In splanchnoptosis there are two factors to study, viz.: (a) congenital and predisposition, (b) exciting cause. The secondary or exciting causes are, any forces which tend to weaken the abdominal walls, as rapid child bearing, abdominal tumors, ascites, septic diseases, constipation, and wasting diseases, such as the disappearance of fat in the abdominal wall and adjacent to the viscera.

Splanchnoptosis may exist without any known symptoms to the patient or to the physician, but the rule is that this may be accompanied by almost all kinds of gastro-intestinal disturbances. The chief symptoms of nephroptosis are (a) palpitation, (b) gastric disturbances, and (c) constipation. Though tight lacing and bands are accused of producing splanchnoptosis, they are only a factor, as a predisposition in a weak abdominal wall no doubt must exist.

FIG. 21 (author) shows the relation of the duodenum transversum, pancreas, celiac axis, superior mesenteric artery, vein and nerve with the stomach drawn proximally. 1 and 2, superior mesenteric artery and vein; 3, aorta; 4 and 5, transverse segment of duodenum passing posterior to vessels; 6 and 7, pancreas; 8, spleen; 9, splenic artery; 10, hepatic, and 11, gastric arteries forming the gastro-hepatic circle; 13, portal vein; 14, duodenum; 15 and 16, stomach; 17 and 18, epiploic arteries. This cut shows how natural the vessels could compromise the distalward-moving fecal current in the duodenum. The fixation of the transverse segment of the duodenum by the musculus suspensorius and the fibrous band from the left crus of the diaphragm is not drawn in the cut.

Gastro-enteroptosis and nephroptosis almost always exist together. Nearly all splanchnoptotics are easily fatigued and show a neurotic existence. In women I observed that splanchnoptosis is commonly accompanied with backache, constipation, flatulence, varied local pains—all of which yield stubbornly to treatment.

Splanchnoptotics manifest vast disturbances in the circulatory system, as (a) palpitation, (b) vigorous beating in the abdominal aorta from partial uncovering of the viscera and thinning of the abdominal wall, also ganglionic irritation, (c) compromising of vascular lumen, (d) headaches from

irregular cerebral circulation, and (c) extensive abdominal venous stasis.

In splanchnoptosis the individual abdominal organs may be distinctly palpated either through the thin linea alba, between the diastatic recti muscles, or through the thin flaccid abdominal walls.

A good test of relaxed abdominal wall is to stand behind the patient and encircle the distal abdomen with the two hands and force the abdomen proximalward, when it will give relief by its support. Also a partial test is to elevate the abdomen and suddenly let it drop, when the degree of fall indicates the degree of relaxation.

The gynecologist must analyze with care the differential diagnosis between reflexes from nephroptosis and reflexes from genital disease.

Nephroptosis frequently produces identical symptoms with those arising from genital disease. One of the tests to differentiate between the two organs will be the application of a well-fitting abdominal supporter to replace and retain the mobile kidney. The sympathetic nervous system holds an intimately and finely poised relation among the three systems of the abdominal viscera, viz.: tractus genitalis, tractus urinarius, and tractus intestinalis. Disturbance of one system unbalances the others through reflexes.

Observe how nephroptosis from trauma of the plexus renalis produces reflex symptoms on the proximal end of the tractus intestinalis, ending in nausea, pain, malassimilation, constipation, and neurosis. Renal calculus induces vomiting, and sooner or later nephroptosis and gastric disease co-exist. Genital disease gives rise to more gastric disturbances than the reverse, because the gastric secretions are deranged more easily than those of the genitals. Trauma or infection of the nerve periphery of any abdominal system of viscera soon deranges the motion and secretion of the other two abdominal systems. The connection between diseases of the uterus (genitals) and gastric (digestive tract) is profound and intimate. Disease of the uterus and stomach frequently coexist. A differential diagnosis between the symptoms arising from nephroptosis, from the genitals or stomach, is often difficult, as symptoms may be referable to any one of the viscera. This may be due, first, to the nerve tract, whose centre is not in the brain or the spinal cord but in the sympathetic nervous system. From reflex action symptoms arise which relate to kidney or genitals. The reflex tracts being anastomosis ovarica, anastomosis pudendohemorroidalis, anastomosis genitogastrica, anastomosis cutaneo-cavernosa, collateralis and the nervi splanchnici. Also the anastomosis uterocoeleica and anastomosis utero-cerebro spinalis, also anastomosis reno-coeleica. The immediate roads of the reflex are direct connections of the vagus (excluding the ganglion-abdominale) with the sympathetic nervous system. The second manner in which mistakes may occur are due to dislocation of the respective organs. The circulation only plays a minor role in this connection.

As splanchnoptosis is a general disease, local op-

erations, as nephropexy, uteropexy, will appear of limited value.

The tartaric acid and bicarbonate of soda method is a practical means to demonstrate the gastro-duodenal dilatation. Inflation of the stomach by air is also a good method. The two operations I offer after 5 and 6 years of test are both general and local. The local is gastro-enterostomy, which can be immediately followed by a general operation, i. e., the union of the two recti abdominales in a common sheath.

The non-surgical treatment for splanchnoptosis is through water drainage of the tractus intestinalis, tractus urinarius and tractus perspiratorius, with exercise and massage of the muscles.

Of the abdominal supporters I consider the best an ordinary elastic support, with a rubber air pad which can be placed inside of the binder and distended with air. I have invented such a pad and find it gives excellent results. Glenard, Schwert, Virchow, Stiller, Meinart, Ewald, Landon, Boas and Ameill have written excellently on splanchnoptosis.

The photographs in this article were executed by Dr. William E. Holland, from my wall charts. The other drawings were finished by Mr. Zan. D. Klaffer, from my sketches which were nearly all from autopsies.

Chyliform Pleural Effusion.—In the *Bulletin Medical* (July 10, 1901. No. 54.) F. Barjon and A. Cade report a case of chyliform pleural effusion. While chylous effusions contain chyle, much albumen, and some sugar and result from injury to the thoracic duct, chyliform or chyloid effusions are much rarer, containing no fibrin, little albumin, and no sugar, and are rich in fat, which is found in emulsion. It is as a rule due to fatty degeneration of the cells present. It lasts a long time, but does not greatly affect the general health. They report their case in detail. Inoculation of the fluid into rabbits gave lesions containing true tubercle bacilli. This had long been suspected, but had never been demonstrated. They conclude that chyliform pleural effusion is the result of a chronic inflammation of the pleura, due to tubercular infection. [M. O.]

Pneumothorax with Bronchiectasis in Diabetes Mellitus.—Maurice Letulle reports the case of a man of 52, with diabetes mellitus, who suddenly developed right-sided pneumothorax. The symptoms became so severe that on the sixth day a puncture was made, and liquid and gas evacuated. Death occurred with syncope on the ninth day. The autopsy showed a circumscribed patch of recent tuberculosis adjacent to an ancient bronchiectasis. A caseous patch between the bronchiectatic cavity and the pleural cavity ruptured, and thus the pneumothorax was produced. There were also atrophic cirrhosis of the liver and an enlarged spleen, both pigmented. Letulle explains in detail the mechanism of the occurrence of the pneumothorax. (*Bulletins et Memoires de la Societe Medicale des Hôpitaux de Paris*, June 27, 1901. No. 22.) [M. O.]

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended December 7th, 1901:

VRATCH.

September 15, 1901. (Vol. XXII, No. 37.)

1. A Chronicle of Corporal Punishment in Russia in the Twentieth Century. D. N. ZSHBANOFF.
2. Chronic Suppurative Inflammation of the Middle Ear and Its Treatment. P. P. GELLAT.
3. The Influence of Organic Combinations of Phosphorus (Lecithine) on Assimilation (fixation) of Nitrogen (albuminous substances) in the Human Body.

M. D. ILIN.

- 2.—Gellat points out that diseases of the naso-pharynx,

especially adenoids, form a most important predisposing factor in the causation of acute and chronic catarrhal and suppurative inflammations of the middle ear. It is held by some that adenoids are rare in very young infants. This view the author considers erroneous, as shown by 198 autopsies on infants performed by him. The author made the interesting observation that in Russia (St. Petersburg?) grave forms of otitis media are far less frequent than in Western Europe. Thus, in Strassburg of 77 operations 36 were performed on account of cholesteatoma. Hallé reports 209 cases of otitis media of which 96 were due to cholesteatoma. In Russia, on the other hand, the latter affection is so rare that many ear-specialists never see a case. During a period of 11 years the author has seen only two cases. The cases of otitis media observed by the author run a milder course and are, as a rule, free from serious complications. This he attributes to the climate. The routine treatment of suppurative otitis media by the usual irrigations is severely criticised on the ground that while far from accomplishing the results for which it is intended, it does actual harm by increasing the suppuration. The use of tampons is also condemned. The method advocated has been successfully employed in a large number of cases with very happy results. It consists in thorough cleansing the cavity by means of small, dry-cotton swabs on long thin wooden sticks. As soon as the swab saturated with pus is withdrawn, it is broken off and a fresh one made. In this manner thorough cleansing is accomplished with considerable ease and rapidity. In cases where the pus is stringy and removed with difficulty by the dry method, careful syringing may be resorted to, but even in these cases the irrigation should be followed by the application of dry swabs. Insufflation of dry boracic acid does no harm and may do some good. If the case is protracted beyond 1-1½ months and exuberant granulations, together with pain and headaches occur, further local treatment is inadvisable and surgical intervention is indicated. Stacke's operation, which has been somewhat simplified by the author, is recommended. The operation is described and details of the after-treatment given. 9 illustrative cases are reported. [A. R.]

3.—Danilievski, Kolpaktshi. Umlkoff and Tamasheff have proved experimentally that assimilation and organization of albuminous substances in the animal organism are determined by the organic combinations of phosphorus, especially lecithine. Ilin endeavored to verify the findings of these observers on man by the following experiments. A laboratory servant was placed on a special diet for 14 days divided in 5 periods. During the first period (3 days) an ordinary diet, but deficient in proteids, was given; during the second (2 days), the diet was almost free from proteids and organic phosphorus; during the third (4 days), it was rich in albumin, but poor in phosphorus, especially lecithine; during the fourth (4 days), the amount of albumin was gradually diminished and that of lecithine increased; during the fifth (1 day), the man received an ordinary diet but deficient in proteids. The food was carefully weighed each day, and the various constituents calculated according to a special table. The man was weighed daily, his urine collected, the nitrogen determined by Kjeldal's method and the phosphorus by uranum acetate. The feces were not analyzed, it being assumed that 90% of the eliminated nitrogen is excreted with the urine (Neumeister) and 80% of phosphorus on a mixed and 94% on a meat diet is eliminated through the same channel (Noorden). The following results were obtained: During the first period the man had neither nitrogen nor phosphorus equilibrium. During the second he lost both in N and P. During the third the nitrogen assimilation was increased and phosphorus equilibrium established. During the fourth nitrogen assimilation was increased despite the gradual diminution of the intake with the food, this being due to the increased ingestion of phosphorus. During the fifth, with a diet poor in N, nitrogen assimilation still kept up, owing to the presence of P. It is thus evident that the presence of organic phosphorus in the human body aids in the process of nitrogen assimilation. [A. R.]

A New Operation for Tic Douloureux.—The proof of a surgical operation is in the success of it; and, provided the surgeon attains his wished for result, the theory upon which he has worked becomes in the opinion of many persons a matter of secondary importance. The division of the sensory root of the fifth nerve must *a priori* abolish sensation, and therefore pain; and its simplicity, as compared with avulsion of the whole Gasserian ganglion, commends it both to the surgeon and to the neurologist. The one obstacle that may stand in the way of a perfect success is the possible reunion and regeneration of the sensory root; and this conjures up an old physiological or pathological problem about which surgeons and neurologists have been contending—and even wrangling—for years.

In their valuable and highly interesting paper, published in last week's number of the Journal, Drs. Spiller and Frazier present this subject from both the theoretical and practical standpoint. Dr. Spiller has done well to seek for light in this field by experiments on dogs before advising the operation on man, and he has presented some results of experiments that are of great interest. These results, however, it may be noted, point to the degeneration of the fibers of the sensory root rather than to their regeneration. The experiments do not seem to disprove the possibility of a reunion of the divided root, but merely make such reunion seem highly improbable. This may be due partly to the fact that the experiments are not reported in full detail, and that it is not indicated for how long after the experiments the animals were kept under observation before they were killed. The fact that certain fibers degenerated was, of course, entirely in accord with well known neuropathological laws, and needed no experiment; but the question whether a divided sensory root can or cannot reunite does not seem exactly proved either way. These facts are fully recognized by Dr. Spiller, who presents them with judicial impartiality.

In his review of the literature of this subject Dr. Spiller presents the results of other observers who have studied the regeneration of divided nerves. Perhaps the most interesting of these is the obser-

vation of Bethe, who claims that he observed the regeneration of nerve fibers from the nuclei in the sheath of Schwann in the peripheral portion of the divided sciatic nerve in a dog. This is a recurrence to an old idea, and one which had been regarded as well nigh exploded. It has been claimed of recent years that a divided nerve fiber can only be restored by an outgrowth or budding from the proximal end, or the end which is still in union with the cell body; but Bethe's observation, it is seen, tends to prove that, for the sensory nerve at least, this is erroneous. It is well to recall in this connection, what Van Gehuchten so fully insists upon, that the peripheral prolongation of a sensory neuron is its protoplasmic end and is different from its central or axis-cylinder prolongation. This protoplasmic portion seems to have some special nutritional function of a higher degree of activity than the axis-cylinder or central prolongation. Hence it more readily regenerates.

From the practical or surgical standpoint Dr. Frazier's case has thus far been a brilliant success. It is too soon, of course, to claim that the sensory root in his patient cannot reunite and regenerate, and the further history of the case will be awaited with interest. But if prophecy and *a priori* reasoning are at all justifiable, we think we are safe in predicting that reunion will not occur. When we consider how almost inconceivable it is that the two stumps of the divided root should apply themselves accurately to each other, and that the divided axis-cylinders should then reunite, we feel almost justified in a prediction that the patient will never have a restoration of function and of suffering.

The Quarantine Against Tuberculosis.—Last summer the supervisor of immigration issued an order that immigrants suffering from tuberculosis should be debarred from entering the United States. Since that time there has been an effort made in various lay and medical journals to cast discredit upon the wisdom of this order and to secure its repeal on the part of the United States, with the avowed intention or turning the entire matter over to the local boards, who should have discretionary power to refuse such cases admission to the

United States. The advocates of repeal make the following arguments. That consumption is not a contagious but a communicable disease. It is admitted on all hands that it is a germ disease; that the germs are discharged in great numbers in the sputum of patients suffering from pulmonary tuberculosis, and probably also in the feces and urine, and that they do not lose their virulence when dried in the dust. Under these circumstances tuberculosis must certainly be classed as a highly dangerous disease; not dangerous so much perhaps to the individual coming in direct contact with the victim, as to the community at large, to whom every new case is an added source of danger. Secondly, that it is a chronic disease. This only increases the danger by prolonging the period during which the patient may spread the germs broadcast. Third, that it is easily preventable. This is perhaps true in hospitals and sanatoria, but it is a matter of daily observation among the physicians that the consumptive is by no means so careful as he should be with his sputum, and utterly disregards all other material in which tubercle bacilli may be eliminated. Fourth, that it is often a curable disease. We should say rather that under favorable hygienic conditions and in suitable climates some cases get well. A recovery in one of the large cities of the Atlantic seaboard—and it is to these cities that the immigrant chiefly goes—is of such rarity as to justify its immediate publication. Another group of arguments claims that this measure is inhumane inasmuch as it may separate children from parents, husbands from wives, or dependents from their source of support. Unfortunately there is no method of dealing with a contagious disease that does not involve an element of inhumanity toward the victim, but it is possible that when the ruling is more generally known, even if it is not already the case, families including cases of tuberculosis among their numbers will elect to remain at home. A more reasonable argument perhaps would be that a case might come to this country in search of the favorable climate that exists in many of our western states. It is possible that for them, providing they possess sufficient wealth to enable them to carry out the treatment rationally, relaxation should be permitted. Finally, the fear is expressed that other countries will retaliate and prevent our citizens suffering from tuberculosis from seeking the beneficial climate of Algiers or the Riviera. We fear that this is only too likely to occur, and that it will not be a matter of retaliation, but rather of protection on the part of the foreign governments. This subject must be regarded from a purely rational stand-

point. We must not be sentimental in treating with tuberculosis, for it is unquestionably the most serious malady that confronts us at present. Before we agitate any measure likely to cause the repeal of this order we should carefully consider whether in our efforts to be humane to a few we are not cruel to a multitude.

Tetanus in Camden.—It seems desirable that a rational view should be taken in regard to the deaths from tetanus supposed to be conveyed during vaccination in the city of Camden, New Jersey. The Board of Health took energetic measures to discover the cause of these deaths, and incidentally the best method of preventing their occurrence in the future. An official report has been distributed generally to the medical profession in Philadelphia, and we presume throughout the country. The conclusions stated prove that in no case can the tetanus be supposed to have been introduced by the vaccine virus. In one case the patient had not been vaccinated, and in all the others the disease developed so late that it is reasonable to assume that the tetanus bacilli were introduced by scratching or contamination after the removal of the scab. They explain that the dry weather and high wind had probably caused a very wide dissemination of the tetanus germs.

Upon two points the report may be criticized: Exactly the same climatic conditions existed in Philadelphia and yet cases of tetanus did not occur. The nature of the experiments made with the vaccine virus upon white rabbits in order to prove that it did not contain tetanus bacilli, are given so briefly that they are of imperfect value to enable an impartial reader to arrive at a conclusion. But the clinical histories of the cases seem to prove satisfactorily that their conclusions regarding the time of infection are unassailable, and excepting these the cases fail utterly as material to support the dangerous contentions of the anti-vaccinationists.

The results in Porto Rico where the mortality has been reduced from over 600 to less than 2 per year since the universal vaccination of the population by the officers of the United States Government, are sufficient proof, if any were needed, that vaccination is, as someone has expressed it: "the greatest boon conferred upon mankind".

The Canary Islands as a Health Resort.—The United States Consul at Teneriffe, has recently communicated to the Secretary of State an interesting report on the Canary Islands as a resort for tuberculous cases. The resort is situated between 27° 4' and 29° 3' N. and 13° 3' and 18° 2' W. The Canaries

in consequence of their geographical position form an almost ideal home for those who do not thrive in the trying climatic surroundings of the northern countries. The mean winter temperature of the principal towns in the islands averages about 65°. The islands are easily accessible as they are used by many of the principal lines of steamers as ports of call. Good hotel accommodations are to be found, and an English physician, Dr. Stamford Harris, has chosen Guimar, on the Island of Teneriffe as a site for the construction of a hospital to be devoted to the treatment of tuberculosis. The hospital stands 1200 feet above the level of the sea, and commands a beautiful view of mountains and ocean. The Consul who makes this report, Berlinger, quotes several writers' opinions of the possibilities of the Islands. He warns physicians against sending patients in late stages of tuberculosis to the Islands, as many cases of death have been known to take place with no friends near the sufferer. Those who go to the Islands seeking health, may be encouraged by the fact that numbers of apparently hopeless cases have been completely cured in those patients who have followed absolutely the regimen laid down by the local medical men who have devoted their lives to the study of the climate and its effects. It would appear from reading this report that the Canary Islands are deserving of consideration in the selection of a suitable location in the proper climatic conditions, which will benefit many incipient cases of tuberculosis. But if there is to be an iron-clad international quarantine against tuberculosis, we suppose these islands would be closed to American invalids.

Hepatic Drainage.—In another column Dr. John B. Deaver, in discussing this subject refers generally to the various pathological conditions of the gall-bladder and its ducts which confront the surgeon. The question of early diagnosis and treatment in diseases of the gall-bladder and its ducts is one of the greatest importance not only to the operating surgeon but to the general practitioner. Oftentimes the diagnosis is obscure, the symptoms being in no sense proportionate to the pathological condition present. It has been shown clearly enough, however, that early operative treatment gives a very low mortality, whereas late treatment, instituted after complications such as adhesions, obstruction of the ducts, jaundice, etc., have set up, presents a much higher mortality. Much has been done within recent years, particularly by Mayo Robson, Richardson, Halsted and others, to perfect the technique of gall-bladder surgery, and every general practitioner should be informed of the progress that

has been made in the treatment of these conditions and the great necessity for an early operative interference. In all cases of persistent disordered digestion, particularly when accompanied by dilatation of the stomach, and possibly attacks of so-called "biliousness," the attendant should most carefully examine the gall-bladder region and if he cannot clearly eliminate this organ and its ducts as a causative factor, he should call a surgical consultant. Dr. Deaver shows the great similarity between appendicitis and inflammation of the gall-bladder. None but the experienced knows how much more serious operations upon the gall-bladder become in the presence of jaundice; the mortality from hemorrhage in these cases is extremely high. Dr. Deaver very rightly asserts that "temporizing and Carlsbad" can only be productive of harm in cases in which the gallstones have already developed. As a preventive measure medicines and waters may be of advantage. With one statement which Dr. Deaver makes, namely, that the gall-bladder should be removed when there is any marked change in its wall, many surgeons will hardly be prepared to agree, and yet his argument in favor of the removal of this organ is very plausible.

Pharmacological Experiments.—The subject of pharmacology has been largely turned over to the drug manufacturing firms, and there can be no doubt that in spite of the pure spirit of commercialism that has inspired them, they have contributed considerably to progress in this subject. It is to be regretted however, that the subject of pharmacodynamics inspires relatively little interest on the part of the medical profession. In the olden days studies of the physiological action of drugs occupied no inconsiderable portion of the space devoted to original work in our medical journals, but nowadays an article on this subject is exceedingly rare. It is not necessary for the prosecution of these studies to await the discovery of new drugs. On the contrary, the careful examination of the physiological action of drugs supposedly well known is still a fruitful field for the investigator; this is particularly true of their various chemical derivatives. A recent article upon the effect of some of the salts of morphia, by Barnes (*Archiv für experimentelle Pathologie und Pharmakologie*, Vol. 46) shows how much there is to be studied in connection with this oldest of drugs. He found that cooking an alcoholic solution of potassium morphinate with an equivalent amount of calcium chloracetate produced a new salt, probably morpho-oxylacetate in combination with potassium. The addition of hydrochloric acid liberated the acid from

its potassium base. This acid experimentally tried on frogs and rabbits produced very slight symptoms of diminished brain function. If, however, the methyl and aethyl ester of the salt were employed and administered subcutaneously or by intravenous injection, there were in frogs, first exaggeration of the reflexes, then violent clonic convulsions resembling those produced by picrotoxin, and finally paralysis and death. In rabbits the drug produces violent clonic convulsions, and death may be caused by respiratory cramp, or if artificial respiration is employed, the animals may remain in persistent convulsions for hours. The drug, however, has no effect when administered by the mouth. Various studies convinced Barnes that in frogs the spinal cord was involved in the action of the drug, whereas in rabbits only the mid-brain. It is not very clear just what the therapeutic value of these studies will be, but at least they are a step in the right direction.

Some Medical Solons.—A brilliant scheme for the abolition of drunkenness has been devised by Dr. Archdall Reid, who has just written a book on "Alcoholism." Dr. Reid would punish severely every drunkard who should beget a child. As alcoholism (according to Dr. Reid) is hereditary, it can be eradicated if only the drunkards will stop procreating their kind; but as experience shows that inebriates will not of their own accord stop procreating, the remedy evidently is to compel them to stop. This sovereign remedy could be applied, according to Dr. Reid, by magistrates, "sitting in open or secret session as the accused preferred", who would impose as a penalty, "a month's imprisonment" on every tippler who should dare to beget a child. The plan, as can readily be seen, is simplicity itself. It is not proposed as a joke, but as a measure of law. The book in which it is expounded is actually in print, and for sale.

Our only suggestion is that the penalty is not severe enough. The term of imprisonment is too short, and leaves the offender an early opportunity to repeat the offense. If it were for fifteen or twenty years, there might be some chance of reducing the birth-rate of incipient drunkards. Dr. Reid's suggestion reminds us a little of that equally sapient plan which has been proposed for eradicating venereal diseases in the army. The victim is to be regarded as a criminal and docked of his pay as long as he remains unhealed! We suppose he would be put in the guard-house instead of in the hospital, or even walked around with a placard on his back announcing the diagnosis. The depth of the knowledge of human nature that evolves such schemes is truly beyond fathoming.

Cancer "cures" are rather too numerous to find place in the overcrowded columns of our Journal

—and the newspaper story of another alleged cure slipped into our news columns recently without the critical comment which it needed. We have not the slightest belief in the efficacy of an infusion of violet leaves for cancer, and regard the story as a "fake". It will probably do some harm by arousing temporarily the false hope of cure in some victims of the disease, and therefore we are all the more indisposed to give it countenance.

The Kaiser has assumed many rôles, but he never played a more eccentric part than when he started out to investigate the beer-drinking habits of the German workingman. Reports say that the daily average for each mechanic is about eight pints of beer. In some German factories there are morning and afternoon "beer recesses". Investigation shows that the producing capacity of the workingman is seriously impaired, especially toward the end of the day. The Kaiser's crusade will be watched with interest. If he can control the beer drinkers he is indeed fit to command an army.

Dispassionate critics have always recognized that among the advantages of college athletics is the regard for physical health which they encourage in the student. A course of training for athletic honors is a discipline not only for the body but also for the mind; it promotes bodily vigor at the same time that it inculcates mental and moral control. The risks even from football are not so great as the risks from alcohol and cigarettes. Dr. Seaver, of Yale University, finds in the Freshman class this year an unusual lung capacity, with marked athletic tendencies and a reduced consumption of tobacco. His figures are interesting, his deductions are warranted, and his studies are to be commended.

Current Comment.

A GOOD WORD FOR ATHLETICS.

Dr. Jay W. Seaver, director of the Yale University gymnasium, has furnished the most effective argument against smoking yet given. He finds that the average lung capacity of the members of the Freshman Class is five inches greater than last year's class, and as the number of users of tobacco in the present Freshman Class is 10 per cent. less than in the last class, Dr. Seaver feels authorized in ascribing the average greater lung capacity to the smaller use of tobacco. The fact that the present class has also a larger number of athletes among its members than usual helps to strengthen this theory. If the truth of this statement could be established by a long series of experiments, it would be the most convincing argument that could be brought against the use of tobacco in any form. Many young men who can not be persuaded by moral arguments

would yield to proof that smoking injured their health. The experiments should continue at the Yale gymnasium and the results be made public. — *The Philadelphia Press*.

FEEDING THE NURSE.

Evidently things are getting in bad shape in England, if we are to believe the statement made by a correspondent in a recent number of *The Lancet*. There are rumors that there is a division of the fee among some of the members of the profession here, but this division is between the surgeon or the consultant and the family physician of the patient. On the other side, however, they seem to have gone one better and a division of the fee is made with the nurse. According to the correspondent, certain medical men over there are paying sums from a shilling to half the confinement fee, or more, to the nurses in attendance, who, to use their own words, make their living from "following the doctors." This tipping of the nurses is done with the hope that the recipient of the fee will recommend the doctor to future patients and, in other words, act as his drummer. As *The Lancet* editorially comments, the probability is that things are not quite so bad as this correspondent makes them out to be, even in England, where tipping is such a common every-day and every-where affair.

—*Journal of the American Medical Association*.

IT DEPENDS UPON WHOSE OX IS GORED.

In some cases in which the diagnosis is difficult, or may require considerable time, experiment upon animals aids us greatly, and so is of immense value to man. Thus in supposed anthrax, or wool-sorter's disease, a most dangerous malady, by inoculating a guinea pig with the discharge the diagnosis can be cleared up quickly and proper treatment instituted. If a case suspected to be one of bubonic plague arises, the diagnosis can be established within 24 or 36 hours by a similar injection into a rat or a guinea pig, the apprehensions of a community (to say nothing of the patient and his friends) relieved and the greatest damage to its commerce averted by discovering that it is not the dreaded pestilence, or, if it is the plague, by showing the necessity for most stringent measures of prevention. I do not think any community will or ought to allow sympathy with the unavoidable suffering of a few rats or guinea pigs to weigh in the balance for a moment against the safety of many human lives or the ruin of large business interests.

An amusing instance of how sentiment gives way before affection and facts occurred not long since in England. The brother of the Duke of Newcastle was bitten by a dog supposed to be rabid. The Duke was a Vice President of the Anti-Vivisection Society, but knowing that whether the dog was rabid or not (and, therefore, whether his brother was in danger or not) could only be settled by inoculation experiments upon animals, he took the dog to Mr. Horsley, in London, and had the experiment done.—Dr. W. W. Keen, in *The Philadelphia Record*.

Correspondence.

GONORRHEA COMPLICATED WITH SCIATICA, EPIDIDYMITIS, DOUBLE CONJUNCTIVITIS, AND RHEUMATISM IN GREAT TOE.

By F. ALAN G. MURRAY, M. D., Fligel, P. O., Md.

To the Editor of the *Philadelphia Medical Journal*:

Harry R., aged 20 years, 3 days after intercourse developed a severe gonorrhea. He came to me July 27, 1901, for treatment, 4 days after the disease set up. There was a profuse purulent discharge which showed microscopically many intracellular gonococci, there was also a slight balanitis and conjunctivitis of both eyes. The upper and lower eyelids were swollen and very red and the conjunctivae were red and inflamed and thrown into rugae and had a profuse discharge which showed many intracellular gonococci. Gave him 1% solution sulphate zinc for urethral injection, and 1/2% solution nitrate silver for his eyes with

minute directions as to use of each. I was called to see him the evening of July 28 and found him with a severe pain in the left hip in the course of the great sciatic nerve. The pain was so severe that he could not turn himself in bed or move the leg. Gave him morph. sulph. 1/4 gr. and applied hot applications over course of nerve.

July 29.—Patient had not slept any for pain, gave him 1/4 gr. morph. sulph. hypodermically at point of greatest pain, this relieved him for a time. He had no fever or constitutional disturbance but suffered extreme pain necessitating the free use of morphia for several days. His eyes gradually improved and in two weeks all inflammation had disappeared. The urethral discharge also became much less, and the pain in his hip after several exacerbations gradually subsided. August 14.—Patient was taken with severe pain in right testicle and along course of cord up into the abdomen. Pulse 120, temp. 104°, the epididymis was swollen and very painful, gave him 1/5 grain pilocarpine muriate by the mouth and in a few minutes he had a profuse sweat and his temperature dropped and pain left.

August 15.—Feeling much better, some soreness in testicle on handling. Patient got along all right until August 19, when he had another attack of epididymitis which responded to the same treatment.

At this time he reinfected his right eye and when I saw him two days later he had a severe conjunctivitis with profuse discharge and gonococci present. Gave him 5% protargol solution to use 4 times a day and same care to be exercised as before. The urethral discharge had almost ceased, but I gave him 1/2% protargol as injection. About August 31 he developed a red swollen joint of his right great toe, at that time he had had no urethral discharge for 10 days and his eyes were well, and his sciatica much improved, so that he was able to walk around.

September 9.—Toe still swollen, not very painful. Sciatica improving rapidly. October 13.—Still has twinges of pain in the sciatic nerve occasionally, joint of toe still swollen.

Sciatica is not a very common complication of gonorrhea as the *Twentieth Century Practice of Medicine*, Vol. 1, page 457, is the only one of several books on practice and surgery that mentions its occurrence. In this case the sciatica began on the 5th day of the gonorrhea and continued all through the disease, and the patient still has attacks of pain occasionally at the present time. The pain was so severe that morphia was necessary for some time, and in addition, sodium salicylate, iodide of potash, acetanilid and other drugs were used but without much effect.

The conjunctivitis was treated vigorously by silver nitrate 1/2% solution 3 times a day, and 1/2 hour by washing with hot borax and chlorate of potash solution, and responded kindly.

The epididymitis was rapidly aborted by the pilocarpine muriate on each occasion of its onset and the swelling was reduced by hot poultices.

The rheumatism came on late in the disease, about 10 days after the urethral discharge had ceased. The joint is still, at the present time, somewhat sore and swollen. The treatment was hot applications and tonics.

The case was of remarkably short duration considering all the complications. The urethral discharge lasted only 28 days. The patient was in bed 4 weeks and went to work in 7 weeks.

TUBERCULOSIS: A REPLY TO DR. KNOPF.

By LAWRENCE F. FLICK, M. D., of Philadelphia.

To the Editor of the *Philadelphia Medical Journal*:

Dear Sir:—A letter written by Dr. S. A. Knopf, of New York City, is making the rounds of the newspapers. In this letter Dr. Knopf arraigns Surgeon General Wyman, of the U. S. Marine Hospital Service for declaring pulmonary tuberculosis a "dangerously contagious disease" and di-

recting the superintendent of Immigration to issue an order debarring consumptive immigrants from all American ports. The gist of Dr. Knopf's diatribe is that Surgeon General Wyman, in the action which he has taken, is at variance with scientific medicine, and stands unsupported by the medical profession. It would be an injury to the cause of science to let Dr. Knopf's statements go unchallenged.

Aside from the merits of the question at issue it is a grave mistake for a member of the medical profession to harangue the public against the official acts of the highest representative of the profession in the Government. If such methods are to be countenanced by the profession, can we hope to gain the confidence of the public in scientific medicine? Surgeon General Wyman is an honor to the medical profession. He has done more probably than any other man to win the confidence of law makers in medical science and to pave the way for proper representation of the medical profession at the counsel board of our Chief Magistrate. He of course is not infallible nor impeccable, but if he has made a mistake, the proper place to lecture him is not in the newspapers, but in our medical societies and in medical journals. The lecture, moreover, should be along scientific lines, and not a toot to the galleries.

Now let us examine Dr. Knopf's letter upon a scientific basis and see whether he makes out a case against Surgeon General Wyman. The gravamen of Dr. Knopf's charge lies in the Surgeon General's use of the word contagious. Dr. Knopf claims that "pulmonary tuberculosis is not a contagious, but only a communicable malady" and that "the contact *per se* of a consumptive individual does not transmit the disease." He admits, however, that "ever since the discovery of the tubercle bacillus it has been demonstrated by clinical and bacteriological experiments all over the civilized world that the germ alone is the direct cause of the disease, and without its presence tuberculosis cannot be conveyed" and that "the bacilli are usually contained in the expectoration, more rarely in other secretions, very rarely in the muscular or osseous tissue." Here are two contradictory statements which Dr. Knopf seems to think he reconciles by saying further that "the destruction of tuberculous expectoration and other secretions, also of the tuberculous food substances, suffices to do away with all danger of infection and transmission." Let me ask Dr. Knopf how the one hundred thousand annual new implantations of tuberculosis in the United States or the one million annual new implantations of tuberculosis of the world take place? Is it by keeping away from the people who have consumption or by coming in contact with them? Is the tubercular matter given off by a consumptive a source of danger and the center from which that matter is given off not? We know that the room which a consumptive occupies, the clothing which he wears and the implements and utensils which he handles are capable of conveying the disease to others even after he is dead and gone, and the source of pollution has become extinct, and are we to believe that the source from which this pollution is given off is innocuous during its activity? The more theoretical possibility of its being made harmless means nothing so long as we have ocular demonstration that in one million instances annually it is not made harmless.

When Surgeon General Wyman applied the words dangerously contagious to tuberculosis he no doubt did so advisedly, and science supports him. Except perhaps leprosy there is no disease which so absolutely depends upon contact for implantation as tuberculosis. Not only contact, but intimate prolonged contact. It was by reason of the spread of tuberculosis along the family tree that the disease got its reputation of being hereditary. At least sixty per cent. of all cases of tuberculosis are developed from prolonged intimate family relationship and occupation of houses which have been occupied by consumptives. Probably twenty-five per cent. of the remaining forty per cent. are developed from prolonged intimate contact in occupation and social relationship. Thus we have eighty-five per cent. of all implantations of tuberculosis which

can be demonstrated to be dependent upon prolonged intimate contact with persons who have the disease or with places or things which have been in contact with such persons. That the remaining fifteen per cent are likewise probably due to contact, direct or indirect, would appear from the fact that the number of new implantations in any one year is seldom larger than the number of old cases. Surgeon General Wyman's justification in using the word "dangerously" appended to the word "contagious" is to be found in the number of deaths annually from the disease. Surely a disease of which there are annually upwards of a million new implantations and a million deaths merits the epithet dangerous. Dr. Knopf admits that every new implantation must come from an old case, and whether he calls this communicable or contagious, the danger exists and is the greatest danger which threatens human life. Dr. Knopf also admits that the danger is a preventable one and by admitting this stultifies himself in quibbling over the meaning of words and trying to embarrass the Surgeon General in his praiseworthy efforts to prevent it.

As to the matter of debarring consumptive immigrants from American ports, whatever sentimental reason there may be against such action, the safety of our own people undoubtedly demands such a step. It is true that there are some consumptives who, by reason of their financial ability to take care of themselves and their cleanliness and intelligence, might be admitted without danger to anyone. But what is true in theory is often false in practice. So far as my experience goes, no consumptive is absolutely innocuous to those around him, no difference what his wealth or intelligence, unless he has been scientifically trained to make himself innocuous, and this training is seldom obtained outside of a sanatorium. The Government has no way of determining who would be harmless and who would not be harmless, and so long as it cannot determine this question it is proper that it should exclude all.

In conclusion let me say one word about alarming the public. The public is never alarmed by a knowledge of the truth. It is fancy and doubt which alarm. Tell the public that tuberculosis is a communicable, but not a contagious disease, and they become alarmed because of the doubts and fancies which arise in the mind when trying to reconcile those two statements. The question at once arises, how am I to avoid a disease which is communicable and which millions of people contract, but which is not contagious? There is a mystery about such a disease which is inscrutable. On the other hand, tell the public that tuberculosis is a contagious disease which is implanted by prolonged intimate contact either with the person who has the disease or with something which has been in prolonged intimate contact with such a person and you tell them something which they can understand. They will then know where to look for the danger and it will not be a difficult matter further to make them understand how they can overcome that danger.

Reviews.

Anatomy in its Relation to Art. By George McClellan, M. D., Professor of Anatomy in the Pennsylvania Academy of Fine Arts. W. B. Saunders, Philadelphia and London, Publishers, 1901.

As a rule, when the scientific anatomist condescends to write and to illustrate a text-book for the use of the artist, he appears to deem it necessary to cast his knowledge into such a form as he supposes may best fit the very limited requirements for which it is intended. He handles a very weighty subject very lightly; instead of a solid and thorough treatment of the matter in hand as a scientific problem, he is too apt to give what he supposes to be a disquisition upon the subject from the artist's standpoint. He is apt to expend a great deal of time and care upon a distortion of the facial muscles which he terms "expression,"

or an equal distortion of the muscles of the frame which he calls "action."

These efforts of the scientist to adapt his knowledge to the limited comprehension of the artist appear funny sometimes to him whom the pictures are intended to instruct—the effort does not in the least fulfill the needs of the case. As a rule the scientist does not know nearly so well how to indicate an expression or how to draw an action as does the artist whom he is instructing. What the artist desires is not to have a supposititious statement of his views, but a clear explication of the scientist's own knowledges. That which he seeks when he is studying a book of anatomy is facts from which he may draw his own inferences. He does not desire supposititious results, but something from which he may deduce his own conclusions.

I very well remember of one fledgling artist and his fellow students—it was in the old days when the world was young—unable to find within the lids of the printed book the solid knowledge of which they stood in need—how he and his brethren went down into the dissecting room, donned an apron and entered with all the good will in the world into the not very congenial task of separating a human frame in the endeavor to discover its secrets.

Since then the same artist having, with gray hairs, obtained pupils of his own, has desired many a time some text-book that might supply a quicker and easier method of imparting the required knowledge to those students than the dissecting knife and scissors might afford.

The best source of knowledge, I think, that has yet fallen under his attention is the work, just published, of Dr. George M'Clellan, "Anatomy in its Relation to Art."

That Dr. M'Clellan, who is Professor of Anatomy at the Philadelphia Academy of Fine Arts, is well equipped to deal with his subject in such a way as to supply the artistic desire for information, goes without the saying; that he has dealt with it well, the book (which is monumental) itself attests. It is limited well and closely with in the lines of its subject and is thorough in the field which it is intended to cover. "The object of this book" he premises to the reader, "is to contribute to that knowledge of human anatomy with which artists are chiefly concerned, and it should therefore be understood, as preliminary to so complex a subject, that the deeper structures are here set forth solely for the purpose of explaining their influence upon the surface anatomy."

Accordingly, beginning with the bony framework of the body and with the articulations of the joints, he proceeds to build upon it, layer by layer, first the interior, and then the superficial muscles, until the entire figure is constructed thoroughly and entirely from the anatomist's standpoint.

Only when treating of the facial muscles does he appear to deem it necessary to make that descent to the artistic intelligence already mentioned. It is, perhaps, impossible that he should touch upon that subject without giving his ideas as to how the face appears when the human soul is perturbed by the emotions of fear, rage, surprise, etc. I do not feel that the faces there depicted evoke in my imagination an echo of any such emotions as are labeled upon the more or less distorted visages. But, perhaps, this wandering into other fields than those covered by a purely scientific disquisition upon superficial anatomy may be allowed in view of the traditions that surround the treatment of the matter, and of the very great value of the work where it deals entirely with facts. As for the facts themselves, they are not only extremely well presented, but are equally thoroughly and equally clearly set forth. His analysis of the hand is particularly good, and cannot be too strongly recommended to the attention of those art students who so often fail to devote adequate study to this most important part of the human figure. His study of the foot is equally thorough and complete.

A very useful, as well as very interesting feature of the work, is the comparison by photographs of the human figure to certain famous antique statues; the two being placed side by side in as nearly as possible the same attitudes. The living figure, to be sure, strained into an assumed position, cannot render the play of muscle so wonderfully represented in those great masterpieces of art;

but the comparison, nevertheless, is both interesting and instructive.

Taken all in all, the work is one of the best and the most thorough text-books of artistic anatomy which it has been the writer's fortune to fall upon and, as a text-book, it ought to make its way into the field for which it is intended.

HOWARD PYLE.

Athletics at Princeton.—A History Compiled and Edited by Frank Presbrey, '79, and James Hugh Moffett, '00, with Introduction by Henry van Dyke, '73. Fully illustrated, and published under the Sanction and Supervision of the Graduate Advisory Committee. Frank Presbrey Company, New York City.

This is a volume which every graduate of our eastern colleges may consult with interest and, within certain limits, the older the graduate, the greater will be that interest. To one, who, like the writer, has witnessed the origin of organized athletics at Princeton and assisted therein to the best of his ability—*quarum parva pars fuit*—the interest derived from the perusal of old "scerers" is intense, and yet this interest is not without a tinge of melancholy. There is a celebrated picture in the Louvre by the great painter of the seventeenth century, Nicolas Poussin, which represents four shepherds grouped about a tomb in the foreground of a landscape in Arcadia. The oldest shepherd is tracing with his finger, and evidently explaining to his companions, a half defaced inscription in which, however, the words are still legible: "Et in Arcadia ego"—I, too, was an Arcadian. So may the descendants of one whose name is recorded in this volume discover, with pleasurable surprise, that their ancestor whom, perchance, they may remember as a decrepit valetudinarian, was, in his college days, as eager as themselves in the pursuit of athletic fame, and as successful in acquiring it.

Many questions are suggested by this book; but the most important is whether the pursuit of athletics is detrimental to the student while at college or in after life. The Index of Princeton Representatives, which covers more than thirteen double columned pages, answers this question most emphatically in the negative. In it are found, in great abundance, the names of men who have achieved distinction in every walk of life: in the church, at the Bar and Bench, in science, in finance, and last, and by no means least, in medicine. [F. P. H.]

Diseases of the Stomach and Their Surgical Treatment.

By A. W. Mayo Robson, F. R. C. S. and B. G. A. Moynihan, F. R. C. S. Svo., pp. 308. Wm. Wood & Co. New York, 1901.

Few English surgeons are better known on this side of the Atlantic Ocean than the senior author of this monograph. His work in, and writings on, abdominal conditions have long been conspicuous for painstaking care, good judgment and an abiding faith in the truth of the doctrines of aseptic surgery. His recent visit to this country has served to increase the confidence of the American surgical profession in his scholarly attainments and surgical acumen. Much interest will be felt in this formal statement of the opinions of Mr. Robson and Mr. Moynihan on the surgery of the stomach; but most readers will naturally attribute the weight of authority to the senior author. Both writers are connected with the surgical staff of the General Infirmary at Leeds, and, according to the preface, hold themselves jointly responsible for every statement of the book. They have each carefully revised the manuscript of the whole work. Such collaboration cannot but add to the value of the finished product.

It is also interesting to know that this valuable monograph is a development of Mr. Robson's Hunterian Lectures delivered before the Royal College of Surgeons of England in 1900. It is sometimes said that endowed lectureships in medical science are of little value. This opinion is probably based on the limited audience which the lecturer often

addresses. The real value of the endowment, however, is frequently the stimulus given to the chosen lecturer and the printed monograph, which comes from his study of the subject and from the clinical opportunities brought by the delivery of the lectures. It seems not impossible that this book would never have appeared, if the Hunterian Lectureship had not been established.

The authors insist upon the surgeon going over the whole of the medical evidence before resorting to operation, but show clearly the advantages of surgical treatment of many conditions of the stomach. An impressive statement is that which deprecates the too early resort to operation and suggests that a second or third examination of the patient may clear up the diagnosis, by the discovery of new symptoms or by knowledge of points in the history of the case which were previously not brought out by questioning the patient. The following sentence shows their reason for this opinion: "The surgeon may on the next visit focus his attention on different points or group his data differently, and so perhaps arrive at a truer conclusion." In speaking of exploratory operations, followed by the discovery of a gastric tumor, they caution the surgeon to "know when to stop," which is "a matter of common-sense combined with experience."

Exploratory operation is said to be justifiable whenever cancer of the stomach is suspected, because the smaller the tumor the greater is the hope of radical cure. In gunshot wounds of the stomach in civil practice, exploration is said to be safer than uncertainty. The great prominence given to the discussion of gastric ulcer is an evidence of the attention recently given by physicians and surgeons to the study of this serious lesion. About one-third of the book is devoted to the consideration of this subject. The volume is beautifully illustrated and will be of great value to those engaged in the study of pathological conditions of the abdomen. [J. B. R.]

"First Aid" to the Injured and Sick. An Ambulance Handbook. By F. J. Warwick, B. A., M. B. Cantab., M. R. C. S., L. S. A., and A. C. Tunstall, M. D., F. R. C. S. Ed. Philadelphia and London: W. B. Saunders & Co., 1901.

This little volume contains much valuable information for those who are apt to have the immediate care of the injured. It possesses the advantage over many other books of its kind in that it is supplied with numerous good illustrations. It is a book well adapted for the instruction of nurses and hospital corps orderlies.

The first part of the book is given up to a discussion of practical anatomy and physiology, the second part to bandages, and the latter portion to the immediate treatment of injuries, hemorrhage, etc. It well fills the purpose for which it was written. [J. H. G.]

"The Surgical Treatment of Disfigurements and Deformities of the Face." By John B. Roberts, A. M., M. D., Professor of Surgery in the Philadelphia Polyclinic, Surgeon to the Methodist Hospital. Second edition with a chapter on the Reconstruction of Syphilitic Noses. Illustrated with 62 figures. Philadelphia: The Phila. Medical Publishing Co., 1901.

It is a gratification to find Dr. Roberts' writings upon facial deformities and their treatment in a volume of such convenient size. This little book contains his Mütter Lectures on "The Surgical Treatment of Congenital and Pathological Disfigurements of the Face" delivered at the College of Physicians of Philadelphia, and also a supplementary chapter on "Reconstruction of Syphilitic Noses."

Dr. Roberts' experience in plastic surgery of the face has been very extensive and the book contains a great deal of valuable information and instruction. It is well illustrated and as a book of reference will be found of great use to the general surgeon who only occasionally operates for the conditions here discussed. [J. H. G.]

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA NEWS.

Smallpox in Philadelphia.—During the week ending December 14 125 new cases of smallpox were reported, the greatest number in any one week during the year. There were but 8 deaths. 965 cases have occurred since January 1st, with 127 deaths. 349 cases are now under treatment in the city, and 53 persons recovered last week. Over 11,000 persons have been vaccinated by the city's physicians in a week. For students of the University of Pennsylvania who have not been vaccinated in the past five years, revaccination has been ordered. All public school houses are being disinfected weekly. Dr. Gray, a Frankford physician, has contracted the disease.

Municipal Hospital, Philadelphia.—The Philadelphia Municipal Hospital, where over 360 cases of contagious diseases are under treatment, about 260 of them being smallpox patients, has very little room for many more patients. When a supplementary hospital was begun six weeks ago, neighboring property owners got out an injunction which stopped the erection of the building. Should the epidemic of smallpox still spread, further hospital accommodations will have to be secured by the city. Meetings have been held frequently, lately, to protest against the present site and probable sites for the Municipal Hospital.

Philadelphia Hospital.—Ground was broken for the three new hospital buildings to be erected on the grounds of the Philadelphia Hospital, December 10. The buildings will cost, when completed, \$80,000, and will be known as the Maternity Home, Children's Hospital and the Hospital for the Treatment of Contagious and Venereal Diseases. The Department of Charities and Correction instructed its Secretary to communicate with Directors of the different hospitals and ask their judgment as to the advisability of establishing a staff of gynecologists at the Philadelphia Hospital. A vacancy in the hospital staff was filled by the election of Dr. George M. Boyd, of the Medico-Chirurgical Hospital staff.

Society Meeting Next Week.—The only society meeting to be held next week will be the Neurological Society, at the College of Physicians, Philadelphia, Monday evening, December 23, at 8.15 P. M.

Hospital for Consumptives.—At the next meeting of Councils' Finance Committee, Dr. John V. Shoemaker, Director of the Department of Charities and Corrections, will ask an appropriation of \$180,000 for the erection of a hospital for the treatment of consumptives and a clinic hall, on the grounds of the Philadelphia Hospital. The former building, which will be two stories high, will, it is estimated, cost \$80,000, while the clinic hall, with its equipment will cost \$100,000. Dr. Shoemaker says these two buildings are imperatively necessary, and must be erected to relieve the crowded conditions of the other hospital buildings.

Appointment of Dr. Pearce.—Dr. F. Savary Pearce, professor of nervous diseases at the Medico-Chirurgical School, was elected, December 9, neurologist to the Howard Hospital, Philadelphia.

Outbreak of Diphtheria.—Nearly one-fourth of the pupils attending the Barton Primary School, Frankford avenue and Buckius street, Richmond, are said to have been stricken with diphtheria during the last few days. Four of the little ones died this week, and forty-five others are suffering from the disease. The building has been thoroughly disinfected, and every precaution is being taken to prevent a further spread of the disease. There were about 215 children enrolled, of whom about 120 were boys and about 95 were girls.

Keystone Veterinary Medical Association.—At the meeting held in Philadelphia, December 10, Dr. Leonard Pearson reviewed foreign veterinary medical schools, making comparisons with the veterinary schools of this country. Dr. M. P. Ravenel told of recent observations made at the Tuberculosis Congress in London, saying that the medical and veterinary professions throughout the world are not yet ready to adopt the theory advanced by Koch. Dr. B. M. Underhill read a paper on the treatment of tetanus by antitoxin with good results.

Dr. Amick Fined.—Dr. J. H. B. Amick, member of Com-

mon Council from the Thirty-seventh ward, who was under arrest, charged with failing to report a case of smallpox, was discharged after paying a fine of \$10 and costs. Dr. Amick testified that he diagnosed the case typhoid fever, and that smallpox subsequently developed. The patient was removed to the Municipal Hospital two weeks ago, after an examination by the assistant medical inspector, who pronounced the case smallpox.

Death of Dr. Huidekoper.—Dr. Rush Shippen Huidekoper, creator of the Veterinary School of the University of Pennsylvania, died December 17, at the Presbyterian Hospital, Philadelphia, in his 48th year. The cause of death was pneumonia following an operation for abscess of the lung. He was graduated from the University of Pennsylvania medical department in 1877, and spent the following years at work in European laboratories. He had been coroner's physician, dean, professor of internal pathology, contagious diseases, zootechnics, and hygiene in the University of Pennsylvania veterinary department, and professor of comparative anatomy and veterinary surgery in the New York College of Veterinary Surgery. He was surgeon to the First City Troop, Philadelphia, and surgeon in chief at Chicamauga. He was also editor of the *Journal of Comparative Medicine and Veterinary Archives* from 1889 until his death.

NEW YORK AND NEW JERSEY.

Regimental Skin-Graft.—In Englewood, N. J., 56 members of the Second Regiment, New Jersey National Guard, will give from two to four square inches of skin to save the life of one of their number who was severely burned in a gas explosion August 27. Dr. Currie, who is colonel of the regiment, operated upon 22 men December 15, removing portions of skin from their left arms, soaking them in normal salt solution, and transferring them to the body of the patient. The men had but a slight conception of the pain of the operation, and gave evidence of suffering keenly. When the operation was concluded, new skin had been grafted on the patients left arm, left chest, one side of the neck, and a portion of the head and face. The entire process took ten minutes less than four hours. At another operation next Sunday, skin will be grafted on the patient's left side, part of the abdomen, and both legs.

Physician Contracts Smallpox.—Dr. Beekman, health physician in Sayreville, N. J., has been attacked by smallpox. He assumed care of the smallpox cases when half the population fled. In two weeks the disease has spread from four cases to 22 cases, and each day new victims are recorded.

The Camden County Medical Society has adopted resolutions asking the Legislature to adopt a law providing for a State sanatorium for incurables.

Report of the New Jersey State Board of Health.—The State Board of Health has discovered that the death rate from cancer throughout New Jersey is phenomenally large. The report does not explain the prevalence of this disease in this State, neither is any reason given for the fact that although smallpox cases have been alarmingly numerous in contiguous States, New Jersey has had only 325 cases and five deaths in a year. During the year there were reported 3,444 cases of diphtheria and 426 deaths, 2,496 cases of scarlet fever and 78 deaths, and 944 cases of typhoid fever and 119 deaths. The deaths from cancer numbered 1,001, or nearly twice as many as those from smallpox, diphtheria, scarlet fever and typhoid fever combined.

Smallpox in Camden.—The Camden Board of Health has given a contract for the erection of an addition to the Isolation Hospital in the New Camden Cemetery property. The building will be 24 by 100 feet and will accommodate a hundred smallpox patients. Smallpox cases have been discovered in six public schools in Camden and the disease is still increasing.

Pathological Institute of the New York State Hospital for the Insane.—The Lunacy Commission of the State of New York, Dr. Frederick Peterson, president, has appointed Dr. Adolph Meyer, of the State Hospital and Clark University, Worcester, Mass., director of the Pathological Institute of the New York State Hospital for the Insane, replacing Dr. Ira Van Gieson, who resigned last summer. The scientific and clinical work of the reorganized institute will be begun as soon as possible in a build-

ing connected with the Manhattan State Hospital for the Insane, on Ward's Island. The scheme of investigation and research will be developed along lines to be formulated by Dr. Meyer, in association with the Advisory Board of the Pathological Institute appointed not long ago by the Commission on Lunacy. The composition of this Board was announced in the *Philadelphia Medical Journal*, October 26th.

The Eastern Medical Society, of New York City, at its annual meeting, held December 14, elected the following officers for the ensuing year: President, Dr. A. Abrahams; vice-presidents, Drs. Joseph Barsky and E. K. Browd; secretary, Dr. Maurice Flashberg; treasurer, Dr. B. Gordon; chairman of ways and means committee, Dr. A. Hymanson; chairman of committee on ethics, Dr. A. A. Himovitch; trustees, Drs. A. Brothers and William S. Gotthell.

The Annual Meeting of the Medical Society of the State of New York will be held at Albany, January 28, 29 and 30, 1902.

New York City.—The first graveyard (God's Acre) was laid out in 1633, west of Broadway, above Morris street. The first physician was Dr. Johannes La Montagne, who began practicing here in 1636. He was the only doctor in Manhattan for a number of years. The first public school was established in 1652 at Peter Stuyvesant's suggestion. The first prison on the island was a small room on the first floor of the Stadthuys, (City Hall); it was opened in 1655. The first official census was taken in 1656. The inhabitants were found to number 1,000, of whom a large percentage were negroes. The first undertaker was Conradus Vanderbeck, who was licensed in 1683. The first poor house was opened in 1698. The first quarantine was established in 1737.

Dr. Barney's Patient Has Tuberculosis.—Dr. Barney, of Brooklyn, announced December 13 that Miss King, who was inoculated by him November 23 with tuberculosis germs from an infected cow, has been removed by him from her home in Brooklyn to Jersey City. She has developed tuberculosis as a result of inoculation, and he is treating her to bring about her cure. He says he is certain he will cure her, having demonstrated that Dr. Koch's theory of the non-intercommunicability of bovine tuberculosis is all wrong.

A Blunder.—A surprising piece of carelessness was brought out in connection with the new marine hospital on Ellis Island, New York. When the work was almost completed, it was discovered that no means were provided for artificial illumination. While it was supposed that the contractors had made the blunder, they exonerated themselves by showing that no provision for lighting the hospital was mentioned in the plans or specifications furnished. The hospital is so near completion that the walls, ceilings and floors will have to be torn out to remedy this defect. This will entail an additional expenditure, and it would seem as though an investigation were needed to fix the responsibility for the blunder which caused a waste of public money.

Federal Control of Virus.—Federal supervision of the manufacture and sale of diphtheritic antitoxin and vaccine virus is advocated by Dr. H. M. Biggs, director of the laboratories of the New York Board of Health, as the most effective means of protecting the public from spurious preparations. Sweeping aside the controversy raised by Dr. Dalton's attack upon the municipal laboratories of New York and St. Louis, Dr. Biggs takes the ground that wherever deaths have occurred from tetanus, inferior virus or antitoxin had been used. Dr. William H. Park, acting head of the division of bacteriology of the Department of Health, declares that there has been no death from tetanus since the manufacture of the serum was begun in New York.

NEW ENGLAND.

A Hospital for Harvard Men.—The Stillman Infirmary at Harvard, which will be ready by Christmas, is the most fully equipped hospital yet opened by any university for its students. At Harvard the system of medical supervision includes medical visitation, the infirmary and an endowment for a prospective professorship of hygiene. At the beginning of the term a card is sent to each student calling attention to the college rule requiring that every case of illness shall be immediately reported to the medical

visitor. The janitors also are instructed to report any cases of sickness. The medical visitor visits all cases reported to him, a task that sometimes reaches 40 visits a day. All consultations are confidential, and the relations between student and medical visitor differ in no way from those between a private physician and his patient, except that the university pays for his services. His advice is free to every student, but for regular medical attendance those students who can afford to pay are expected to employ a private physician. The total number of cases thus visited during four years, according to a recent tabulation, amounts to \$495, more than one-third of the cases being "colds," very few of the others being of a serious nature. The system benefits the individual in that it keeps constant watch for the appearance of contagious disease. The Stillman Infirmary, which has grown directly from this system, is the gift of Mr. James Stillman of New York, who contributed about \$10,000. The building, a four-story structure built of red brick and limestone, stands on Mt. Auburn street overlooking the Charles river, about half a mile from the Harvard yard. It contains 30 beds, there being two wards of eight or ten beds each and 12 private rooms. The class of '68 has donated \$3500 for endowing a free bed. The infirmary will be used exclusively by members of the university. Last year the university authorities appropriated a sum of money for conducting a diet kitchen in connection with Randall Hall, the new student commons, from which a student confined to his room by sickness, not sufficiently serious to necessitate hospital attendance, may nevertheless be supplied with food properly prepared in accordance with the prescription of the medical visitor or his own physician.

The Effect of Smoking.—Dr. Seaver, gymnasium director at Yale, who has just completed the measurements and the physical statistics of the Freshman class, says that fewer of its members smoke, than the members of any class at Yale in recent years. He finds that the average lung capacity of the class is 260 cubic inches. The number of men using tobacco in the present Freshmen class is 10 per cent. smaller than for many years. Dr. Seaver finds that the average age of the class is 19 years 1 month, which is 56 days younger than the average of last year's class. The average weight is 134 pounds, 6 pounds less than last year. The average height is 5 feet 7.8 inches, or .4 of an inch less than last year. The average size of the chest when inflated is 35.9 inches, and the average measurement of the biceps is 11.4 inches, which is .2 of an inch smaller than last year.

Typhoid in Adams, Mass.—There are 18 known cases of typhoid fever in Adams and many others have probably not been reported. The state board of health is investigating.

Framingham Hospital, South Framingham, Mass.—The Framingham Hospital corporation has voted to authorize the trustees to solicit subscriptions for an annex, two stories in height, to contain two wards of four rooms each, for private patients, and for a diet kitchen in the basement where student nurses may be taught to cook delicacies. The cost will be about \$4000.

Diphtheria in Maine.—The State Board of Health is taking measures to cope with the epidemic of diphtheria now prevailing in Fort Fairfield. In the extreme northern part of Maine, and in Portland. These places are four hundred miles apart, and yet the disease has caused several deaths in both towns. Strict quarantine is being enforced by the State Board, the local boards having called upon the higher authorities to assist in handling the epidemic.

Surgical and Gynecological Society.—The 58th session and the 25th annual meeting of the Massachusetts Surgical and Gynecological Society was held in Boston December 10. Dr. Henry E. Spaulding presided. The following officers were elected: President, Dr. G. F. Martin; vice-president, Dr. N. H. Houghton, and Eliza B. Cahill; general secretary, Dr. T. Morris Strong; associate secretary, Dr. Herbert B. Boyd; treasurer, Dr. Grace E. Cross; auditor, Dr. Frederick A. Davis; censors, Drs. Horace Packard, J. P. Rand, and F. C. Richardson.

Smallpox in New England.—Smallpox still exists in Boston, in spite of widespread vaccination. Not only have the large stores, corporations, mills, etc., had employes

vaccinated, but the students at Harvard have also been revaccinated. Over 30,000 people have been vaccinated during the past few weeks. Smallpox appeared in Boston first in August, 32 cases were reported in September, and 52 in October. During November over 100 cases occurred, but last week 60 cases were reported, with 6 deaths. Hospitals are closed to visitors, and the accommodations for smallpox patients on Gallup's Island have been enlarged to hold over 250 patients. Scattered cases have appeared throughout Massachusetts, in Chelsea, Wakefield, Oxford, Brockton, New Bedford, Dedham, Malden, Lynn, etc., and in Bath and Bangor, Maine.

Diphtheria in Brookline, Mass.—The fashionable residential section of Brookline has been attacked by diphtheria this winter. Previous epidemics have been confined to the poorer classes in the thickly populated districts. Thus far not a single case has been found among the poorer people this year. Bacteriologists examined the sanitary arrangements of infected dwellings, but it was found that these conditions were not at fault. After further examination it was found that along one milkman's route 12 cases of diphtheria had broken out, and the agent of the board of health says the disease is due to infected milk.

CANADA.

(From our Special Correspondent.)

The College of Physicians and Surgeons of Quebec will henceforth issue licenses to practice, on the presentation of candidates' university diplomas, without further examination. This applies only to those who come under the statute of the Quebec Legislature, known as the Roy law, which was adopted two years ago. Recently the Courts have rendered several decisions, holding that the College was bound to give licenses to those who came within the statute of this law.

New Smallpox Hospital, Toronto.—A fine new smallpox hospital has just been opened in Toronto, probably the best of its kind in the Dominion of Canada. It is constructed of wood and brick, has accommodation for 25 patients, the wards being divided into two divisions, one for convalescents, and the other for those in whom the disease is in its active stage. In addition to these, there is a large attic which can be pressed into service should an extensive outbreak appear at any time. Before it was declared open a week, it had an occupant, the only case at present in the city. This patient inadvertently gained admission to St. Michael's Hospital, and the disease was well established before it was discovered that he had smallpox. As a result, the medical wards of St. Michael's have been under strict quarantine.

A Case of Poisoning from Chloroform has been recorded in Toronto. A gentleman came to the Western Hospital for operation. Chloroform was administered by the house-surgeon, which is said to be competent, though he has not as yet fulfilled all the requirements of the Ontario Medical Council to admit him to actual practice, being in his fifth year, at post-graduate work as is required by law. The patient, a man of 53, died on the table, all attempts at revival proving futile. The inquest showed that death was the result of poisoning by the anesthetic. The coroner's jury strongly recommended that each hospital in the city have a specially appointed and competent physician to look after the administration of all anesthetics.

Ottawa's Death Rate.—From the report of the Ottawa Medical Officer of Health, Dr. Law, the death rate for the past year reached the total of 1,273, a slight increase over the previous year, when 1,146 were registered. The largest number of deaths among adults was from tuberculosis, 125, while pneumonia came next with 102; heart disease, 88; convulsions, 72; old age, 73; diphtheria, 65; scarlet fever, 52.

The Medico-Chirurgical Society of Montreal is now seeking for incorporation at the hands of the Lieutenant-Governor of the province of Quebec. The names of the following well-known practitioners of Montreal appear on the petition for incorporation: Drs. J. G. Adams, G. E. Armstrong, A. T. Bazin, H. S. Birkett, F. Buller, J. M. Craik, J. M. Elder, W. Gardiner, Sir William Hingston, J. M.

Jack, H. A. Lafleur, F. A. Lockhart, J. G. McCartney, James Perrigo, F. J. Shepherd and J. W. Stirling.

Smallpox in Quebec.—The extent of the outbreak in the province of Quebec is shown by the statement recently issued by the Provincial Board of Health. Since the appearance of the disease in the lower province there have been 81 centres infected, with a total of 340 cases, and new ones are developing every day. In the city of Montreal alone there have been over 30 cases in the Civic Hospital. One or two cases of tetanus have been reported following vaccination. The Board of Health recommends only glycerinated vaccine.

Victoria Hospital for Sick Children, Toronto.—The Twenty-sixth annual report has recently been issued and shows that since the institution was organized, 13,201 children have been treated and that 20,000 of these have been cured. In the last hospital year, ending September 30, 770 children were cared for in the wards, and 5,152 in the out-patient department. Of the indoor patients, 530 were cured, 154 improved, 41 unimproved, and 43 died, 32 dying within a month after admission. The cost of maintenance per patient for the year just closed was 75.50 cents per day, against 89 cents for the previous year. There is at present a deficit of \$13,000. This hospital can accommodate 195 patients, and in addition has a fine summer home on Toronto Island, "The Lakeside Home," the largest of its kind in the world.

Tuberculosis in Toronto.—The reaction appears to have set in. The hospitals closed their doors against tuberculosis patients when a consumptive sanatorium was only being talked of. A short time ago a by-law was to have been submitted at the coming municipal elections in January, but the National Sanatorium Association has come forward and offered to accommodate 100 of Toronto's consumption population within the next twelve months. In the meantime, some place must be found for the consumptive; and there is much discussion upon the action of the hospitals in so quickly closing their doors against this form of illness, when there is not really so much to fear from contagion after all. Then the proposal to stop spitting in the streets is taking shape and one cannot help wondering how people are going to be prohibited from spitting after dark, because sputum expectorated after dark may yet be proved more of a menace to the health of a community than spitting in sunshine.

Ottawa University Quarantined.—On December 9, Ottawa University was placed under quarantine, since three cases of smallpox developed there in the two days previous. Many of the students at the University are from the United States.

Smallpox in Saint John, N. B.—Over 11,000 people were vaccinated before December 1st. There have so far been 60 cases of smallpox reported, with 13 deaths.

Death of Dr. Sweetman.—Dr. Leslie M. Sweetman, a prominent surgeon of Toronto, died December 11, in Johns Hopkins Hospital, Baltimore, from blood poisoning which set in several weeks ago, after an operation performed in Toronto.

MISCELLANY.

Positive Signs of Locomotor Ataxia.—Fournier gives six signs which should be sought when there is reason to suspect tabes. The first is Westphal's sign, the absence of the patellar reflex, found in two-thirds of all cases in the early stages. Next is Romberg's sign, unsteadiness of the body when standing erect with the eyes closed. Third is the difficulty experienced in walking downstairs. Fourth, while sitting and attempting to place one leg across the other, an undue effort is observed, a swinging, circular movement of the leg. The fifth test consists in noting the promptness and decision in halting at command and turning about while walking. The movements in the early ataxic condition are performed with unsteadiness and uncertainty. The sixth test consists in requiring the patient to stand on one foot, first with the eyes open and then with them closed, and noting the muscular instability. This test is regarded as the most important of all.

Danish West Indies.—The Government has imposed a quarantine of 15 days against vessels arriving at St. Thomas, Danish West Indies, from the Port of Philadelphia, on

account of the epidemic of smallpox existing there. Jamaica has already established a similar quarantine.

Sanitation in the Middle Ages.—The Greeks and Romans paid special attention to physical culture, water supplies, and baths, and Athens and Rome were provided with sewers early in their history. During the Middle Ages, sanitation received a decided check. Most European towns were built compactly and surrounded by walls. The streets were narrow and winding, and light and air were excluded. The accumulation of filth was frightful. Stables and houses were close neighbors. The dead were buried within the churchyards or in the churches. Wells were fed with polluted water. All conditions were favorable for the spread of infectious diseases, and in the fourteenth century alone bubonic plague carried off a fourth of the population of Europe. The birth-rate was much less than the death-rate normally. The cities had to be continually repopulated from the country.

Bubonic Plague.—A death from bubonic plague was reported December 11, in the suburbs of Sydney, N. S. W.

Cure for Insomnia.—Dr. von Gellhorn recently reported a cure for insomnia. A piece of calico, about eighteen inches wide and two and three quarter yards long, is rolled up like a bandage, and a third of it wrung out of cold water. The leg is then bandaged with this, the wet portions being carefully covered by several layers of the dry, as well as by a layer of gutta-percha tissue, and a stocking drawn on over the whole. This causes dilatation of the vessels of the leg, thus diminishing the blood in the head and producing sleep. It has been found by Winternitz that the temperature in the ear begins to fall a quarter of an hour after the application of the bandage; the decrease amounting to 0.4° C., and the normal not being again reached from one and a half to two hours afterwards. It is especially useful in cases where there is congestion of the brain.

Havana Sanitary Congress.—The Superior Health Board of Valparaiso, Chile, has strongly recommended that the government be represented at the Sanitary Congress to be held in Havana in 1902.

Trichinosis in The United States.—Carefully collected statistics show that the white population of the United States has trichinosis less frequently than the colored population, or the white population of other nationalities. The nationalities suffering most are the Canadians and Italians, and the Germans are very close to them.

The Drinking Habit.—It is said that in serious cases of the drinking habit, the average duration of life is about fifteen years; the duration of life among moderate periodical inebriates is about nineteen years. The capacity to get drunk more than a thousand times is rare. The maximum capacity for any man during ten or fifteen years is about two thousand gallons of whisky.

The Age of Man.—According to the latest announcements scientists have traced man back 9,000 years, but it took him about 7,000 to get a start for what he has done within the past 2,000, and it required more than 1,800 of these to prepare him for what was done in the last two centuries. And about now he is beginning to make a real start in knowledge and progress. Man is a great animal, but he needs time.—*Philadelphia Times*.

Obituary.—Dr. Moses Marshall, at Easton, Mo., December 2, aged 48 years—Dr. John W. Brock, at Caldwell, Ohio, December 3, aged 51 years—Dr. Charles B. Osborne, at South Waterloo, N. Y., December 2, aged 54 years—Dr. Charles S. Essig, at Wallingford, Pa., December 2—Dr. C. L. Broadus, Wallonia, Ky., December 1, aged 40 years—Dr. C. C. Miller, at Halifax, Pa., December 9, aged 42 years—Dr. Leslie M. Sweetman, at Baltimore, Md., December 11, aged 42 years—Dr. B. F. Kibler, at Dayton, Va., December 11—Dr. Francis A. Utter, at New York City, December 10—Dr. J. B. Sickler, at Peckville, Pa., December 11—Dr. William H. S. Leake, at Philadelphia, Pa., December 13, aged 80 years—Dr. Jesse G. Shoemaker, at Phoenixville, Pa., December 14, aged 35 years.

GREAT BRITAIN, ETC.

Deaths of Children in South Africa.—A blue book on the concentration camps in South Africa, issued in London, December 14, shows that in October the deaths in the camps were 3,155, of which 2,633 were children. In November the deaths were 2,087, 2,051 being children. The figures for October and November make the total number of deaths for the last six months 13,941, or a death rate approximating 252 per year per thousand.

Yellow Fever in the West Indies.—Mail advices received in Kingston, Jamaica, from Saint Lucia, British West India, report the existence of yellow fever at that place. A case has appeared also at Barbadoes.

Government Expert on the Plague.—The British Government has appointed Professor W. J. L. Simpson an expert on plague to advise the Hong Kong Government as to the best means to check the continued prevalence of that disease.

Appointment of Colonel Trotter.—Colonel Trotter, late Professor at the Royal Victoria Hospital, Netley, has been appointed to succeed Surgeon-General O'Dwyer as principal medical officer at Aldershot.

Ireland has 408 able-bodied persons to 1000 inhabitants, Scotland 424, and England 432.

Macclesfield Infirmary.—The election of a female junior house surgeon in opposition of the wishes of the medical staff has resulted in the resignation of the entire medical staff.

Obituary.—On November 28, in Glasgow, Dr. Archibald Campbell Clark, a graduate of the University of Edinburgh, lecturer on psychology at St. Mungo's College, Glasgow, and superintendent of the new Lanark District Lunatic Asylum at Hartwood, died, aged 50.—Francis Henry Lyon, a graduate of Dublin University, died in Dublin, aged 54 years.—The death of J. D. Harries, consulting surgeon to the Salop Infirmary, has just been announced.—Surgeon General Harvey, director of the Indian Medical Service, died of peritonitis, December 1, at Simla.

CONTINENTAL EUROPE.

Capital Punishment.—Professor Mareclin Berthelot, the renowned chemist, whose fiftieth anniversary as professor of chemistry in the Collège de France, Paris, has recently been celebrated, suggests the use of carbonic oxide for the production of death for criminals, as employed for the destruction of stray dogs. He says that this is a quiet and painless death and one that does not shock the sensibilities.

Spring Water in Auvergne, France.—Numerous methods are related in Auvergne, by which the peasants, renowned as the most stupid throughout France, decide whether the water of a spring is fit to drink or not. When it contains salamanders, leeches, etc.; when, upon expectorating into it, sputum does not separate; when bread, thrown in, does not sink rapidly, then the water is not drinkable. After a bit of bread has been held four or five minutes in the water, to absorb all harmful properties, the water may be drunk. Finally, wherever frogs are seen, the water must be good, since they destroy all venomous insects.—*Gazette des Eaux.*

Hospital Overrun by Rats.—A patient who fled from the Cochin Hospital, Paris, says the hospital is infested with thousands of rats which gallop about the wards night and day, devour the patients' food, and even bite helpless patients. A similar state of affairs, it is said, prevails in the temporary hospital at Aubervilliers.

A Treatment for Diabetes.—An important communication on the treatment of diabetes has been contributed to the Academy of Medicine of Paris, by Dr. S. Nourse. His theory is that potatoes in an equal quantity contain the same amount of salts of potash as bread, and by giving large quantities and suppressing bread, an alkaline treatment is set up, the diminution of sugar being an important factor. The treatment is not a cure, but is a powerful aid to doctors.

To Make Cattle Immune.—Professor Behring, who was recently awarded the Nobel medical prize of \$40,500, has announced that his experiments have demonstrated the possibility of making cattle immune to tuberculosis by inoculation. He proposes employing the Nobel prize money in combating cattle tuberculosis.

A Medical Certificate Obligatory.—The Bohemian Society of Physicians has procured the introduction of a bill

in the Austrian Reichsrath compelling both sexes to undergo a medical examination previous to marriage and to show a medical certificate of physical and mental capacity to either the priest or magistrate before the ceremony can be performed.

A Tablet to Dr. Molina.—A tablet in honor of Dr. Martinez Molina was unveiled November 17, upon the front of the house in Madrid in which he formerly lived. Addresses were delivered at St. Charles Hospital after which the procession formed and marched to the site of the tablet, which was then unveiled.

New Devices for Training the Blind.—The Paris Academy of Medicine has just been shown an invention by Dr. Dussard that completely revolutionizes the system of writing, calculation, and musical notation for the blind. The system marks a decided improvement on the Braille method, and is hardly less important than the improvement made by Braille himself. The primary advantage is that the blind are enabled to read and immediately correct what they have written. It does away with the cumbersome calculating board, and all of the apparatus necessary to the blind student may be folded and carried in the pocket. Dr. Dussard's appliance consists of a frame on which runs a ruler containing sets of square spaces, disclosing small dice fixed on a flexible metal band beneath. When the writing point is pressed on one of the concave spots of the dice, a raised dot appears in the paper. The position of the dots being mechanically determined, perfect regularity in the characters is obtained. The writer has but to lift the ruler, which is hinged and cannot be displaced, to read by the touch the characters which he has just formed. Erasures are accordingly made at once. Arithmetical notation on paper is thus rendered easy. The invention was brought before the Academy of Medicine December 2d, by Dr. Laborde, and two girls from the Braille School showed how easy it was to make use of the machine. Their speed in writing was equal to that of the average writer using pen and ink.

Deaths Placarded in Venice.—When any one dies in Venice it is the custom to fix a placard before the house, and in adjacent streets, a public notice stating his name, age, place of birth, and illness, affirming that he received the holy sacrament and died a good Christian, and requesting the prayers of the faithful.

Measles in France.—A severe epidemic of measles has broken out at Etaples, near Arras, 20 children dying in three days. Stringent prophylactic measures are being taken.

New Children's Hospital, St. Petersburg.—The foundation of a new children's hospital, intended as a memorial of the coronation of the Czar and Czarina, has recently been laid in St. Petersburg. The hospital, which is to be built on the pavilion system, will contain 400 beds. The cost, which is estimated at 1,700,000 roubles, approximately \$850,000, will be defrayed by the State.

Exterminating Rats at Marseilles.—The port authorities at Marseilles have experimented with carbolic acid instead of sulphuric acid in exterminating rats. The results have been effective, the carbolic acid not damaging the cargoes. They hope it may be the means of preventing the plague, which has been brought by rats generally.

Horse-flesh.—The consumption of horse-meat in Frankfurt has increased. The first horsemeat dinner was given on October 6, 1847, at Bornheim, a suburb of Frankfurt. As soon as a horse was slaughtered, and at that time only young horses were killed, the meat was sold at six kreutzers (about 4 cents) a pound. Yet it was not until fifty-four years later that the first horse meat restaurant was opened. At the present time about 1000 horses are slaughtered annually, and a separate slaughter-house has been built. The horsemeat butcher shops of Vienna, of which there are no fewer than 185, present a clean and attractive appearance, and at in no way distinguishable from the shops where the usual kinds of meat are sold, save by the sign announcing their specialty. Restaurant keepers who serve horsemeat must designate this fact in a special column on the bill of fare offered to patrons.

Obituary.—Dr. Hermann Löhlein, professor of obstetrics and gynecology in the University of Glessen died of apoplexy, November 25, in his 55th year.—Dr. G. Chiarleoni, professor of obstetrics at Palermo, Sicily, has died recently.

6. Observations on the Rate of Vibration in Ankle Clonus. J. A. MacWILLIAM.

1.—Gowers reports the case of a woman aged 25 years, who suffered for 3 months from headache, which was severe from the first, and which was referred to the front and back of the head. After it had existed for a month, vomiting was added and both symptoms continued. Toward the end of another month the patient was noticed to become strange in manner, and the mental disturbance increased, so that she is said to have been "always talking nonsense." Soon afterwards, 3 weeks before admission, to the hospital some loss of power of the right side was noticed, and she also had a fit of some kind. The family physician stated that the patient had probably had syphilis. She was an ill-nourished, anemic girl, very weak, and in a condition of stupor, foot clonus was present on the right side and the optic discs were normal. Inunctions of mercurial ointment were ordered and following their use there was distinct improvement; although the benefit was not greater than that we often see from the first influence of the rest and suitable food a patient receives in the ward of a hospital, and the improvement soon ceased. At the end of a week 15 grs. of potassium iodide, 3 times a day, was added to the mercury; but, in a few days more, the increase in weakness was so distinct that the inunctions were stopped, the iodide being continued alone. At the end of another fortnight the patient had several slight convulsive attacks and almost complete paralysis of the left side came on suddenly. The stupor deepened to coma, the temperature rose to 104°, and 3 days later the patient died. The symptoms suggested a rapid cerebral growth. The necropsy showed that, although the disease was syphilitic, there was no growth. There was extensive syphilitic disease of the arteries, which was most intense at the commencement of each middle cerebral artery. In this situation the thickening of the wall had encroached on the cavity of the artery to the point of obliteration; this was especially great on the left side. The right middle cerebral artery contained a thrombus which was the cause of the final hemiplegia. There was a partial thrombus in the left middle cerebral artery, the occurrence of which must have caused the onset of the right hemiplegia. An abnormal artery from the posterior cerebral carried enough blood to the distal side of the clot to prevent the paralysis being complete. A clot which was situated in the anterior cerebral artery may be assumed to have caused the onset of the mental symptoms, although its effect was lessened by the supply of blood brought by a second anterior communicating artery. The progressive increase in the symptoms, the increasing palsy, the deepening speechlessness and stupor were undoubtedly due to the alteration in the structure of the brain produced by the endarteritis.

[J. M. S.]

2.—Bennett publishes a clinical lecture in which he cites a typical surgical case which would mislead a careless observer. He cautions against the so-called pathognomonic signs of disease and deprecates too readiness which is sometimes shown to operate for diagnostic purposes only. [F. T. S.]

3.—Bradshaw reports the case of a married woman aged 24 years, who was suffering from jaundice, impaired vision, and choreiform movements. Three weeks before her admission to the hospital she was seriously frightened by a large dog which sprang at her and following that, she had nausea and vomiting occasionally for 2 or 3 days. Two

days later she was slightly delirious, threw her arms about and jerked her head from side to side, the tongue was tremulous and she could not distinguish the features of people about her. The temperature was 99°. Two days later jaundice was distinct, and she appeared to be almost blind, there was, in addition, profuse metrorrhagia. Later, the patient became cyanosed, the breathing became irregular, the liver dulness was obliterated and the splenic dulness was unusually distinct. The urine contained a moderate amount of bile, but no albumin; the proportion of urea was estimated at 2.6%, and neither leucin nor tyrosin could be found. A diagnosis of **acute yellow atrophy of the liver** was made which was confirmed at the post-mortem examination. The liver weighed 25½ ounces, the capsule was loose and wrinkled, as if it was too large for the organ and numerous yellow spots the size of a pea or less showed through it. On section, the organ was mostly a bright cherry red, with patches of yellow here and there. The substance was perhaps rather harder than normal. The kidneys appeared normal; the spleen was enlarged. The portions of the liver which appeared yellow to the naked eye consisted chiefly of hepatic cells, arranged in lobules or irregular clusters, and showing marks of degeneration in a greater or less degree. These yellow areas were surrounded by areas of red atrophy, consisting of a fine connective tissue network infiltrated with blood and containing scattered collections of bile ducts, for the most part grouped around the portal vessels. At the periphery of the yellow areas, and in the neighborhood of the portal canals, there was an extensive infiltration of small round cells. The substance of the hepatic cells was converted into irregular aggregations of fine and coarse granules, many contained bile pigment, and a few contained fat droplets. As a rule, the nucleus was regular and had a distinct nucleolus; occasionally it was double, but without any evidence of karyokinesis. Some of the hepatic cells contained small, round, deeply-staining bodies resembling leukocytes, apparently the endocytes of McPhedran and Macallum. The intralobular bile capillaries appeared to be large and their lumen was occupied by a clear homogenous material which stained pink with eosin. The areas of red atrophy were composed of a delicate felted network of connective tissue and scattered endothelial plates, containing numerous red blood corpuscles. The author failed to recognize the existence of any obvious predisposing or exciting cause of the disease, unless it was the occurrence of severe mental shock.

[F. T. S.]

4.—In discussing the treatment of wounds in war, Cheyne expresses the opinion that the experience thus far gained does not warrant any modification in the surgical procedures adopted for similar injuries in civil life. He believes the good results attained in the South African War were due to the modern bullet and to the dry hot climate and not to modern surgery and asepsis. A small wound quickly heals because of the slight amount of bruising of the envolving tissues and because it is rapidly covered with a scab owing to the dry atmosphere, wounds larger than an inch in size were invariably infected. To speak of the field dressing which every soldier carries with him as aseptic is an absurdity, as it is frequently laid on the ground before it is applied to the wound and is always handled by dirty fingers. For the first treatment on the field Cheyne recommends a free use of a drying antiseptic powder and an exposure of the wound to the sun and air. When the first dressing was covered with a piece of mackintosh which kept the moisture in, suppuration frequently occurred. That the excellent results were not due to asepsis is self evident, since it was impossible to obtain and maintain perfect cleanliness; the regimental surgeon's hands are dirty, the men must lie on the field some time before being transported to the rear, the air is filled with sand, dust, and flies, and the water is scarce, muddy, difficult to filter, and hard to boil because of the absence of facilities.

[J. M. S.]

5.—Sawyer recommends the following basis for **medicated lozenges**: Take of decorticated liquorice root 4 drams; water 4 pints; macerate for 12 hours; strain and add 2½ pounds of picked gum arabic and 2½ pounds of refined sugar; dissolve, strain, and evaporate to the thickness of honey, constantly stirring, and add gradually the

whites of 12 eggs well beaten with 4 ounces of orange water; evaporate with constant stirring till the paste is so firm as not to adhere to the hands. [J. M. S.]

6.—In the case of a man, aged 40 years, who was suffering from hemiplegia of 10 months duration, and who presented ankle clonus, the rate of vibration was found to be as a rule 13.5 or 14 per second. The clonus excited in the quadriceps by traction on the patella exhibits a rate of about 7.5 per second. When the movement of the foot was recorded, the vibration showed only half as fast. [J. M. S.]

9. The Lighting of an Operation Theatre.

P. T. B. BEALE.

1.—In discussing the symptoms and treatment of movable kidney Henry Morris reaches the following conclusions:

"1. When movable kidney is associated with enteroptosis, no operation should be performed on the kidney unless it is evident that the more serious symptoms are due to the mobile kidney alone, and not until after the trial of a well-fitting abdominal support and the careful dietetic and medicinal treatment of the gastric and intestinal disorders. Should these means fail and the kidney evidently be most at fault, nephropexy means fail and the kidney evidently be most at fault, nephropexy, followed by the wearing of an abdominal belt, should be tried.

2. When a movable kidney is complicated by a movable liver, or when both kidneys move, the same rule should be followed as in general enteroptosis; in the case of both kidneys moving (when both organs have been given trouble) they should be fixed one after the other at an interval of a week, so that convalescence from both operations may be taking place simultaneously. I have in several instances thus operated upon both organs with the most satisfactory results.

3. When the movable kidney occurs in an hysterical or neurasthenic patient, all palliative means should be tried before resorting to an operation, and the patient's friends should be informed of the uncertainty of the result from operation. The statistics show that a cure may be hoped for by nephropexy in about half of these cases.

4. For uncomplicated movable or floating kidney, in which the principal symptoms are pain and gastro-intestinal troubles, the operation may be confidently advised and carried out without any previous trial of belts or of rest.

5. When renal crises are a feature of the case, nephropexy ought to be strongly urged because of the impossibility of keeping the kidney in its proper place by a belt, and because of the constant risk of hydronephrosis and recurring pain, even if the renal crises can be kept under control.

6. When a movable kidney gives rise to no inconvenience, an operation ought not to be thought of and a belt need not be worn." [J. H. G.]

2.—(Will be considered in the surgical critical review of January.)

3.—In this third lecture Browne takes up the question of urethral stricture and deals at length with that variety which does not yield to dilatation. For this condition he recommends internal urethrotomy. The instrument which he uses is the urethrotome of Civiale. Browne claims that there is no stricture however severe through which it is impossible to pass an instrument. The use of the filiform bougie is heartily condemned as being an instrument capable of misleading the surgeon and inflicting severe damage upon the patient. The treatment recommended is that the patient should be profoundly anesthetized and the passage of a small steel bougie attempted. When the tip of this instrument has become fixed in the stricture, it is not forced through it but is withdrawn and the next size is then introduced. This gradual dilatation of the stricture is kept up until a No. 6 English instrument can be passed readily into the bladder. The urethrotome is then introduced and a free incision made from behind forward, being at least an inch long through the stricture. A rubber catheter, No. 10 or 11 (English scale) is introduced and fastened in the urethra. This instrument is allowed to remain in position from two to three days. Browne objects most strongly to the performance of external urethrotomy, largely because of the danger of a permanent urinary fistula. There are, however, four conditions which call for an incision in the perineum; (1) when there is an extravasation of urine; (2) when pus requires an exit; (3) in some cases of prostatic calculi; and (4) in certain rare cases of urethral calculus. In cases of periprostatic abscess and of perineal abscess a free incision must be made at once, because delay is productive of the most serious damage to the tissues. In certain cases of perineal abscess it is Browne's custom first of all to divide the stricture, introduce a soft rubber catheter into the bladder, and then incise the abscess. "The urethra should never be opened in cases of vesical calculus, urethral stricture, perineal abscess and extravasations, or for vesical exploration or drainage or for any prostatic operation." [J. H. G.]

5.—Garrod contributes an article on "alkaptonuria" which throws fresh light upon its nature and causation. He emphasizes that this condition may be met with in several members of a family. A considerable number of the cases demonstrate this point. This condition affects brothers and sisters alike, but no facts at hand point to show its transmissibility from one generation to another. He has inconclusive evidence that children of first cousins show a special liability to alkaptonuria. The older members of a family are less liable than the younger ones. He gives an account of a case of alkaptonuria occurring in an infant. The condition developed very soon after birth. The urine which was collected between the eighth and eleventh day reduced Fehling's solution and had the characteristics common to alkaptonuria. He believes the condition manifested itself after the entry of proteid food into the alimentary tract and that "the evidence available points to tyrosin, formed as a product of pancreatic digestion, as the parent substance of the homogentisic acid which imparts to alkaptonuria its peculiar properties." A certain amount of homogentisic acid can be destroyed by the human tissues, but when their powers become overtaxed, this substance is excreted. He quotes from a paper of Mittelbach who has observed, "that at different periods of the day of twelve hours, the maximum excretion of homogentisic acid follows within two or three hours after the chief meal." The author has also estimated the reducing power of several specimens of urine passed by a patient during the course of twenty-four hours. The results he embodies in three tables. The first table shows the results after partaking of an ordinary hospital diet for children. The first meal was at 5 A. M.; dinner at 12 noon, which consisted of minced meat and rice pudding; at 3.45 P. M., an egg and tea, and at 6 P. M., bread butter and

milk. Eight observations were made during the course of the twenty-four hours, and it was found that between 4 P. M. and 5 P. M. (about four hours after the chief meal) the maximum excretion of homogentisic acid occurred. The second table embodies the results which were obtained after partaking of a diet rich in proteid at the chief meal (twelve noon). The maximum excretion then took place between 3 P. M. and 7 P. M. The third table includes the results after the ingestion of a meal richest in proteid at 9 A. M. instead of noon. It was found that the maximum output of reducing substance occurred between 12.15 P. M. and 4.25 P. M. or about three hours earlier than when the chief meal was given at 12 noon. The author's results do not correspond with Mittelbach's observations who found the reducing power of urine at its height within two or three hours after a proteid meal. Garrod remarks "that his observations lend support to the view that the change from tyrosin to homogentisic acid takes place in the tissues after the absorption of the former, rather than the alternative view that the change in question is brought about in the alimentary canal." [F. J. K.]

6.—Overend reports "a case of myxasthenia" which occurred in a woman 44 years of age. For twenty years the patient's health had been much impaired. She had had a number of illnesses; among these were diphtheria, pertussis, and acute gastritis. At the time this patient came under observation she complained of dryness of the tongue and throat, loss of appetite, flatulency, and pain after taking food. Sleep was disturbed on account of the parched feeling in the throat. The mucous membrane of the mouth was dry, pale, and shiny. Two small granulations about the size of a pea existed below the left tonsil. These caused her much discomfort and at times pricking pains below the angle of the jaw. Gastric pain developed about two hours after food was taken and was most intense at midnight. The ingestion of milk seemed to induce more pain than the ingestion of meat. The bowels were constipated. The author prescribed powders consisting of mucin (mucin and bicarbonate of soda) to be taken before and after meals; the throat to be swabbed or painted before retiring at night with a solution of mucin containing menthol, in a wine glass full of water; and powders of bismuth and sodium sulphate. He states that the presence of mucin in abundance within the synovial fluid where uric acid deposits most frequently occur in cases of gout, and diminution of saliva and the desiccated tongue of diabetic patients are suggestive facts which may lead to the discovery of some interesting relationship. [F. J. K.]

7.—Leaf, in discussing the necessity for taking steps to prevent dissemination of carcinomatous material in operations for cancer of the breast, recommends that the fascia in which run the veins and lymphatics from the breast should be ligated by a number of ligatures introduced on large curved needles. He presents an illustration showing the various lymph channels and the positions for the ligatures. It is claimed that the use of these ligatures will prevent to a considerable extent the possibility of infection of neighboring structures during the process of removing a malignant breast and infected lymphatic glands. [J. H. G.]

8.—Stalker reports a case of lead poisoning causing insanity which occurred in a man 30 years of age, a plumber by occupation. He was admitted into the Surrey County Asylum on August 19, 1901. The patient's illness began very suddenly on April 12, 1901, with chilly sensations and pains all over the body. Mental symptoms were quite marked; delirium was persistent. He remained in this condition until his admission to the Asylum. A marked degree of wasting occurred during the period between the onset of the disease and the time of admission to the Asylum. His mental condition on admission closely resembled alcoholic mania, he was restless, noisy, excited and utterly incoherent. There was paralysis of the extensor mus-

cles and wristdrop was pronounced. A tremor appeared upon any attempted movement. Ankle clonus was absent. The knee jerks were slightly increased. A well defined blue line was found on the gums and a certain amount of optic atrophy existed. The treatment consisted in the administration of iodide of potassium. Six days after admission stimulants were resorted to on account of collapse. On the 25th of August the patient developed well-marked epileptic seizures. He steadily improved from this time on and was discharged on Oct. 11, 1901, when he was mentally sound, but there was evidence of a certain degree of cirrhotic change in the kidneys. The diagnosis of lead encephalopathy and epilepsy seemed justifiable. This case differs from the usual type of lead encephalopathy in its suddenness and acute mode of onset. [F. J. K.]

MEDICAL RECORD.

December 14, 1901.

1. Optimism vs. Pessimism in the Surgical Treatment of Cancer. ROBERT ABBE.
2. An Epitome of the Subject of Rheumatism as Cause and Effect in Inflammation of the Throat. WILLIAM CHEATHAM.
3. Rheumatic Affections, Their Pathogenesis and Treatment. MARTIN A. H. THIELBERG.
4. Municipal Sanatoria. ALFRED MEYER.
5. Treatment of Delirium Tremens and Alcoholic Toxemia. T. D. CROTHERS.

1.—Robert Abbe presents a paper on optimism vs. pessimism in the surgical treatment of cancer. His observations have caused him to affirm that a radical cure can occasionally be hoped for in a few cases of cancer by extirpation, and that the resources of surgery have greatly mitigated the suffering from malignant disease and prolonged life. He states that out of more than 150 excisions of the breast for cancer he found 25 per cent of the number of the 75 cases who responded to his inquiries had survived the three-year limit. One case survived six years; one five and a half, and one four years. He includes in this report many favorable results which followed a number of operations for sarcoma and epithelioma. [T. L. C.]

2.—William Cheatham has inquired into the subject of rheumatism, and its relation to inflammation of the throat. In his experience chronic rheumatism causes frequent attacks of inflammation of the tonsils, pharynx, and larynx, and that acute exacerbations in chronic and acute rheumatism are frequently ushered in or preceded by an acute tonsillitis; that following these attacks we may have all the heart, joint, and other lesions that are found in any other rheumatic affection. He emphasizes the fact that these lesions may not be rheumatic, but depend upon other toxins. As yet we are not able to distinguish them. [T. L. C.]

3. M. A. H. Thielberg discusses the pathogenesis and treatment of rheumatic affections. Rheumatic fever has of late years been classed by many authorities as a bacterial disease, and various microorganisms, especially diplococci, staphylococci, and bacilli, have been found in the nodules, synovial membranes, fibrinous and serous exudates, blood, urine, in persons suffering from acute rheumatism. He refers in this direction to the researches of Poynton and Paine, Achalmé and Thierloix. It may be safe to predict that many cases of apparent typical rheumatism will, without doubt, be due to pyemias, or infections with microorganisms, differing from those of true rheumatism, as pus-cocci, gonococci, etc., while again many cases of chorea, tonsillitis, and even of rheumatoid arthritis will prove true rheumatic affections. If we accept the definition, which seems to be a correct one, that "rheumatism is a general disease of bacterial origin, characterized by especially arthritic and cardiac manifestations," we may also be allowed to add: "Contracted by persons whose blood, on account of perverted metabolism, is of especially low alkalinity and immunizing power." In such persons he states that the nervous equilibrium is disturbed by the toxic and irritant products of retrogressive metamorphosis, or disassimilation. Treatment, in his cases, has been directed almost exclusively in the line of digestion and general hygiene. He states that he has found all his rheuma-

tles to be chronic dyspeptics of some sort or other. His patients have, as a rule, been divisible into two distinct classes. The first are spare, nervous men, or especially women, who often suffer from headache, lack of appetite, distress after eating, and constipation. They are, as a rule, extremely light eaters, but drink instead a great deal of tea and coffee. Whatever food taken is low in nutritive value, and the food is bolted and imperfectly masticated. Fresh air, sunlight, and exercise is insufficient; hot baths taken in excess, or not at all; cold baths are never indicated. The second type is the ruddy fat woman, or especially man, with flabby, distended abdomen, and with sedentary or lazy habits. Such persons are usually hearty eaters and drinkers, and suffer from a chronic gastro-intestinal catarrh. His first class of cases he treats with small doses of calomel followed by saline. He recommends a teaspoonful of sodium bicarbonate and sulphate every morning, as well as a pint of hot water and one-tenth grain strychnine sulphate half an hour before each meal. He advises cold sponge baths every morning, and a brisk rubbing down and light massage an hour daily; warm baths once a week and close attention to the diet. Tonic treatment is to be added to this general treatment after a few weeks. In his second class of cases he advises small, repeated doses of calomel alkali, and saline cathartics in some form, a few hypodermic injections of morphine, and ice to the affected joint. Cold sponging followed by some antipyretic, together with dietetic, hygienic, and hydrotherapeutic measures. This treatment he regards as more valuable than the salicylates. He has not found that meat is contraindicated in rheumatism after the temperature has subsided. Attention to the elimination, however, cannot be too rigid. [T. L. C.]

4.—Alfred Meyer discusses municipal sanatoria. In the autumn of 1900 he made a plea before the New York Academy of Medicine for action under the Henry Bill, showing that in Greater New York alone there were about eight thousand deaths a year from consumption, and that there were probably over twenty-five to thirty thousand cases in various stages of the disease. As the final outcome a committee of five physicians was appointed by the council to co-operate with other bodies to further the erection of a municipal hospital for consumptives, and the following resolutions were adopted, which contain, the writer believes, an excellent enunciation of principles for all similar institutions: First. Resolved, That the Committee appointed by the Academy be instructed to use its influence to have the municipal hospital constructed for cases in the early and presumably curable stage of phthisis. Second, Resolved, That while the proper designation for such a hospital would be for curable cases, yet in view of the bad effect a refusal to be admitted would produce upon others, the designation be "Hospital for Incipients." Third, Resolved, That the Committee be instructed to use its influence to have the hospital placed in a locality which would be most productive for good; where there shall be such space that it shall not become an injury and danger to the neighborhood, as would be the case were it placed in a populous locality. Fourth, Resolved, That the Committee be instructed to use its utmost endeavors to have such examinations for admission made by thoroughly competent physicians possessed of such moral stamina as shall prevent advanced and incurable cases being sent to the hospital for incipient cases. Fifth, Resolved, That the Committee be instructed to use its influence to have the rules and regulations of this hospital such that it shall not become an unnecessary burden upon the community. He regards it as important that often the incipient cases of phthisis may do a small amount of work, not only without injury to their health, but with actual benefit to it. This work must be regulated in amount and character by the physician in charge. This system has been introduced at the Bedford Sanatorium of the Montefiore Home, and he shows the economical value of such a method by the food stuffs produced. He believes that no system of municipal care of consumptive poor will be complete which does not also provide for the care of advanced cases within the corporate limits. He believes that the two types of cases should be kept strictly separate; that the incipient and presumably curable cases should be kept in a sanatorium outside of the city limits, and that the

advanced and presumably incurable cases should be treated in an institution within the corporate limits.

[T. L. C.]

5.—T. D. Crothers discusses the treatment of *delirium tremens* and *alcoholic toxemia*. If the delirium comes on abruptly; the exciting causes are acute and point to the formation of toxins. If the delirium has been preceded by mental changes, and transient alterations of thought and conduct occur, gradually becoming more constant and fixed, there are indications of organic lesions of the brain. It is important to ascertain whether the delirium follows from a long period of continuous drinking, or whether the drink period was preceded by some physical or mental disturbance arising from organic disease, traumatism, or mental strain. Whether it followed acute disease, severe exhaustion, or whether there was mental instability as the result of hereditary influence, preceding this state. Alcohol in these conditions may be both an exciting and predisposing cause. Should the delirium follow prolonged excess in the periodic drinker, where the alcohol is abandoned before the delirium comes on, intense hallucinations of short duration, prolonged delusions concentrated upon one subject, will follow. The general pathology of these cases is a vasomotor paralysis, particularly of the blood vessels of the brain; the dilator and constrictor nerves in the walls of the arteries are affected, and a subsequent congestion of the veins is the result. Alcohol also acts directly on the composition of the blood, increasing the number of white blood cells, but diminishing their uniformity and movement, and form. There is at the same time a decrease in the number of red blood cells. The removal of the alcohol is the first step in the treatment. The cessation of the delirium must not be expected to follow the removal of the spirits. Slowly reducing the amount of alcohol, giving narcotics, forcing the feeding with an idea of overcoming the supposed exhaustion, is extremely dangerous treatment. The elimination of the toxins is also indicated. Small doses of calomel with the salines should be given until free catharsis is induced. He recommends a combination of magnesium sulphate and potassium butyrate, two parts of the latter to one of the former, given in small doses according to the conditions present. Next in importance, he believes, are hot-water and hot-air baths, hot packs followed by vigorous rubbing, are useful means in promoting the elimination through the skin. Frequent sponging with hot salt water is another effective measure. He distinctly forbids the use of narcotics to produce sleep. For the craving for alcohol that follows the withdrawal in some cases, strong solutions of quassia or elnchona, given every hour, will soon break up this impulse and produce an intense disgust for spirits. He advises against the prevailing practice of allowing alcohol to be given, and also both solid and liquid foods very freely. Restraint depends largely on the patient, and in certain cases should be associated with as much liberty as possible. The condition of the heart should be carefully watched. He found that ice on the nape of the neck is one of the most powerful excitants that can be used. When the delirium has subsided, different conditions of prostration follow for which he recommends nux vomica or strychnine. In the convalescent stages, both static electricity and electric light bath are the most valuable agents that can be used. The evils to be avoided in all these cases are overdrugging and over-feeding. [T. L. C.]

MEDICAL NEWS.

December 14, 1901. (Vol. LXXIX, No. 24.)

1. The Modern Urethroscope. WILLIAM K. OTIS.
2. Adherent Pericardium. ROBERT H. BABCOCK.
3. Clinical Facts and Their Meaning. JOSEPH M. AIKIN.
4. An Epidemic of Smallpox at the Michigan Asylum for the Insane, Kalamazoo. ARTHUR MAC GUGAN.
5. Rectocolitis. WILLIAM M. BEACH.

1.—W. K. Otis recommends a urethroscope of which the following is a description: It consists of a metal tube or cylinder, an inch and a quarter in length by somewhat less than half an inch in diameter, the first half inch of which is narrowed down conically to form a funnel-shaped diaphragm, leaving an opening of a quarter of an inch in

diameter through which the rays of light emerge. At the other end of this tube of the same diameter forming an elbow at right angles to the first tube, three quarters of an inch in length, into which the handle of the instrument fits. The funnel portion unscrews from the upper tube and a plane-convex lens is placed at this point to concentrate and direct the rays of a small electric lamp placed immediately behind it. This lens can be readily removed for cleaning. The handle consists of a cylindrical piece of hard rubber about one-half inch in diameter and one and a half inches long, to the upper end of which is fixed the electric lamp, while the lower end is arranged to receive the cords leading the current from the battery. A small electric switch in the form of a milled wheel is placed on one side of this handle, a half-turn of which makes or breaks the current. The two small screw-heads are seen on the other side of this handle; the upper serves to clamp fast the hood, the lower to fasten the lamp in position. The lamp is of a variety known as "high efficiency," differing from the others in a special preparation of the filament which enables it to give out a very intense light without a corresponding increase in heat; it is unusually strong and capable of withstanding a current of from sixteen to twenty volts. It is attached to a wire running through the centre of the handle, so that it may be raised or lowered and clamped in position by the lower screw. The only adjustment which may be necessary is, when changing the lamp, to see that the filament of the new lamp comes exactly opposite the center of the lens; a small piece of brass with a pin-hole in it has been placed on the handle behind the lamp socket, so that, by holding this to the light and moving the lamp up or down until the filament is exactly across the center of the hole, the lamp may be clamped in the correct position. The length of the handle and the weight of the instrument varies according to material used and the desire of the operator. The author in his experience with this instrument found an illumination of field such as is not found with any other instrument. It gives the entire field of the tube used, offers no obstruction to the use of applicators, and at the same time nothing is inserted into the urethra which cannot be rendered thoroughly antiseptic by boiling. It is simple in construction, strong, inexpensive, and fulfills all the indications of a good, practical working instrument. [T. M. T.]

2.—R. H. Babcock divides adherent pericardium into two forms: (1) As a result of pericarditis interna, which has led to a more or less complete and firm union of the two layers of the sac without adhesion to the surrounding structures; (2) as a result of pericarditis interna et externa, which has caused adhesions not only between the pericardium and epicardium, but also between the sac and the contiguous structures. This form has also been called chronic adhesive or fibrous mediastino-pericarditis on account of the extensive development of fibrous tissue within the mediastinum, with consequent union of all the structures therein contained. The symptoms vary. In one case they are referable to stasis within the pulmonary vessels, shortness of breath on exertion, cough due to bronchial congestion, and a marked disposition to attacks of bronchitis. In another palpitation either with or without dyspnea are produced by efforts and excitement, occasioning much discomfort and at times alarm. In these cases the pulse is apt to be persistently rapid; it may be irregular and the cardiac impulse is exaggerated in force and extent. In a few cases without co-existing valvular defect, the disturbance of circulation is not pronounced, being shown only by digestive disorders lasting for years and attributed to simple dyspepsia. Generally there is nothing to distinguish them from ordinary cases of mitral disease or from chronic dilatation. Physical examination generally discloses enlargement of the liver, which always has a tendency to return to its large size as soon as treatment is discontinued. Diagnosis is sometimes easy; at other times very difficult. It is difficult when the sac is adherent to the heart, but not to the neighboring structures. The diagnostic signs are inspiratory distention instead of the normal inspiratory collapse of the external jugular or other superficial veins, known as Friedreich's sign, pulsus paradoxus (not always constant nor reliable) and cardiac hypertrophy. When the pericardium is adherent to the chest wall or diaphragm it is easy and certain. Finally, in some cases in which positive signs cannot be obtained, the diagnosis of this

condition is rendered possible by a process of exclusion, together with the history of a previous rheumatic attack and the discovery of an hepatic enlargement for which no other predisposing cause can be ascertained. [T. M. T.]

4.—A. McGugan described the following treatment for smallpox. A few divided doses of calomel followed by a saline. Plain milk or malted milk diet during the febrile period. No medicinal febrifuge was used, depending entirely upon cold water; the bath, pack, the moist girdle, throat and head compress, depending upon the case. During the period of eruption the patients were sponged frequently with a 1:2000 bichloride solution, and during the few hours when the pain was severe from distention of pustules, the hands and face which were the parts complained of usually, were covered with a few layers of gauze kept constantly wet with cold soda bicarbonate solution. As the eruption began to dry it was anointed in the first cases with carbolized vaseline. In the latter cases ichthyol with enough lanoline to give it consistency was used. The application of silver nitrate and of pure carbolic acid to individual pustules was tried, but without any remarkable result. The severest cases wore no bed-gown and were covered with one sheet only. Everything about the patient was kept scrupulously clean. Great care was taken with diet and bathing. [T. M. T.]

5.—W. M. Beach concludes his article on rectocolitis as follows: (1) It is a condition of the rectum and colon of varying degrees of inflammation; (2) a knowledge of the anatomical bearings of the rectum and colon is necessary to understand the symptoms and reflexes; (3) the symptoms are local and systemic; (4) rectocolitis may be catarrhal or ulcerative; (5) it may be acute or chronic; (6) When dependent upon polypus, hemorrhoids, fistula, etc., the cure depends upon their removal; (7) chronic rectocolitis, due to altered secretions, anemia and congenital narrowing of the sigmoid strait, is difficult to cure.

[T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

December 14, 1901. (Vol. LXXIX, No. 24).

1. Laryngeal Paralysis and Their Importance in General Medicine. J. W. GLEITSMANN.
2. Concerning an International System of Quarantine. FRANK W. FOXWORTHY.
3. The Ethyl Bromide and Chloride, respectively, as Surgical Anesthetics, with a Description of an Apparatus for Their Scientific Administration. S. ORMOND GOLDAN.
4. The Daily Medical Inspection of Schools. D. S. LAMB.
5. Hysterical Dissociation of Temperature Senses, with Reversal of Sensibility to Cold. G. W. McCASKEY.
6. Mycosis of the Tonsil and Base of the Tongue. E. HARRISON GRIFFIN.

1.—J. W. Gleitsmann considers the organic causes of laryngeal paralysis under two separate divisions: Those emanating from the bulbous and spinal column and peripheral ones. The former are softening processes, hemorrhages, syphilis, tumors, diphtheria, progressive bulbar paralysis, amyotrophic lateral sclerosis, syringomyelia and locomotor ataxia. Peripheral causes are tumors of the neck (cancer of the esophagus), aneurysm of the aorta, of the innominate, or of the right subclavian (on account of the greater frequency of aortic than subclavian aneurysm the left recurrent is oftener paralyzed than the right), mediastinal tumors, such as malignant growths, infiltration of the peritracheal or bronchial glands in syphilis, pericarditis, pleuritic adhesions, as in tuberculosis, traumatism and injuries; further, infectious diseases, influenza, scarlet fever, typhoid fever, toxic influences principally lead, which is apt also to produce abductor paralysis or rheumatism, both causing peripheral neuritis, although the diagnosis of rheumatism ought not to be made hastily and before an earnest and conscientious search for other factors has been made. The importance of these paralyzes, especially of the abductor muscle, for the practitioner results from the fact that it has very often been accidentally discovered at a laryngoscopic examination and is also frequently observed before the underlying grave affection has been recognized or caused any perceptible symptoms.

For instance in a case in which abductor paralysis antedated all the other symptoms of locomotor ataxia and further, in which the position of one vocal cord in the median line in an otherwise apparently healthy person was the incentive to a careful examination of the entire organism and an aneurysm was found. [T. M. T.]

2.—F. W. Foxworth, after studying the international system of quarantine very thoroughly has come to the following conclusions: (1) Variations in quarantine in the same country, as seen in Calcutta, Bombay and inland cities of India; (2) variations in quarantine between different countries; (3) because of these numerous variations the liability of the spread of the infectious disease is increased; (4) dangers to travelers detained at quarantine stations from infection received there; (5) injurious effects on commerce from variation in quarantine system; (6) the use of pernicious disinfectants; (7) the absurdities of different systems. The author quotes Dr. Robert Koch, who states he believes that unless some international commonsense system is adopted soon, it would be far better to abolish the quarantine system and let commerce and travel be without restrictions of any kind.

[T. M. T.]

3.—S. O. Goldman, in his article on ethyl-bromide and chloride, respectively, as surgical anesthetics, states that these drugs are only applicable to minor operations, and comparisons cannot properly be made with chloroform. Everything considered, chloroform is less safe than either gas or ether, and the ethyl-bromide and chloride are both less safe than chloroform, were they used in the same class of cases. Ethyl-bromide is safer than ethyl-chloride for the reason that it does not require the same concentration as does the latter. It is the same in convenience, rapidity in action and absence of after-effects and is more economical. Compared with ether, these anesthetics are inferior in adaptability and safety. They compare better with nitrous oxide gas than any other anesthetic. All three are particularly valuable as precedents to ether in general anesthesia. Ethyl-bromide and chloride as precedents to chloroform are quite unnecessary, if not dangerous. These anesthetics are administered by the so-called air restrictive methods. The ethyl-bromide is generally placed upon gauze or a handkerchief and closely applied to the patient's nose and mouth; anesthesia is almost instantaneous. With ethyl-chloride various devices have been employed for restricting the waste of the anesthetic; at the same time they also restricted the amount of air. As both the anesthetics are extremely volatile, especially the latter, a certain amount of concentration must be practiced, but this should never be at the expense of the air inhaled. It is far better and safer to use a large quantity of the anesthetic with a free complement of air than a small quantity with a small portion of air. The devices used for ethyl-chloride are tending toward this latter method, a particularly dangerous one. The inhaler used is described as follows: A thin metal horizontal cylinder into the center of which is set a chamber for gauze upon which the anesthetic is placed; upon the superior surface of the horizontal cylinder is placed an expiratory valve protected by a metal box perforated with apertures to give vent to the exposed air. Immediately anterior and posterior to the anesthetic chamber is placed an inspiratory valve, and it is by these valves that both active and passive evaporation of the anesthetic is completely avoided, thereby affording the greatest possible economy in the quantity of the anesthetic used. Both ends of the apparatus are open, affording the freest passage of atmospheric air with the anesthetic during inspiration, while during expiration the anesthetic chamber is entirely closed, the expirations passing through the expiratory valve. When ethyl chloride is used, the small opening in the center of the cap covering the chamber is opened. This affords an aperture just large enough into which the capillary end of the graduated tube fits. Ethyl-bromide may be introduced through this opening or the entire cap may be removed. The valves are made of mica discs perforated in the center with springs just strong enough to effectually close the openings and not impede in the least either inspiration or expiration. The face-piece is made of transparent celluloid with a pneumatic rubber rim; this celluloid feature permits a perfect view of the nose and mouth during administration.

Depending upon the nature and duration of the operation, activity of respiration, the type of patient, weight, etc., from two to five cubic centimeters of either anesthetic is at once placed in the chamber, which is tightly closed and the inhaler applied to the face. After from three to five or six inhalations, anesthesia is induced for the performance of the operation. Before a second application of the anesthetic is made, the patient should become, at least partially, conscious. Neither of these anesthetics should ever, under any circumstances, be administered as chloroform is. [T. M. T.]

5.—G. W. McCaskey reports a case of the above condition in which the interesting features were remarkable disturbance of the sensibility to cold. Thermal anesthesia in cases of hysteria is not perhaps so very rare, but is nearly always associated, according to Oppenheim, with analgesia, as was the fact over the lower extremities of the case reported, although there was no analgesia over the trunk and upper extremities. So far as the author can recall dissociation of the sensibility to heat and cold has not been reported in hysteria, although it has been recorded as the result of organic disease. Dejerme and Thulant, for instance, have reported a case of syringomyelia with complete dissociation of sensibility to heat and cold. In their case, however, there was complete loss of sensibility to heat over a large area. As a matter of fact in the author's case, above reported, thermo-anesthesia in the proper sense did not exist at all. It was rather a hyperesthesia of the sensations excited by cold, the perception being recognized as that of heat instead of cold. Associated with it, however, were other phenomena of the true anesthetic type. [T. M. T.]

6.—E. H. Griffin's treatment of mycosis of the tonsils and base of the tongue is as follows: The patients' throat was treated by the application in succession of chromic acid, carbolic acid, nitric acid and sulphuric acid. This treatment seemed to irritate and produce an extension. It was discontinued and boric acid, nitrate of silver and various other applications were used, but these seemed to act as fertilizers and the growth increased in size. The patient was then ordered to smoke, cigars or pipe, as often as circumstances permitted. This seemed to retard the growth of the plant and greatly diminished the growth on the palate. The next procedure was picking out the root with forceps. The part was then cauterized with chromic acid by a bent probe. The membrane was carefully sprayed with alkaline solution to limit the action of the acid. As the treatment was only partially satisfactory, the patient was given a prescription of iron, glycerine and water, a drachm every three hours to be used without water as a gargle and then swallowed. This solution seemed to have more effect upon the growth than any other preparation. [T. M. T.]

THE BOSTON MEDICAL AND SURGICAL JOURNAL.

1. Twelve Cases of Pneumonia Treated by Antipneumococcus Serum. GEORGE G. SEARS.
 2. Use of Antistreptococcus Serum in a Case of Septicemia Following Mastoid Operation; Recovery. MARY F. HOBART.
 3. A Synopsis of a Three Months' Service in the Gynecological Department of the Boston City Hospital. CHARLES M. GREEN and FRANK A. HIGGINS.
 4. The Treatment of Tumors of the Breast. JOHN H. GLEASON.
 5. Massage and Movements of Hemiplegia. DOUGLAS GRAHAM.
1. Sears reports 12 cases of pneumonia treated by antipneumococcus serum. Six of the patients were over 30 years old; of the other 4 cases one was excessively alcoholic and 2 confessed to its moderate use. Of the 8 cases referred to, 3 used alcohol to excess, 2 others had mitral regurgitation, nephritis and 1 arteriosclerosis. Albumin was found in the urine of 10. There were 9 recoveries from this unpromising series. The only conclusion that can be drawn is the negative one that the course of the disease is not lengthened by the use of serum. It is certainly no specific against the pain resulting from the inflamed pleura. While in some cases a drop in the temperature of a degree or 2 followed an injection, the author was unable to succeed.

by repetition of the injections, in keeping the temperature down, and as an equal rise was occasionally noticed, it is impossible to assert that they produced any influence on the fever in these cases. Skin eruptions, together with pain and swelling in the joints, were occasionally produced.

[J. M. S.]

2.—Hobart reports the case of a woman aged 63 years, who, after complaining of slight malaise, awoke at 2 A. M. with some carache and after that slept very little. At noon her temperature was 102°, pulse 120 and of high tension, face anxious and flushed, and there was great pain in the ear and much tenderness over the mastoid. Paracentesis of the tympanum resulted in a free discharge of blood and serum, after which there was general improvement for 5 days. Then the patient seemed less well, had more pain in the head and the pulse became higher in tension. It was then decided to open the mastoid cells. These were found filled with granulation tissue and pus. After the operation delirium became marked, there was constant restlessness, the temperature had reached 105.2°, pulse 122. Three cc. antistreptococcus serum were given and, 2 hours later, 10 cc. were injected and oxygen was administered. At midnight the pulse became regular and fell to 120, and toward morning the patient slept more. At 10, the following morning, the temperature was 103°, pulse 112 and regular. About this time erysipelas developed in the wound and spread over the eye on the same side, and eventually attacked the nose and the other cheek and eye. The pus, on examination, was reported loaded with streptococci. Two other doses of antistreptococcus serum were injected. The patient recovered.

[J. M. S.]

3.—Green and Higgins report the results of three months' service in the gynecological department of the Boston City Hospital. [J. M. S.]

4.—Gleason divides tumors of the breast into 3 main divisions for treatment: (1) Those coming early in the disease for operation; (2) well advanced cases; (3) inoperable cases. It is of great importance to make a prompt diagnosis; for if we are to save our cases we must get them early in the disease. The author hopes for the early success of those men who are working on the specific organism of carcinoma; that they may soon produce a serum—an antitoxin—which, when developed through careful laboratory experiment and clinical investigation, may stand the test of time. Then we may be able to combat with the knife primary growths and broken down tissue; and to fight successfully, hypodermatically, that great enemy of good results—metastasis. ([J. M. S.]

5.—When paralysis of central origin has come on suddenly, Graham prefers to abstain from the use of massage until the perturbation in general has subsided, and the patient has become somewhat accustomed to his natural condition. Interference with the supply, and return of the circulation, lowering of temperature, passive hyperemia; hypertrophy of interstitial connective tissue with subsequent cicatricial retraction, giving rise to contracture and atrophy of the muscular fibres; formation of adipose tissue or fatty degeneration; vasomotor and trophic disturbances are all rational indications for the use of massage, either as a preventive or as a palliative. [J. M. S.]

16. Notes on Smallpox. S. L. JEPSON.

1.—W. E. B. Davis, in his presidential address at the 11th Annual Meeting of the American Association of Obstetricians and Gynecologists, chose for his subject the surgical treatment of binary calculi with special reference to hepato-tomy. In every case in which gallstones can be diagnosed they should be removed. Reference is made to the great rarity at the present time of binary fistulae after cholecystostomy, due to the fact that the gallbladder is sutured to the peritoneum and fascia instead of to the skin. When gallstones are found during pelvic operations, Davis suggests that they should be removed after the pelvic wound has been closed and not as recently suggested by Kelly. Cholecystectomy is indicated "in gangrene of the gallbladder, multiple or perforating ulcers, stricture of the cystic duct, phlegmonous cholecystitis, empyema with great danger to the walls of the viscus, and malignant disease." The operation is not recommended in cases of chronic cholecystitis; in such cases it is thought that drainage is better. The writer refers briefly to the history of the various operations upon the gallbladder and its ducts. When a stone is present in the common duct and cannot be pressed up into the gallbladder or down into the duodenum, it should be removed through an incision into the duct which should not be closed with sutures, but allowed to drain. Kehr is quoted as supporting drainage in these cases in preference to closing by suture. Kehr's unusual success in the treatment of these cases (six deaths in ninety-seven choledochotomies) is thought to be due to his having drained in extreme exhaustion and cholemia and when marked cholangitis was present. Davis refers to the operation of hepatotomy which he has suggested in cases of obstruction of the ducts with enlarged liver where the gallbladder or ducts cannot be isolated or the patient's condition from exhaustion or cholemia will not permit of a protracted operation. The operation is only exceptionally called for, but the writer relates a number of cases in which he has freely incised the liver, where the ducts have been obstructed, with the most satisfactory improvement in the patient's condition. When this drainage of the liver has resulted in its contraction and improvement in the patient's condition, an exploration of the gallbladder and its ducts can be made. [J. H. G.]

2.—Stengel believes that symptoms occurring in pericarditis are largely the result of the underlying myocardial disease. He emphasizes that pericarditis is the source of danger in one of the three ways. (1) As a focus to infection, (2) as the cause of mechanical or reflex disturbance of the heart action, (3) as a starting point for a spreading inflammatory lesion. He thinks that the sign elicited by a physical examination offers the best evidence of myocardial disease associated with pericarditis. Hypertrophy of the heart develops rapidly in acute cases of pericarditis. He contends that we are forced to adopt the view held by Jürgensen "that pericarditis is the diagnosis of the future, its type may be endocarditic, pericarditic, or myocarditic, but the immediate result and the final prognosis are to a large extent dependent upon the degree of involvement of the myocardium. A few dangers, such as general infection,

embolism, or mechanical interferences with the heart with extensive effusion, are independent of the condition of the heart wall, but, these conditions excepted, the important criterion for prognosis is the condition of the heart muscle."

7.—See Philadelphia Medical Journal, June 15, 1901. Page 1141.

9.—Wm. Frick reports an interesting case of carcinoma of the skin that extended over a period of 35 years. The growth did not present either clinically or microscopically the usual appearance of carcinoma. Sections of the growth are reproduced as illustrations in the article. The fact that the tumor had its origin in the epidermis and that the cylindrical cells alone proliferated separates it from the ordinary cutaneous epithelioma. It is thought that the case is similar to one described by Krompecher as "carcinoma epithellale adenoides." It resembles also a growth described by Brooke as "epithelioma adenoides cysticum" and by Fordyce as "multiple benign cystic epithelioma." The patient refused operation and the growth was removed by an arsenical paste. The resulting cicatrix is being carefully watched for a recurrence. [J. H. G.]

10.—Allen reports two cases of rhinoscleroma. The first occurred in a married woman, 64 years of age. When the patient first came under the observation of the author, the growth occupied the whole thickness of the lip and extended well within both nostrils. On the right side it extended almost to the labio-nasal fold and on the left to the labio-nasal fold. The growth had existed for 16 years. It first appeared as a small mass about the size of a bean in the upper lip. The growth increased in size and finally broke down in a gangrenous slough, exposing the bones of the upper jaw and nasal septum. Surgical interference was out of the question. The second case occurred in a male, 49 years of age. Nineteen years before the patient came under observation, he noticed a small growth upon the right side of his nose. For 13 years it did not increase in size. It then grew rapidly and at the time this report was made, the entire nose was much enlarged and the nares were almost occluded. The article is illustrated by photographs of both cases. [F. J. K.]

11.—Williams discusses the role of the mast-cells in acute and chronic infections. He is inclined to the view that it may be said when mast-cells become increased, plasma-cells are likely to be present in much greater numbers, and he further thinks that plasma-cells appear to be more closely associated with infectious processes than mast-cells. Finally, he states that sufficient evidence is lacking to show that mast-cells have any special relation to infections or to a particular infection. [F. J. K.]

12.—McFarland relates some investigations upon antivenene and suggests the following conclusions: "1. It is not difficult to produce immunity to the nervous poison contained in serpent's venom, as shown by Wolfenden, Phisalix, Bertrand and Calmette. 2. This immunity when carried to a high degree is associated with a marked antitoxic power of the blood. 3. It is very difficult if not impossible to produce immunity to the irritative poison of the venom. 4. Antivenene does not protect very powerfully against the irritative poison. 5. Antivenene protects against the nervous poisons of various venoms. 6. Immunity to the unmodified venom is better secured by intravenous than by subcutaneous injection. 7. Calmette's methods of immunization with the modified venom is greatly to be preferred to the method of immunization to the

modified venom as tried in these experiments, because of the modicum of danger and suffering to the horses used. 8. Calmette's antivenene is more useful for the treatment of the bites of cobras and colubrine serpents than for those of vipers, etc. 9. As the antivenene protects against the chief death-dealing elements in the venoms, it is of great use in the treatment of all serious bites, and should be used whenever possible. 10. The neutralization of the nervous poison of the venom by antivenene will enable the individual to devote all his vitality toward overcoming the local injury done by the irritative globulin in the venom. 11. All individuals—certainly not all horses—are not equal in their resisting power against venom. Two of my three horses succumbed quickly to the venom injections. 12. The antivenene producing power varies in different horses. 13. The quantity of antivenene in the blood varies from time to time, according to circumstances." [F. J. K.]

13.—See Philadelphia Medical Journal, June 15, 1901. Page 1141. [F. J. K.]

15.—Hugh T. Patrick, in discussing traumatic neuroses, asserts that the diagnosis or recognition of the condition is not difficult but that the essential step is the exclusion of organic disease and for this a single examination is not always sufficient. In my experience incorrect diagnoses are ordinarily made because of failure to recognize: 1, that pain, tenderness, paresis or paralysis, hyperesthesia, anesthesia, incoördination, tremor, dizziness, tachycardia, syncope attacks, vomiting, loss of weight even to emaciation, impaired speech, convulsions and poor vision, are not necessarily indications of organic disease, no matter how continuous or how long continued the symptoms may be; or 2, that atrophy, reaction of degeneration, incontinence of urine or feces, retention of urine (generally), loss of deep reflexes, bedsores, Babinski's sign, ocular or facial paralysis, optic atrophy or neuritis, hemianopia, glossy skin, rapid (five or six per second) and uniform ankle clonus, impaired pupillary reaction, semi-erection of penis, and anesthesia corresponding exactly to a peripheral nerve or spinal segment, indicate organic disease. In trying to elicit the presence or absence of organic disease one of the best methods is the establishment of the line between normal and abnormal sensation. In nearly every organic case it is impossible to definitely locate when anesthesia ends and normal sensation begins, whereas in functional disease the distance between complete anesthesia or analgesia and normal sensation is frequently not more than 1/16 or 1/32 of an inch. In order to bring out these points the patient must be blindfolded and the greatest care taken in the examination of the sensation. In functional sensory disorders it is also shown that if the patient is re-examined after a short interval, the line of demarcation will not remain the same and not infrequently the tender points will not be the same at the second as at the first examination. A traumatic neurosis is never produced complete and at once by an accident, but develops slowly. It is a product of evolution. The great necessity of an early diagnosis is shown since so much will depend upon the way in which the patient is treated. Attention is also called to the bad effect upon these patients of litigation, quack literature, and the advice and sympathy of friends. These patients "are to be protected from ignorant doctors, foolish friends, designing lawyers, and their susceptible selves." It is extremely important to divert the patient's mind from the constant thought of his injury and to get him back at work and into a wholesome and cheerful frame of mind. A settlement out of court of the damage suit will result in a much more rapid return to health in these cases. Stress is laid upon the fact that the diagnosis should be made early and the treatment should be prophylactic. [J. H. G.]

16.—Jepson mentions some of his views in regard to the mild smallpox, that has been so prevalent during the past two years, and he thinks that as yet no satisfactory explanation has been offered to explain the mildness of recent

cases of variola. He informs us that the mortality has nowhere been greater than 2% which is less than the mortality from whooping-cough. He states that we can do very little to prevent the spread of whooping-cough and believes that the only protection necessary against smallpox is to be found in vaccination. [F. J. K.]

7. What Protection Have the People Against the Dairy?
D. M. McMASTERS.

1.—J. M. T. Finney and Louis P. Hamburger discuss the relation of appendicitis to infectious diseases. During the past year they have observed cases of propagated appendicitis following in the wake of an enterocolitis. They have also seen three cases of appendicitis associated with arthritis which has called their attention to a second group—namely, those forms of appendicitis which may be the local expression of a general infection. In at least six instances during the recent epidemic of influenza the appendicular inflammation appeared soon after the attack. There seems to be occasionally an intimate relation between polyarthritis and appendicitis, and there may or may not be a family or personal history of rheumatism. It is important to note that the articular disease may precede, or follow the appendicular inflammation. It is well known that an acute disease or a trauma may produce an attack of gout, and postoperative and posttraumatic malaria are quite familiar to us. They believe that there is a relation between appendicitis and rheumatism observed in their series of cases, in view of the proof adduced in the case of influenza and the collateral support afforded by the production of appendicitis by infecting the blood of animals. Finally a third argument in favor of the existence of this class of appendicitis is the favorable influence which the salicylates exert. They would not, however, be understood to imply by this that our present view of the treatment of appendicitis should be influenced by the effect of the salicylates in these selected cases.

[T. L. C.]

2.—J. E. Rhodes reports a study of 35 cases of chancre of the tonsils. His conclusions are: (1) Chancre of the tonsils is often unrecognized because hypertrophy and inflammation are so frequent and are so closely simulated by the early symptoms, which often differ little from an ordinary sore throat; (2) an enlarged and indurated tonsil with a superficial ulcer upon its surface, accompanied by enlargement and induration of the contiguous submaxillary gland and which is unchanged by a prolonged course of treatment, renders a diagnosis of chancre probable; (3) the character of the chancre depends upon the original condition of the tonsil as to size, the amount of follicular inflammation and the coincidence of a mixed infection; (4) a certain diagnosis cannot be usually made until the general eruption of the disease; (5) the explosion of the disease is no more severe than in chancre elsewhere; (6) the disease is contracted by direct contact or by various media, carrying the virus; (7) when we consider the frightful contagiousness of syphilis and the frequency with which it is conveyed to innocent persons, the most careful use of the throat and nose, dental and other surgical instruments, clinical thermometers, etc., is necessary; (8) separate instruments should be used for examination and treatment of known syphilitics, but the possibility of contamination before the existence of the

inc has been recognized make it imperative that every operator should employ a rapid and efficient disinfection or sterilization of instruments after the examination or treatment of every patient.

3.—Krusen reports a case of **instrumental perforation of the uterus** without ill results, and gives a short review of several remarkable instances of this accident. In the case he reports a perforation large enough to admit of the index finger was found in the fundus, through which a piece of the omentum protruded. The patient was relieved by oeliotomy. [W. A. N. D.]

4.—F. W. Langdon and D. I. Wolfstein report a case of **gunshot wound of the spine**. Paraplegia with the persistence of the flexor plantar reflex resulted. An operation was performed and it was found that the canal was penetrated by the bullet. The fifth thoracic spine was found attached to this place. The dura presented a ragged opening. No gross lesion of the cord could be discovered. The plantar reflexes were present, and flexor in direction in all the toes. The necropsy revealed a condition of **central hematomyelia**. [T. L. C.]

5.—A. J. Downes discusses **appendicitis in the female**. He states that no surgeon is justified in diagnosing a case as appendicitis in the female without a deliberate and careful examination, including a bimanual vagino-abdominal one. Rigidity of the right rectus muscle alone is of no importance as a diagnostic feature. He recommends that the incision for appendicitis in the female should be with few exceptions either in, or close to the right semilunar line to control the pelvis and appendix. Gynecologists should in all cases, in which the abdomen is opened for pelvic disease, expose the appendix and remove it if it shows the slightest tendency of disease. [T. L. C.]

6.—W. J. Conklin discusses the **cardiovascular system in interstitial nephritis**. In this condition we have a slowly progressive degeneration of the kidneys, which ultimately results in granular contraction and atrophy. In addition there is a widespread and very constant cardio-vascular change which points to some profound toxemia, and renders the blood irritating to the entire vascular apparatus of the body as well as to the capillaries of the kidneys. The view most generally accepted regards the arteriosclerosis, which is the essential lesion of the circulatory organs, as secondary to the renal disease and dependent upon the failure of the kidneys to remove from the blood certain offending toxins. He considers the question of diagnosis of interstitial nephritis, the condition of the cardiovascular system in this disease, and the treatment of the condition. He states that a typical case of granular contracted kidney, even with extensive cardiovascular lesions, usually does well just so long as the vascular tone is maintained in good condition, but any failure in this direction adds immensely and immediately to the gravity of the prognosis. The only remedies to be needed are the vasodilators. A severe hemorrhage anywhere in the body not only justifies a bad prognosis, but life is rarely prolonged beyond two years. In the latter stages of a chronic nephritis, when we are confronted with dilated chambers, leaking valves, and serious degeneration of the cardiac muscle, the therapeutic problem is quite different. The paramount indication now is to improve the nutrition and tone of the heart and to lessen its work. This is best met by absolute rest of body and mind and with the so-called heart tonics, of which digitalis, strophanthus, caffeine and strychnine are those of choice. He believes that the diuretic wine of the *Hôtel Dieu* is an old but effective combination.

[T. L. C.]

7.—D. M. McMasters discusses the question: "What protection have the people against the dairy?" He believes that the law in regard to dairies should be such that a rigid inspection should be made twice yearly. It should be impressed upon the man in charge that the number of bacteria in milk depends upon four things: (1) The original amount of germicidal substance in the milk over which they have no control; (2) the number of bacteria falling in during the milking or afterward; (3) the length of time which has passed since milking; (4) the temperature at which it is kept. He advises physicians who suspect that milk is impure and is having a deleterious effect upon his patient, to have an examination

made at once. He also recommends that the Bureau of Health keep careful watch upon the milk from the time it reaches the city from all depots, and that it should be carefully examined if it is suspected. [T. L. C.]

1. On the Chemical Composition of the Capsules of Bacteria and the Nuclein Substances of their Bodies. N. P. KRAVKOFF.
2. Forms of Hypnotic Sleep and their Relation to Treatment. PII. E. RIBAKOFF.
3. On the Question of Epigastric Hernias. I. A. ROMANIN.
4. On the Casuistic of Extrauterine Pregnancy. G. W. WARSCHAVSKI.
5. The Composition of a Mineral Spring in the Government of Pskoff. N. A. ORLOFF and A. F. DRZSHEVETSKI.
6. A Case of Spontaneous Cure of a Fibroma of the Esophagus. K. D. SARKISOFF.
7. A Rare Case of Toxæ Gastritis with Complete Separation of the Gastric Mucosa. F. L. SAMSONOFF.

1.—Kravkoff has made some very important observations on the chemical composition of bacteria. Having cultivated the *b. pyocyaneus* in large quantities of bouillon at noon temperature, he separated the various constituents by a modification Schmiedeberg's method, as follows: A one-month bouillon culture of the organism was precipitated by successive and alternating portions of acetate of copper and caustic soda. Within 24 hours a well marked sediment formed, the clear supernatant fluid showing the biuret reaction. The sediment was removed by decanting the clear fluid, washed in water, dissolved in weak acetic acid, filtered and again treated with acetate of copper and caustic soda, this process being repeated several times until the supernatant liquid no longer gave the biuret reaction. The absence of the biuret reaction served as an indication that all of the albuminous substances were extracted from the bacteria. The sediment and the albuminous substances in solution were collected separately for examination. The sediment was freed from copper by repeated washing with weak acetic or hydrochloric acid, washed with water, alcohol, ether, and dried in the dessicator. When examined microscopically, it was found to be composed of the membranes of the bacteria, while a chemical analysis showed its composition to be closely allied to chitine, having the elementary composition of C-46.20, H-6.70, N-8.82 and O-38.28. When burned, the ash was found to be composed principally of oxide of iron (16%) and a little silica. This large amount of iron, the author believes, plays an important role in the fermentative and oxidizing processes in which bacteria are concerned. The albuminous substances in solution were precipitated by means of weak acetic acid, the sediment washed with water, dissolved in weak alkali, again precipitated, washed with water, alcohol and ether, and dried over sulphuric acid. A chemical analysis showed the substance to belong to the group of nucleo-albumins or nucleoproteins, showing the elementary composition of C-52.73, H-6.91, N-16.50, P-2.11, S-1.00, O-20.75. These nucleo-albumins were found to possess marked toxic and pyrogenic properties. This they shared with the nucleo-albumins of other bacteria and fungi isolated by Ivanoff by the author's method. The nucleo-albumins of pus were found to be pyrogenic to a far lesser extent, while those of the normal spleen and frog's eggs were devoid of pyrogenic properties, showing the specific nature of the bacterial nucleo-albumins. [A. R.]

2.—Ribakoff presents the following conclusions to his discussion of the forms of hypnotic sleep and their relation to treatment: 1. Practically, for therapeutic purposes, it is important to distinguish the forms and degrees of hypnotic

sleep. 2. Into the foundation for the classification of hypnotic sleep into various forms should enter the view which on the one hand does not exclude the possibility of taking into consideration the personal peculiarities of the hypnotic person, and on the other gives a representation of the degree of sleep independent of the fact as to whether the degree of sleep is a constant peculiarity of a given person, or may become more profound under certain circumstances. 3. The probabilities of a favorable therapeutic action, aside from the peculiarities of the disease, are determined by the suggestion as well as to the ability to permanently assimilate a given suggestion. 4. The degree of natural susceptibility bears no physiological relation to the intellectual development of the individual nor to the natural will-power. 5. Susceptibility to suggestion in one form or another is peculiar to every psychically normal person. 6. Congenital absence of susceptibility to suggestion is an indication of mental degeneracy. 7. The chances for therapeutic success, all things being equal, are in direct proportion to the natural susceptibility to suggestion. 8. Hypnotic sleep increases temporarily the natural susceptibility, and is therefore utilized for therapeutic purposes. 9. There is no direct relation between the stage of hypnotic sleep and the degree of the natural susceptibility to suggestion. In persons possessing this susceptibility to a high degree, the hypnotic sleep may be light and vice versa. 10. The extent of therapeutic action bears only a relative correlation to the degree of the hypnotic sleep (depending on the degree of natural susceptibility and psychical assimilation of a given person. [A. R.]

3.—Romanin's observations on epigastric hernia led him to the following conclusions: 1. Epigastric hernias were frequently met with, occupying the second place in relation to the other forms of hernia. In contradistinction to the inguinal and umbilical hernia, epigastric hernia is very rare in children. It is twice as frequent in men as it is in women. 2. The diagnosis of epigastric hernia is not difficult. It is much more difficult to determine whether the morbid symptoms of which the patient complains are due to the hernia or some other conditions. 3. The morbid manifestations in epigastric hernias may be very painful, but in the majority of cases the suffering is slight, and the patients submit to an operation much more rarely than they do in other forms of hernia. Statistics are given, comprising 829 cases of hernia among patients treated at the county hospital during a period of 3 years (total number of patients 36,340). According to age and the variety of hernia, the cases are tabulated as follows:

[A. R.]

Age.	Inguinal		Femoral		Epigastric		Umbilical	
	M.	F.	M.	F.	M.	F.	M.	F.
1-10	121	7	—	—	1	3	47	36
11-20	57	—	—	—	—	—	7	2
21-30	50	5	—	4	12	3	—	3
31-40	69	9	1	3	29	16	3	6
41-50	65	19	1	11	30	11	3	4
51-60	81	9	3	1	15	7	2	5
61-70	27	3	—	3	12	1	—	2
71-80	5	2	1	—	—	—	—	1
81-90	5	—	—	—	—	—	—	—
Total	480	51	6	25	169	44	62	59

4.—Warschavski reports a case of extrauterine pregnancy in a multipara, 38 years old, in whom the clinical picture led to a diagnosis of endometritis following miscarriage and ovarian cyst. The error was discovered upon operation.

This was one of those rare cases in which a tubal pregnancy ruptured into the tube. [A. It.]

6.—Sarkisoff reports a case of fibroma of the esophagus which was cured spontaneously. The patient, a girl of 27, suffered for 2 years from pain in the cardiac region and in the left of the chest. The pain was made worse by eating, drinking, lifting heavy weights and bending. One morning she fell nauseated and coughed violently. With the expectoration a bloody mass, the size of a pigeon's egg, was discharged. This, upon microscopical examination, proved to be a fibroma which had undergone necrosis. From the clinical symptoms the author concludes that the growth was located on a level with the sixth dorsal vertebra where the esophagus crosses the left bronchus. After the discharge of the growth all subjective symptoms disappeared. [A. R.]

7.—Samsonoff reports a rare case of toxic gastritis, with complete necrosis of the gastric mucosa, in a man, 39 years old, who ingested two tablespoonfuls of strong hydrochloric acid with suicidal intent. At first the patient suffered from excessive vomiting due to the irritation of the necrosed mucosa. This soon subsided and a condition of stenosis of the pylorus supervened. Death from inanition followed at the end of three months. [A. R.]

MAX HERZ.

21. Traumatic Intraperitoneal Rupture of the Bladder.

KARL DOHRN.

12.—Ziegler relates in detail the results of his experiments upon fractures of the long bones in guinea-pigs. Healing occurs as a growth of the inner layer of the periosteum first. Almost at the same time the cortical layer of the marrow and the endothelium of the Haversian canals begin to grow at some distance from the seat of fracture. Thus the bone grows almost as soon as the periosteum in the reparative process. In some cases cartilage seems to be formed very early also. The succeeding stages of the repair after subcutaneous fractures, in animals, are fully described. A number of plates show the microscopic findings. No conclusions can be drawn from his work. [M. O.]

13.—Franke reports a rare case of resection of the stomach for cancer of the lesser curvature and pylorus in a man of 79 years. Though the resection and gastroentero-anastomosis took two hours and a half, under anesthesia, and pneumonia with empyema which necessitated resection of a rib followed, the old man recovered after a siege of three months. The carcinoma covered a large part of the stomach walls, being about 12 cm. in diameter, and 2.5 cm. thick. The only symptoms, beside the tumor, were anorexia, vomiting, and slight emaciation. The position of the tumor could not be diagnosed by abdominal palpation. The operation was complicated by the age of the patient, the pneu-

monia, which came on two days after operation, and the empyema. Franke believes that careful examination of all patients will reveal operable cases of the stomach early. [M. O.]

14.—Pagenstecher reports the case-histories of three deformities of the extremities. The first case was a case of brachydactylia in a girl of 21, the fingers of her left hand being much shorter than those of the right. The left hand is also smaller. Röntgen photographs show that only the phalanges are shorter. The second case was one of pollex valgus in a boy of 11. The terminal phalanx of one thumb was sharply bent toward the ulna. The boy had upon that hand another thumb which was amputated. The third case was a girl of 20, with luxation of the head of the right radius, the metacarpal bones of both thumbs included in the hands, and the phalanges of the thumbs abnormally abducted. Röntgen photographs show that the metacarpal bones of the thumbs are lengthened. Besides, numerous contractures existed in many of the fingers. While heredity may predispose to such anomalies, chance alone can explain them. [M. O.]

15.—Blecher gives the case-histories of 16 patients with joints which had become stiff from injury or following immobilization. In every case hyperemia was produced artificially. In all but a few cases great improvement with excellent movement resulted. No other influence was exerted in any of these cases. The long shrunken muscles again become well nourished, and normal motion soon develops, as a rule. Unabsorbed remains of old injuries are then rapidly absorbed, all signs of them disappearing quickly. Two other case-histories are reported, in treating which Blecher employed not only artificial hyperemia, but massage and mechanical exercise also. The improvement was then more marked and recovery more rapid. Blecher used the Dumreicher-Helferich method of producing passive hyperemia. He suggests that the hot air treatment afterward, added to this combination of passive hyperemia, massage, and mechanical motion, will, by the production of an active hyperemia, surely cure any stiffness that may remain. [M. O.]

16.—Stempel gives a most detailed review of the literature of senile hip disease, mainly dating from long ago. He then reports the case-histories of his 58 cases in full. To show how rarely this affection is recognized nowadays, Stempel states that it was correctly diagnosed in but four out of the 58 cases which he observed. Exact examinations and regular movements of the hip-joints in every case seen will reveal this condition at once. The affection is common among farm laborers, generally between 50 and 60 years of age. It has been noted, rarely, as early as thirty years. Constant hard work, exposure to all sorts of weather, and subsistence upon very little food, seem to predispose to this affection. Trauma may also cause it. Senile hip disease is slightly more prevalent among men than women. A gradual destruction of the cartilage of the acetabulum and the end of the femur takes place, with a thickening of the bone and the surrounding soft parts. The joint-capsule changes its shape, and the bone becomes deformed, as in arthritis deformans. This deformity is often palpable. There may be pain in the hip, back, thigh, leg, etc., increased in severity upon motion. Crepitation may also exist. Both hips were affected in about one quarter of the cases. In 44 cases the other joints were found normal; in 9 cases the shoulder; in 4 the knee; and in one the hand and vertebrae were also affected. Both emphysema and arteriosclerosis were present. Atrophy of the muscles of the leg followed. In 17 of the 58 cases the attending physician had made a diagnosis of sciatica. Arthritis deformans alone resembles this affection. While senile hip disease can not be cured, care, friction, baths, massage, electricity and a support will benefit the condition. Stempel trusts that in the future physicians will recognize senile hip disease. [M. O.]

17.—After giving a detailed list of the operations and

the experiments found in the literature upon the removal of foreign bodies from the esophagus through the stomach. Wilms reports the case of a man of 28, who had swallowed part of his false teeth. Rontgen photographs showed that the teeth were lodged between the eighth and ninth dorsal vertebrae. An incision was made into the abdomen, to the edges of which the stomach was then sutured. The fundus was opened and the index finger introduced up through the cardiac orifice of the stomach into the esophagus. A sound was introduced at the same time through the nose, and the foreign body directed out through the gastric opening, pushed by the sound and dislodged by the finger. In some cases it will be necessary to insert the whole hand into the stomach. The only danger is infective peritonitis, which, however, seems to be rather rare. The gastric incision must be made near the cardiac end, not near the pylorus. His patient recovered by the sixteenth day after operation. [M. O.]

18.—The good results achieved by von Eiselsberg in implanting the ureter into the rectum led him recently to try implantation of the urethra in the rectum, in a case of epispadias. Rosenstein reports this operation upon a boy of eight. The urethra was first laid open up to the bladder, a distance of only $\frac{1}{3}$ cm. The inner end of the urethra was then bent upward at an angle of 270° , which had no effect upon the incontinence of urine. Three months later perineal and anterior incisions were made, and the urethra implanted into the rectum, a catheter being left in place. About six weeks later pain and tenesmus were noted with urination and defecation. Examination through the rectum showed that the urethral opening had contracted. This was slit open and another catheter put in. For three months he remained continent and well. Then the pain returned. Gradual dilatation of the urethral opening into the rectum was kept up; but the urine continued flowing from the anus, drop by drop. Finally a fistula was established by the Witzel method, and the urethro-rectal connection severed. The boy is now continent, the fistula closing well. There is only a slight cystitis. A catheter is inserted when he wishes to urinate. Rosenstein believes that much can be learned from the different operations undertaken upon this case. He describes them all in full. [M. O.]

19.—von Burekhardt believes that the terms diffuse, general, or total peritonitis should not be used. He prefers progressive peritonitis. Most cases of peritonitis with epityphlitis he believes are cases of progressive, dry, septic peritonitis. He has operated upon 17 such cases, three of the patients dying. A table follows, showing the salient features of each case. He divides them into three groups, the acute group, serious in from 12 to 24 hours; those in which the serious symptoms occur later; and those in which a circumscribed focus of inflammation had existed before the progressive peritonitis appeared. von Burekhardt leaves drainage in the abdominal wound as a rule. The entire article is written to protest again against Sonnenburg's opinions upon peritonitis following appendicitis. [M. O.]

20.—Herz discusses the experiments performed recently by Maas, and compares his deductions with those of Lorenz. Herz believes that the conclusions drawn by Maas, while more plausible, are yet less substantiated by experiment than those of Lorenz. No doubt exists, however, that bone production occurs in spite of mechanical pressure or traction, and that when this is removed, the bony process goes on to recovery as far as is possible. [M. O.]

21.—Dohrn reports a case of intraperitoneal rupture of the bladder in a man of 41, from an accident. Laparotomy was performed 48 hours later, and the patient left the hospital in excellent condition three weeks afterward. [M. O.]

10. A Case of Incarcerated Hernia of the Lateral Abdominal Wall. CARL STERNBERG.
- 11.— Multiple Sarcoma of the Small Intestine. CARL STERNBERG.

1.—Paltauf, in a brief review of the theories of immunity in cellular pathology, states that the irritability of the cell both protects it and causes its death. [M. O.]

2.—Kraus and Clairmont review their former experiments and detail some later series of investigations. Serum from horses treated with diphtheria toxin, pyocyanus, colon, and pest bacilli cultures exerts an antihemolytic influence upon tetanolysin and staphylolysin. Diphtheria immune horses show an increased antihemolytic action, greater against tetanolysin than against staphylolysin. The cause of this specific action is unknown. Normal animals show less antistaphylolysin than antitetanolysin. In pig's serum antitetanolysin, antistaphylolysin, and antivibriolysin were found. When treated with immunizing serum, the antistaphylolysin is found unchanged by the vibriolysin. These investigations prove the difference and specificity of the bacterial hemolysins and antihemolysins. [M. O.]

3.—Eisenberg gives a thorough review of the literature upon the hemolytic influence of a human serum. He reports his investigations in the examination of the serum of 150 patients with different diseases. A positive reaction was found only in cachectic individuals. This is a reaction of immunity, caused by the absorption of the erythrocytes or their component parts, causing the production of iso-agglutinin and isolysin which, while seen exceptionally in normal subjects, are commonly found in the infectious diseases and croupous pneumonia. The isolysins of a serum are ineffectual against the erythrocytes of the individual from whom the serum originates, and can cause no hemolytic influence in that organism. Eisenberg concludes that the occurrence of iso-agglutinin and isolysins is not specific in the infectious diseases, and is of no diagnostic value, being the simple expression of the reaction of the organism following the absorption of the erythrocytes. [M. O.]

4.—Schläfrig reports a case of *ozena* existing for several years in an old farmer. A pure culture of a micro-organism was obtained which proved pathogenic in mice, guinea pigs, and rabbits. It retained its pathogenicity after being passed through several animals. Schläfrig states that the bacteria resembled the *micrococcus tetragenus*, and were undoubtedly *sarcinae*. [M. O.]

5.—Kreissl reports the autopsy in a case of pulmonary anthrax. There were serous effusion in the pleurae, infiltration of the intrapleural and subpleural lymph-glands, bronchopneumonia in the right upper lobe, edema of the mediastinum, bloody infiltration of the bronchial and jugular lymph-glands (without any affection of the upper air passages, gastrointestinal tract, or skin), multiple hemorrhages of the cerebrum, ependyma and meninges, and on bacteriological examination typical anthrax bacilli. Clinically the symptoms resembled those of cerebral hemorrhage, with dyspnea, evanescence, pleural effusion, and bronchopneumonia later. [M. O.]

6.—After fully reviewing the literature, Schwarz states that proliferation of the spinal cells occurs by mitosis, indirect division, and never by amitosis. When a cell

divides, there can be no doubt that the smaller cells are the younger cells. These may contain granules. When a cell shows no signs of proliferation after long watching, it has reached its final form. The changes occurring are twofold, biological, showing the ordinary proliferative changes, and methodical, showing granules and specific staining properties. Staining is exceedingly difficult. Schwarz concludes that all the cells of the spinal cord are reproduced with mitotic changes. One sort of cell never becomes another. Cells containing granules develop in embryo only from those without granules. Later they may form young cells with granules. [M. O.]

7.—Dextrocardia is very rare. Paltauf reports a case in which he performed the autopsy. This occurred in a woman of 22, in whom rheumatism and aortic insufficiency with hypertrophy and complete adherent pericardium followed. The other organs and the large blood vessels occupied their normal positions, the liver alone showing a depression under the heart. Paltauf believes that in this case the heart developed normally, but then was turned to the right, instead of to the left. He shows this *dextroversio cordis* in a series of diagrams, and cites other similar cases. He suggests that a fetal pericardial effusion may cause the condition. While true dextrocardia involves the transposition of the large vessels with the heart, *dextroversio cordis* is the condition in which the heart alone is twisted to the right side, its relations to the other organs, etc., remaining unchanged. [M. O.]

8.—Paltauf reports the case of a child of nine months with chronic hydrocephalus, paralysis and contractures, that died of marasmus following chronic gastro-intestinal catarrh. He describes the occurrence of furrows reaching in from the meninges, in the upper part of the spinal cord, as far down as the thoracic cord. These furrows reach in some distance laterally, below the median line. The pyramidal tracts could not grow on account of the bilateral affection of the cerebrum. Such a condition has never before been described. [M. O.]

9.—von Tannenhain reports a case of *pseudoxanthoma elasticum* upon the shoulders and hips of a woman of 74. The lesions are described fully with histological drawings, showing marked changes in the elastic fibres. Other cases are quoted from the literature. [M. O.]

10.—Sternberg relates the history of a woman of 61, in whom a hernia of the lateral abdominal wall occurred. She refused operation, and died on the fourth day. The autopsy showed an incarcerated hernia of the lateral abdominal wall, a rare condition of unknown cause. A few such cases were found in the literature. [M. O.]

11.—Sternberg also reports a case of multiple sarcoma of the small intestine occurring in a man of 41. Twelve polypi were found in the jejunum, an intussusception in the ileum, and an invagination in the jejunum. The mucous membrane was thickened in places, while the retroperitoneal and mesenteric lymph-glands were enlarged. Histological examination showed the condition to be primary sarcoma of the small intestine. A review of the literature of the subject follows. [M. O.]

1.—To be continued.

2.—Hirschfeld refers to a considerable number of cases collected chiefly from the literature in which there seems to be a more or less definite relation between accidents of various kinds and diabetes. He admits the relation between pancreatic lesions and diabetes, but mentions cases in which old pancreatic lesions existed with acute diabetes

and other cases in which either the pancreas was involved without diabetes, or there was diabetes without pancreatic disease. He inclines to the belief that something besides disease of the pancreas must be active in the production of diabetes. He believes that trauma probably causes changes in the pancreas itself more frequently than we are accustomed to believe, and he strongly inclines to the belief that trauma is a very active cause of diabetes, but offers no very definite proof of this. [D. L. E.]

3.—Solomon refers to the bacilli which he described in 1899 which produce a condition resembling diphtheria in some cases. He also refers to the statistics of 737 cases in which examinations of the throat for the presence of diphtheria bacilli were made, and in 30% of which diphtheria bacilli were present. In 3 instances the spirochetæ bacilli were present, and in all of these instances the diphtheria bacillus was absent. He refers to the results of other workers also, and decides that since this bacillus was practically never present with true diphtheria, its presence indicates the absence of diphtheria. He has been able to find no instance of mixed infection with diphtheria reported in the literature. He reports however, some instance in which an angina produced by these bacilli occurred in association with secondary syphilis of the mouth and throat. In the large number of cases of stomatitis which he has investigated he has found these bacilli present in but one instance.

[D. L. E.]

4.—Bronstein found that by passing the Danysz bacillus through a series of animals (infection per os) the virulence of the bacilli became markedly reduced; a fact which is of very great importance if one attempts to use this bacillus for the purpose of producing an epidemic in rats. The chief causes of this are the unfavorable influence of the acid gastric juice of the animals upon the bacillus, and the marked acid production in cultures. In order to overcome these unfavorable factors he grew the bacillus on strongly alkaline agar, and instead of making a suspension of the bacilli in salt solution, he used fairly concentrated soda solution. The results were that the animals were killed in large numbers, and cultures obtained from them were still extremely virulent. The species of rats also had some influence upon the grade of virulence. If a culture was increased in virulence by passing according to the above method, through white rats, it became less active with gray or brown rats, and vice versa. He therefore recommends that in attempts to kill rats in large numbers, a culture known to be virulent with that species of rats should be used. He believes that this bacillus can be satisfactorily used in exterminating rats. [D. L. E.]

June 13, 1901. (Vol. XII, No. 24.)

1. On the Biology and Morphology of Old Diphtheria-Cultures. V. I. NEDRIGAILOFF.
2. On the Physiology of the Pyloric Portion of the Dog's Stomach. A. I. SCHEMIKIN.
3. Contribution to the Biology of the Labferment.

V. N. OKUNEFF.

1.—Nedrigailoff found that diphtheria bacilli kept on blood serum in sealed tubes preserved their vitality for a period of over 4 years. When tested as to virulence and toxin production, the cultures showed no appreciable change. The observation of Spring (*Centralblatt f. Bakteriologie*, Vol. XXVI) on the mycelium formations in old cultures could not be substantiated by the author. He did find these mycelia, but, as shown by cultivations on agar, they were due to a contamination with moulds. By the use of carbol-fuchsin and methylene blue (1 c.c. of each to 40 c.c. of water; stained 1 minute) he was able to demonstrate the gradual disappearance in old cultures of the Babes-Ernst granules (the *Biophoren* of Marx). The author's conclusions are: 1. Diphtheria bacilli may without reseeded preserve their vitality on horse's blood serum for over 4 years. 2. During this period no changes in the

virulence or toxin production of the bacilli take place. 3. The Babes-Ernst granules are the only morphological elements on which the vitality of the bacilli depends. 4. True spores are not observed in old cultures. [A. R.]

2.—Will be abstracted when concluded.

3.—Okuneff has made a further study of the labferment which, according to his investigations commenced in 1895, was shown to possess the double function of coagulating cases in milk and regenerating the peptones into an anhydrous form of albumin. His conclusions at that time were that the disappearance of the peptones from the digestive tract and their absence from the blood and lymphatics were brought about by a regeneration of the peptones into anhydrous albumin, this constituting one of the biological functions of rennin. The regeneration takes place in the stomach and small intestines and is greatly facilitated by the presence of sodium chloride. The ferment was found in the mucous membrane of the stomach, pancreas, Peyer's patches, the mucous membrane of the small intestines and in the liver. Twice it was found in the mucous membrane of the bladder, once in the mesenteric glands and once in the spleen. Later researches have established the fact that the labferment found in the stomach differs from that of the pancreas, the principal difference being in their respective behavior towards the reaction of the medium. Thus, while the gastric labferment is destroyed by even weak alkalies, the pancreatic labferment acts best in an alkaline medium. The regeneration of the peptones in the stomach is most active when the acidity dose not exceed 0.1% HCl. The favorable conditions are a saturation of the gastric contents with the products of digestion and a low acidity. It is thus seen that the labferment enables the organism to obtain an assimilable form of albumin irrespective of its original source, and at the same time it prevents the poisonous peptones and albumoses from entering into the blood current.

1.—Will be abstracted when concluded.

2.—Will be abstracted when concluded.

3.—Kallionzis, who has used the Tullier method of spinal anesthesia in over one hundred operations, believes that, though it is still in the stage of transition, it is not only valuable, but necessary in a number of cases. The technique of the procedure should be strictly watched, especially in details. [M. O.]

4.—Mendes has seen a case of goundou, a rare condition of the face. Though noticed in Africa occasionally, this is the first case reported in Brazil. All cases occur in negroes. In this case, a mulatto aged 24, the tumor was found just on the left side of the nose, spreading over the superior maxillary bone. It grew painlessly, and he remained perfectly well. The bony outgrowth was scraped off, and he is again in good health. Pathologically it showed the characteristics of an osteoma. Mendes considers it a trophic nervous lesion, an hypertrophy of the jaw bones, found only in descendants of the colored race.

[M. O.]

5.—Jeanselmé explains that goundou or anakhre consists of osseous growths about the root of the nose, increasing gradually, and is only seen in negroes. It is accompanied

by headache, epistaxis, and coryza. The condition is generally symmetrical. [M. O.]

6.—Lenoir has studied the subject of antrectomy, the operation, by which the petrous antrum is opened, as a preliminary step in the treatment of the complications of mastoid suppuration. This operation is not difficult, and is always necessary when suppuration occurs in the mastoid cells. The anatomy of the mastoid cells and the petrous portion of the temporal bone is described in full, with the different measurements in adults and children. Several diagrams of dissections illustrate the conditions found. The procedures in use by different surgeons are mentioned, and the entire literature is reviewed. Scissors are now generally used for the scalp incision, along the retro-auricular fold. In the adult the spot for trephining is below the supramastoid crest, in front of and above the mastoid-squamous suture, behind the auditory meatus. In children the mastoid antrum is slightly anterior to the position it holds in adult life, on the same horizontal line. This procedure is of service for curetting the mastoid cells, for draining the attic, the sinus, or lesions about the sinus and for reaching the cerebral or cerebellar complications of otitis media. Lenoir concludes that every one should be able to perform antrectomy, for it is not difficult, as the position of the mastoid antrum is easily located externally, and no important organ can be injured in performing the operation. The operation is exceptionally useful. [M. O.]

7.—Gorovitz states that genital tuberculosis in the female may be primary or secondary, the latter form being most frequently seen. Most often the Fallopian tubes are attacked, next the body of the uterus, the ovaries, vagina, uterine neck, and vulva. Genital tuberculosis is found at all ages, more especially from 20 to 40 years. Child birth and inflammation of the genital tract predispose to tuberculosis. In genital tuberculosis the bacilli may descend in the circulation, or they may ascend from the vagina. Besides, with enlarged retro-peritoneal or mesenteric lymph-glands, tuberculosis may descend indirectly by the lymph vessels; then the peritoneal lesions heal, leaving genital tuberculosis. Gorovitz details her experiments upon rabbits and guinea pigs. Tuberculosis of the vulva and vagina is rare. Yet, when it occurs, it is generally primary and resembles skin tuberculosis pathologically. The differential diagnosis from other ulcerations is difficult. The treatment of vulvo-vaginal tuberculosis is excision. Uterine tuberculosis is not infrequent, though tuberculosis of the vaginal portion of the uterine neck is very rare; while tuberculous lesions are found upon the uterine neck secondarily, they are much more frequent in the body of the uterus. It follows pregnancy, labor, or diseased conditions of the uterus. Very few cases of transmitted tubercle bacilli from the mother to the child in utero have been reported. Pathologically tuberculosis of the uterus may be acute miliary, or chronic in form. Upon the uterine neck it may appear as tumors or ulcers. In the body of the uterus there may be miliary tubercles, or tuberculous endometritis, which very rarely is polypoid in character. Amenorrhea, of metrorrhagia may be present, yet the diagnosis depends on the examination of the fungosities removed by curetting. When diagnosed, hysterectomy should be performed immediately. Tuberculosis may also affect the ovary, secondary to peritonitis, metritis, or salpingitis. Microscopical diagnosis is not at all easy; clinically it is always associated with salpingitis. Under tuberculous salpingitis comes the majority of the cases of genital tuberculosis. It may be primary, secondary, or associated with mixed infection. The tubercle bacilli reach the tubes from the intestine, across the peritoneum of the mesentery, by the lymph vessels; by the mucous membrane from the vulva or uterus; or directly by the circulation. Microscopically tuberculous salpingitis resembles salpingitis from other causes. It may be miliary, chronic and fibrous, or chronic and diffuse in form. The latter generally leads to surgical interference. The diagnosis is not always possible by microscopical examination. The clinical diagnosis is always difficult, unless peritonitis exists. These tuberculous lesions of the adnexa are an important cause of tuberculous peritonitis in women. Such cases have been

mistaken for typhoid fever. Ascites generally occurs in women from 15 to 30 years old, but has been found in all ages. Whether this peritonitis be acute or chronic, the prognosis is unfavorable. Laparotomy is always indicated, with removal of the diseased adnexa when possible. Not only is the literature of the subject fully quoted, but a long list of case-histories is given. Gorovitz concludes that genital tuberculosis in the female is much more frequent than is supposed. That tubercle bacilli enter the genital tract in the spermatic fluid during coitus has been proved experimentally and clinically. Experiments also show that tubercle bacilli placed upon the genital mucous membrane, without traumatism, will cause tuberculosis. [M. O.]

8.—Raymond and Alexandre report the case of a man of 31, with a **vertebral abscess** in the dorsal region following **furunculosis**. **Staphylococci** were found in the blood, urine, and pus of the abscess. He recovered after incision with drainage. The abscess was localized to those muscles which were most fatigued by his work. It is not generally conceded that staphylococcal infection can run so benign a course as occurred in this case. [M. O.]

LA PRESSE MEDICALE.

September 21, 1901. No. 76.

1. Benign Gangrene of the Eye-lids. H. ROGER and EMILE.

2. The Mechanism of Diabetes. PAUL MACQUAIRE.
3. The Treatment of Wounds. A. GOTTSCHALK.

1.—Roger and Weil report a case of **primary gangrene of the eye-lids** in a man of 33. Edema of the internal angle of the left eye occurred suddenly. This increased until both lids and the soft tissues about them were much reddened and swollen. There were fever, constitutional symptoms, and albuminuria. Upon this erysipelatous lesion appeared spots of gangrene, black and purulent. There were no phlyctenules, nor were the neighboring lymph-glands enlarged. The eye-lids were punctured and cultures made from the fluid obtained. These showed an aerobic micrococcus, pathogenic for rabbits and guinea-pigs, but not for rats or mice. Under hydrogen peroxid the condition cleared up slowly. Slight ectropion and conjunctivitis of the lower lid remained. Primary gangrene of the eye-lids must be very rare, since no case had ever before been reported. Like gangrene of the breast, of the gums, and of the male genitalia, in which aerobic micro-organisms have been found, this condition is curable. [M. O.]

2.—Glycosuria may be the result of the absence of the pancreatic juice, or of the presence of an excessive amount of pancreatin. Either an alteration or a suppression of the pancreatic secretion will cause diabetes. Experiments, which have recently been performed upon rabbits by Macquaire, show that pancreatin always causes glycosuria and marked glycemia. For the absence of pancreatic juice causes the absence of the diastatic ferment of the liver, and sugar ingested is not only not absorbed, and stored up in the liver as glycogen, but is simply held in suspension in the blood until the kidneys excrete it. If this hypothesis of Macquaire's is correct, pancreatin should be given in diabetes in doses of from 45 to 120 grains a day. [M. O.]

3.—Wounds are either aseptic or infected. While the former are rarely found, the latter may heal by first intention, in spite of the microbes present. In either case a moist aseptic dressing of layers of sterile gauze should be applied, after the wound has been thoroughly cleaned. If there is much exudation, this should be repeatedly changed, once a day at least. As soon as all discharge ceases, a dry dressing should be left upon the wound. Antiseptics and impermeable dressings are no longer to be used. [M. O.]

October 9, 1901. (No. 81.)

1. Orthostatic Albuminuria During Convalescence from Scarletinal Nephritis. CHARLES AUBERTIN.
2. The Ligation and Dressing of the Umbilical Cord. A. SCHWAB.

1.—Aubertin reports four cases of orthostatic albumin-

uria, two in men and two in boys, the albumin appearing only after standing, without symptoms of fatigue. Another case, observed by Professor Roger, is appended, a young girl with orthostatic albuminuria, also following scarlatinal nephritis. In all five cases the albuminuria became distinctly orthostatic after the scarlatinal nephritis had begun to disappear. Aubertin concludes that many cases of orthostatic albuminuria may be the terminal stage of a previous nephritis, or any disturbance of the renal circulation. Other cases observed and reported by competent observers, when viewed from this standpoint, seem to confirm Aubertin's theory. [M. O.]

2.—After an infant is born, it should be comfortably placed and left alone until the cord ceases to beat, at some distance from the umbilicus. Then a provisional ligature should be applied, 6 or 8 cm. from the umbilicus, and the child should be allowed to wait until the physclaea has flashed tending to the mother. For the permanent ligature Schwab advises using plaited silk, well sterilized, placed from 1 to 3 cm. from the umbilicus. The cord is then severed another cm. away. The closer it is cut, the quicker it will dry. Other methods of severing the cord have been described, but none compare to ligation. The dressing consists of dry sterile gauze, with powder occasionally. Baths given should be surely sterile. Otherwise they should not be given. [M. O.]

October 12, 1901. (No. 82).

1. The Deformities of Modern Bullets. UZAC.
2. Chronic Bronchitis in Children. R. ROMME.

1.—Modern bullets, of smaller caliber and with a metal envelope, are deformed by ricocheting or by passing through resistant bodies before striking. This occurs at any distance and the bullet may be broken into pieces. The deformity may be from lateral shock, causing a screw-shaped projectile, or from perpendicular shock, causing a mushroom-like projectile. In either group the metal envelope may remain intact, it may be ruptured and partially separated, or ruptured and completely separated, with fragmentation of the bullet. Drawings of these different conditions are given. The weight of the projectile does not change unless it is broken up, its form may be greatly changed, while it can easily become septic. The course of a deformed bullet may be complex, its velocity being generally decreased. The wounds caused are as a rule small, deep, and very irregular. The shape of the wound of entrance depends upon whether the bullet is deformed before it strikes, or not. A wound of exit is frequently not present. The course of the bullet is never the same in different individuals. Comminuted fractures occur, while explosive effects are seldom seen nowadays. When they are found, they are severe. The irregularity of the course of these bullets permits the formation of the diagnosis of a deformed bullet-wound. The prognosis depends upon its localization. Drainage is as a rule necessary, since suppuration is apt to follow. The Röntgen rays aid in the diagnosis. The newer bullets can cause more severe wounds than those formerly in use, but examples of these bad accidents are fewer than formerly. [M. O.]

2.—In simple chronic bronchitis in children the only symptoms found are cough and expectoration. It may follow cold, coryza, laryngitis, the infectious diseases, etc., frequently noted in the children of the gouty, rheumatic, or tubercular. There is no fever, pain, or other symptom, though the child may look pale and thin. Cough occurs in small paroxysms or attacks, and the sputum is mucopurulent but contains no tubercle bacilli. Some rales are generally heard, dry or moist, scattered over the chest. The affection is benign. Massage, alkaline waters, cod liver oil, iodide of arsenic, ipecac, mustard plasters, sodium sulphate, terpin, tannin, etc., may prove of service in the treatment. [M. O.]

EDINBURGH MEDICAL JOURNAL.

October, 1901. (Vol. X, No. 4.)

1. Primary Carcinoma of the Duodenum. W. SOLTAU FENWICK.
2. Volcanic Action as a Cause of Outbreaks of Epidemic Disease. NOEL BARDSWELL.
3. The Means of Arresting Acute Endocarditis. RICHARD CATON.
4. Phlyctenular Conjunctivitis. KENNETH SCOTT.
5. Notes on Surgical Cases Which Came Under My Observation During the South African Campaign. D. W. JOHNSTON.

1.—Primary carcinoma of the duodenum is met with once in about 1500 to 2000 necropsies in London, and thus presents a ratio to gastric carcinoma of 1 to 20. The great majority of duodenal carcinomata belong to the cylinder cell variety, but the spheroidal cell growths are not uncommon, and colloid carcinoma is relatively frequent. Like simple ulcer in the same situation, a malignant growth is more frequent in men than in women, and the average age at the time of death is 53 years. The symptoms of duodenal carcinoma vary according to the situation of the growth. It is therefore convenient to consider the clinical aspect of the disease, according as it is situated above, around, or below the biliary papilla. When the first portion of the bowel is affected, the patient presents all the indications of pyloric stenosis, and a differential diagnosis is extremely difficult. Disease of the second part is apt to involve the orifice of the common bile duct, that its location may often be determined during life by the coexistence of jaundice and enlargement of the liver, while a stricture of the duodenum below the biliary papilla is usually attended by bilious vomiting and the presence of pancreatic juice in the ejecta. Carcinoma above the biliary papilla may either form a ring around the bowel or produce a deep ulcer. The initial symptoms are flatulence after meals, acidity, loss of appetite, general debility and beginning emaciation. This is followed in a month by pyrosis and emesis, which is always acid with masses of undigested food and excess of lactic acid, severe pain in the epigastrium, with blood and bile in the stools. A tumor may be detected upon palpation. The subsequent course of the disease is similar to that of pyloric cancer. The second type gives jaundice as its first indication. The epigastrium is distended, the liver enlarged, the gall bladder distended, the stomach enlarged, but a tumor can seldom be detected. Carcinoma below the papilla begins in the same manner, but the vomit contains bile and pancreatic juice, is of green color and resembles chopped spinach. Attacks of intestinal obstruction supervene. The urine is greatly reduced in amount, and may be entirely suppressed, while that which is voided is alkaline in reaction and opaque from an excess of earthy phosphates. Symptoms of auto-intoxication are often present at this stage of the complaint, the stomach is enlarged and a succussion splash may be obtained as far outward as the right mammary line, or even in the lumbar region, due to the dilation of the duodenum above the site of stricture. If only a ring is formed, no tumor can be detected, but when the pancreas is infiltrated, a hard indefinite mass may be found to the right of the umbilicus. Regardless of site the average duration of the complaint was about 7 months, the extreme limits being 3 and 13 months, death resulting from either exhaustion or auto-intoxication, rarely from the hemorrhage, peritonitis or tetany. Disease of the first part of the duodenum has to be distinguished from benign and malignant strictures of the pylorus, and from the effects of pressure exerted upon the bowel by an external tumor of the second part of the duodenum; from carcinoma of the pancreas or of the ampulla of Vater, from gall stones, and from a simple chronic ulcer in the same situation; and of the third part of the duodenum from pressure on that part by a tumor of any neighboring viscus by undue tension of the transverse mesocolon, by enlargement of the superior mesenteric vessels, from impaction of a gall stone and from cleatization of a simple ulcer. The medical treatment does not differ from that of carcinoma of the

pylorus. Excision of the growth is rarely feasible, but gastro-enterostomy often prolongs life for several months [J. M. S.]

2.—Bardswell believes that earthquakes are responsible for outbreaks of epidemic disease, especially of cholera and typhoid. Even in England earth vibrations are now and again sufficiently severe to cause leakages from drains and water pipes, and when these diseases have previously existed in settlements above the site of leakage, outbreaks below the site are frequent. This was found to be particularly true in volcanic localities, viz.: Yokohama, Japan, and Naples, Italy. The Japanese Government encased the service reservoirs and other water receptacles in puddles freely used, and prepared and laid with greatest care, and used lead joints for the pipes. The health of the town, as regards epidemic disease, has greatly improved since these corrections, the mortality from enteric fever, especially, having notably diminished. This improved system was not in use during the earthquakes at Nice, in 1887, and Charlestown, S. C., in 1885, and for the following years the mortality in enteric fever, malaria, dysentery and cholera was greatly increased. The author also cites types of neurotic cases which may be met with in epidemics after earthquakes, viz.: nausea, vomiting, headache, vertigo, diarrhea, frequent micturition, hysterical epilepsy, disordered sensation, condition of nervous apprehension, depression and prostration, moral instability, loss of control, mania, insanity, paralysis of the limbs, railway spine, multiple neuritis, conjunctivitis, keratitis, tetanus and erysipelas. [J. M. S.]

3.—See Philadelphia Medical Journal, Vol. VIII, No. 18, p. 716.

4.—Scott lays stress upon the fact that the eruption of phlyctenular conjunctivitis which assumes the form of a small nodule, either single or multiple, and of varying size, is not a hollow vesicle containing fluid, as in herpes, but is of solid consistence, and is composed of cellular elements, and that it is a local manifestation of the scrofulous diathesis. In the matter of treatment, he emphasizes improving the general condition of the body, extra nourishment and dieting along special lines as of more import than drugs. Locally, he discountenances the classical method of the introduction of an irritant and tries to alleviate the inflammation, regarding it merely as a local manifestation of the more general bodily condition, rather than as an independent growth which has to be actively eradicated. The eye is put at rest by atropine which also, to some extent, exercises the antiphlogistic action pertaining to belladonna. In the milder cases the application of a dry-cotton-wool pad with a single thickness of muslin smeared with vaseline next the skin seems sufficient. In more severe cases hot fomentations of a mild solution of salicylic acid, tinctures of aconite, arnica, belladonna, and opium give satisfactory results. In eczematous conditions of the cheek, cold starch poultices are used, and when there is marked blepharospasm, canthectomy is advised. The small wound which has been made soon heals without special attention, and leaves no obvious trace. The foregoing treatment often aborts early cases and reduces the liability to the occurrence of permanent opacities and irregularities in more advanced ones. [J. M. S.]

5.—The wounds of the South African campaign were produced principally by the Mauser, Lee-Metford, and sharpshooter bullets. The statement that a soldier may be wounded without knowing he has been hit, or go until he faints from loss of blood, or until his attention has been drawn to the fact that he is bleeding, is not borne out; but instead they describe the effect as like that of a blow from a sledge-hammer, a brick or a crow bar. The character of the wounds of entrance and exit vary in accordance with the range, velocity, angle and the part struck. The bullet at its greatest velocity has an explosive effect and shatters the bone into many fragments, while with less velocity it has a drilling effect. The writer decries the practice of exploring wounds unless all modern antiseptic requirements are at hand, and even then prefers the skiagraph. Johnston believes the forefinger to be the best exploring instrument; a strip of gauze

squeezed out of iodoform emulsion to be the most satisfactory drainage and a small dry borie dressing to be unexcelled. Unless causing trouble, the rule should be to leave a Mauser bullet alone. This holds true in all portions of the body except the head, where thorough exploration for fracture should be made. Conservatism in place of laparotomies in many instances of serious visceral injuries proved the better procedure. Unless the bullet has divided the vessels so as to cut off the blood supply in the extremities, amputation is rarely required. The author states it to be his experience that all the Mauser bullets removed have turned, and the point of the bullet is directed towards the aperture of entrance. He advocates the extreme value of a timely hypodermic injection of morphine, on the field if possible, and before the removal of the patient. In all cases of bad gun-shot injury, as it makes the removal more bearable and lessens the shock considerably, thus possibly in many instances prolonging, if not saving, life. [J. M. S.]

JOURNAL DE CHIRURGIE.

September-October, 1901. (Première Année, No. 9.)

1. Two Cases of Osteospathyrosis. A. GEVAERT.
2. The Danger of Internal Urethrotomy. LAUWERS.
3. Traumatism upon a Hernia, with Intestinal Perforation, Peritonitis, and Death. H. VERNEUIL.

1.—Gevaert reports two cases of that rare condition, *osteospathyrosis* or *fragilitas ossium*. One, a girl of 5, first began to show fractures at the age of two years. All the bones of her legs and left forearm had been broken, and she entered the hospital with 12 fractures. One day she fell and broke her left femur again. Another day she slipped upon the tiled floor, and again fractured her left femur. She had never been ill, but was always pale and thin. At the seashore she improved, but fractured more bones when she returned. The other case was a girl of 14, who had rachitis. She had 18 fractures. Both her brother and father showed a tendency to fractures also. This condition is very rare, but occasionally seems to affect certain families. [M. O.]

2.—In three cases of internal urethrotomy reported by Lauwers, signs of marked infection followed the operation. All eventually recovered upon his treatment. The infection undoubtedly occurs from the peri-urethral tissue, and external urethrotomy may become necessary. [M. O.]

3.—Verneuil reports the case of a man with a left inguinal hernia for twenty years, who had received a severe kick upon his hernia, while intoxicated. He lost consciousness for some time. The pain persisted, and no bowel movements followed. There was no ecchymosis, but decided fluctuation and great pain were noted over the tumor. There was no fever. The sac was opened, and peritonitis with much fluid found. A perforation of the small intestine was seen. Drainage was left in the wound after operating. After an attack of delirium tremens the patient died. Verneuil believes that the traumatism produced a peritonitis, followed by intestinal perforation. [M. O.]

JOURNAL DE MEDECINE DE BORDEAUX.

October 20, 1901. (31me. Anné, No. 42.)

1. A Toxicological Study of Cacodylic Acid.

X. ARNOZAN.

1.—Arnozan agrees with Pery, who has written a thesis upon this subject, that aqueous solutions of sodium cacodylate become decomposed when kept for some time. Sodium cacodylate may be given by the mouth, rectum, or subcutaneous injection. Experimental investigation shows the last to be the best method. The better the arsenic is eliminated by the organism, the better is the resistance of the individual. Therefore when excretion is poor, care must be taken not to give too much cacodylic acid. Sodium cacodylate is eliminated in urine, perspiration, milk, and menstrual blood, in the form of metallic arsenic. Arnozan considers these facts of importance to the general practitioner.

[M. O.]

Society Reports.

THE DUHRING DERMATOLOGICAL SOCIETY OF PHILADELPHIA.

MEETING HELD TUESDAY, NOVEMBER 19.

The President, DR. DUHRING, in the Chair.

Dr. Stelwagon exhibited a man, aged 55, with circinate and segmental lesions upon the face, forehead and neck, dark red in color of several years duration, illustrating the superficial type of tubercular syphiloderma. It resembled ordinary ring-worm. There was a history of previous syphilis, and the areas are now in the process of involution following mixed treatment.

Dr. Schamberg exhibited a case of *Raynaud's disease* in a woman of 33. Her fingers were cyanotic and presented superficial ulcerations. On exposure to cold they become dead white, with burning and tingling. He showed a woman, aged 35, with a nodular eruption on the fingers and ears, varying in size from a pin-head to a pea, deep-seated and tender upon pressure. They gradually became superficial, underwent central necrosis, and disappeared in four or five weeks, leaving a slightly depressed scar. The outbreaks were more frequent in winter than in summer. The patient's brother died of phthisis. There was general agreement that the case was a form of *nodular scrofuloderma* occurring in regions subject to chilblains. He presented a man of 39 with multiple *epitheliomata*, there being almost 40 tumors upon his face, pinkish and shining in appearance, varying in size from a pin-head to a pea. Over the right eye-brow was a large, deep-seated ulcer, one and a half by one inch. The lesions first appeared when the patient was 24 years old. The large growth over the eye-brow appeared two years ago. A small tumor removed from the back showed, under the microscope, the structure of a cystic epithelioma. He also showed a case of *venous nevus* in a girl of 16. The lesions were purplish red, slightly elevated, somewhat verrucose, situated upon the leg from the knee to the great toe. The patches had recently become infected and covered with purulent crusts, for which curetting and cauterization had been done.

Dr. Pfahler exhibited a skin cancer treated with X-rays. The patient was a white woman, 56 years old, who had a cancer on the right side of her nose for two years. This growth was very painful, 2 cm. in diameter and 1.5 cm. in height. A section, removed and examined by the pathologist, showed that it was an epithelioma. Exposures to the X-rays were made on alternate days at a distance of six inches, on an average of ten minutes each. 17 exposures were made. The pains were relieved immediately, and in two months the growth had entirely disappeared, being replaced by glossy skin.

Dr. Hartzell exhibited a patient with *erythema elevatum diutinum*, a man of 45, with 5 bluish-red lesions upon the forearm, hand, and leg of the left side, one large pea-sized nodule on the flexor surface of the forearm, two smaller nodules on the inner side of the thumb, a dime-sized, flat, irregularly-oval plaque over the metacarpo-phalangeal joint of the middle finger, and an oblong plaque, about one inch by one-half inch, over the ligamentum patellae. These lesions are smooth, firm, and elastic, not tender on pressure, and readily movable over the underlying tissues. There are no subjective symptoms. The affection has lasted three years, and has undergone little change during the 18 months that it has been under observation.

Dr. Koch exhibited a child of 6 years with *monilethrix* involving the entire scalp. The hair was dry, lustreless, and broken off, presenting the appearance of a diffuse ring-worm. The condition had lasted for a number of years and was present in two other members of the family. Under the microscope the hairs were typically beaded.

BOSTON GYNECOLOGICAL SOCIETY.

MEETING HELD NOVEMBER 14, 1901.

Dr. G. W. Jones, who opened the discussion upon the surgical treatment of diseases of the gall-bladder, mentioned the important pathological processes met in diseases of the gall-bladder. Obstruction of the gall-bladder is liable to extend to the ducts, when surgical intervention becomes necessary. From 12 to 18% of all adults are affected, women having biliary calculi six times as often as men, possibly from the pressure of tight clothing. Gall-stones are rare in tropical countries. Persons may go through life without giving any indication of the presence of gall-stones, which are only found post mortem. Small calculi readily pass through the ducts, but large stones require surgical intervention for permanent relief. The most frequent demand for surgical treatment arises from calculi in the gall-bladder or their impaction in the gall-ducts. Dr. Jones decidedly opposed aspiration or exploratory puncture of the gall-bladder, since microorganisms may enter. If it becomes necessary to open the gall-bladder, the incision should be so large that the abdominal cavity is not subjected to infection. Cholecystotomy was performed by Bobbs in 1867 and by Marlon Sims and Kocher in 1878. In 1882 cholecystectomy was practiced by Langenbuch. Courvoisier, Sir Spencer Wells, Bernays, Küster and Meredith were the first to perform "ideal" cholecystotomy, by closing the gall-bladder and the abdominal wound without drainage. Dr. Jones regarded this as the best method. If, however, the walls of the gall-bladder have contracted or have become fragile, the final closure of the wound will have to be delayed. The common bile duct not infrequently becomes permanently occluded, and a fistula may result. This may be treated by cholecyst-enterorrhaphy. If the calculus cannot be removed in the ordinary way, the duct may be incised and after the removal of the obstruction, the opening can be completely sutured. He regarded the immediate suturing of the incised tissues of the gall-bladder without leaving the parts united to the peritoneum, or to the abdominal parietes as the best method of operation. He prefers a longitudinal incision, immediately to the right of the rectus muscle. In performing cholecyst-enterostomy, he first raises a portion of the intestine and sutures it to the gall-bladder, and then opens the intestine. Gall-stones do not always cause cholemia nor are they a frequent cause of cancer. Dr. Godfrey Ryder said that the most common cause of gall-stones was the presence of bacteria, which cause the deposit of bilirubin. Dr. Ryder spoke of the difficulties in diagnosis. Clay-colored stools, tenderness over the site of the gall-bladder, and pain extending to the shoulder are important symptoms. He advises early operation. By the early removal of biliary calculi the dangers of infection and hemorrhage are lessened. Dr. A. P. Clarke said that gall-bladder surgery had been worked out lately. Gastralgia, indigestion, dyspepsia, nervous spasms, etc. may be due to gall-stones. Excess of animal food had been a prolific cause. Drainage is only indicated in suppurative cases, or in cases in which injury to the gall-bladder or its ducts has occurred. Gall-stones in the common duct are liable to be overlooked. He did not consider the operation of cutting down upon the gall-bladder and draining it or its ducts a difficult procedure. He prefers forceps, scoop, dilators and other such instruments for dislodging calculi. Experience shows that gall-stones are not only found in the gall-bladder, for the more dangerous ones are found impacted in the hepatic and in the common bile ducts. In answer to the question of Dr. W. S. Brown, Dr. Jones said that, in some cases, at the beginning olive oil is useful. He gives 8 drops of chloroform with 2 table spoonfuls of olive oil, three times a day.

Special Article.

THE VALUE OF BLOOD EXAMINATION IN DIAGNOSIS.

By FREDERICK J. KALTEYER, M. D.,

of Philadelphia.

In the issue of this journal of the 23rd of November, 1901, there appeared an article by Dr. John B. Deaver and Dr. Edward Kemp Moore on "some experience with blood examination" which has attracted more than ordinary attention. To the medical man unfamiliar with blood examination, its technique, the ease with which the various methods are brought into practical use and the physiological and pathological principles upon which hematology rests, the article may suggest adverse criticism as to the value of these examinations in diagnosis. These observers have based their comparison on the results of several thousand blood examinations with the actual pathological findings at the operating table. In this article the aids of hematology to surgical diseases are discussed seriatim under the following headings:—Parasites in the blood; serum examination of hemoglobin; erythrocyte count and leukocytosis.

They concur with the generally accepted view as to the diagnostic value of finding malarial parasites in the blood, but their experience has led to the conclusion "that the more irregular and atypical the case of malaria, the harder are the organisms to find, and therefore in a case where malaria is suspected a single blood examination should not carry much weight". From the above quotation it seems that their results are not in accord with those of most authorities on this subject. Craig, who has recently contributed to the literature of irregular and continued estivo-autumnal malarial fever, states "that it is in this class in malarial cases that the microscope is of the greatest value to the practitioner. These cases which present anomalous clinical symptoms and irregular or continued temperature curves, are very difficult of recognition and are often mistaken for other diseases. In many of them a diagnosis from the clinical symptoms is absolutely impossible, and it is in such that the microscope is of the greatest aid. A few moments study of the blood will often demonstrate the nature of a case which has baffled the diagnostic acumen of eminent practitioners for days". It also seems reasonable to infer that the more irregular the symptoms of tertian or quartan fever, the less difficult should be the finding of parasites in the blood because sporulation then occurs during a longer period than in typical cases and therefore organisms, in various stages of development, may be seen at a single examination.

In their experience bacterial studies of the blood are generally unsuccessful, and have, very little practical significance. They are also bitterly opposed to painful or disturbing examinations that do not promise the patient any benefit, but are made merely because they are interesting. It is hardly necessary to comment upon this point. As a rule, only one or two cubic centimeters of blood are required for a bacteriological study and the technique of procuring the blood is indeed a simple one—a sterilized hollow needle connected with the bulb of

a sterilized syringe is introduced through sterilized skin into a vein—the whole operation producing scarcely more pain than the subcutaneous insertion of a hypodermic needle. Far less pain and discomfort is brought about by this operation than by an examination of the abdomen in a patient suffering from peritonitis or by an examination of the chest in one afflicted with acute pleurisy. Bacteriological investigation of the blood has solved some of the perplexing problems of pathology and has been useful in the diagnosis of many obscure cases of septicemia. Ample proof of this may be found in a study of the literature of septicemia. Undoubtedly the diagnosis of ulcerative endocarditis, which presents great difficulties and is often perplexing to the most skillful physicians, may be aided if pyogenic cocci are isolated from the blood. Grawitz holds the view that in doubtful cases of malignant endocarditis repeated negative bacteriological results point strongly towards its non-existence.

They believe "that a positive Widal reaction can be obtained after the seventh or tenth day of enteric fever in a very large percentage of cases of this disease, but as a diagnostic aid to the surgeon its results are upon the whole disappointing". The agglutination test from a study of statistics is found to be positive in enteric fever in about 95% of the cases some time during their course. To the physician this aid in diagnosis is often of decided advantage, particularly in atypical cases. Drs. Deaver and Moore have found this clinical laboratory reaction most frequently fallacious in cases in which the clinical symptoms are most perplexing, and they may be further quoted: "That a positive Widal reaction is rarely of much value to the surgeon, however valuable it may be to the medical man. A negative Widal reaction, especially after an illness of two or three weeks, seems often of service; for if after two or three weeks the Widal reaction is persistently negative, we can be almost certain that the case is not one of typhoid fever." At the present day the agglutination test has won for itself a place in the field of diagnostics and should be classed among signs and symptoms, such as the occurrence in enteric fever of rose spots, nose bleed, headache, abdominal pain, enlargement of the spleen, etc.; nothing more or nothing less is claimed for this laboratory test. Osler informs us that in the Johns Hopkins Hospital two cases have been operated upon as acute appendicitis, which subsequently proved to be enteric fever. Mistakes of this kind are sometimes unavoidable, particularly during the first week of enteric fever. A positive agglutination reaction in a case in which the diagnosis between appendicitis and enteric fever is doubtful, should render some assistance towards the establishment of a correct diagnosis.

In their study of hemoglobin they have found that no matter what the percentage of color matter may be, an operation for the relief of such a condition as an acute suppurative process or acute or chronic hemorrhage, may be undertaken. They have records of several cases operated upon with only from 10% to 20% of hemoglobin that terminated favorably. It has been demonstrated by clinical

and experimental research that ether, given as an anesthetic, produces certain well defined functional and structural changes in the economy, particularly upon the red corpuscles, and that after an operation a fall in corpuscular hemoglobin occurs. While there are some instances on record in which a general anesthetic has been given to patients with a very low hemoglobin percentage with favorable results, the exceptions do not prove the rule, and therefore the conclusion seems justifiable that a general anesthetic must not be given except under the stress of absolute necessity if the hemoglobin is low. Estimation of the percentage of hemoglobin may be performed with sufficient accuracy for clinical purposes within a few minutes by various methods at our command.

They have also found the sign of leukocytosis "the most valuable and the most disappointing part of blood examination". Reference is made to the important conclusions drawn by Dr. John C. Da Costa, Jr., in regard to the rules governing the leukocyte count in appendicitis. They also detail the history of a case which they believe militates strongly against the value of leukocytosis, occurring in a young man admitted to the German Hospital, who presented symptoms of severe appendicitis and in whom a leukocyte count of 20,000 was present on the day of admission. As the case progressed, improvement in all the symptoms followed. The number of leukocytes gradually fell, until on the sixth day the count was 7,500 per cubic millimeter. An operation was performed at this time and an abscess containing 500 cubic centimeters of pus was evacuated. They contend that the blood examination in this case was entirely unreliable and that it does not take a very large number of such cases to severely shake their confidence in leukocytic counts. From the facts mentioned in the history of the above case it appears that the abscess was thoroughly walled off. It is a well established fact that if an abscess is walled off, a low leukocytic count (from 8,000 to 11,000) is usually present, and when this stage in a pathological process, such as acute appendicitis is reached, the function of the leukocyte has been carried out, the leukocytic forming tissues have rendered their services and are deserving of a rest.

Diffuse Hypertrophic Scleroderma with Coxo-femoral Periarthritis and Sciatica.—Edgar Hirtz reports a case of scleroderma in a man of 46, in the *Bulletins et Memoires de la Societe Medicale des Hopitaux de Paris*, (July 4, 1901, No. 23). The patient came to the hospital with right-sided sciatic neuritis, the symptoms of which improved gradually. But almost complete ankylosis of the coxo-femoral articulation followed, with a swelling of the upper part of the thigh. Then the skin began to swell, to grow hard and thick, over the entire thigh. Reflexes were increased on the left side. Later the abdomen and thorax also became affected. Radiographs showed but slight periostitis of the femur. The cause of the condition is unknown. Hirtz could find no other reported cases of diffuse scleroderma with ankylosis in a large joint, due to periarticular lesions. He will try thyroid extract in the treatment. [M. O.]

Original Articles.

HEPATIC DRAINAGE.*

By JOHN B. DEEVER, M. D.,

of Philadelphia.

Surgeon in Chief of the German Hospital,

and EDWARD KEMP MOORE, M. D.,

of Philadelphia.

Assistant Pathologist, German Hospital, Philadelphia.

The future status of any of the various divisions of the science of surgery is practically impossible to foretell. Yet it is not thought a rash prediction that there is no part of general surgery that will receive more attention in the next few years and see more advancement than the surgery of the gall bladder.

The surgery of the gall bladder and the bile ducts is still in the stage of development, in spite of the able and valuable work that has been done on this subject by Hans Kehr, Mayo Robinson, Richardson, Murphy and many others.

Both the diagnosis and treatment of these conditions are still cloudy and there is much work to be done, which will be amply repaid before this subject is brought into the full sunlight of clear understanding. The diagnosis, in many respects, is still far from clear. What the work of the future will reveal is a method of early diagnosis that will enable us to recognize the very beginning of the pathological processes in this region; in order that a careful watch may be kept on its advancement and surgical interference instituted at that time which logic and surgical experience shall indicate as the best.

Diseases of the gall bladder and ducts occur with remarkable frequency. The best observers have said that in 9 per cent. of the human race gall stones are present, and if we add to that the large number of cases in which there is gall bladder disease without stones, we can see how large a percentage of our patients must have imperfect gall bladders. However, since the overwhelming majority of these cases remains apparently latent and innocuous, the proper course to pursue is very puzzling.

Gall bladder disease is markedly protean in its character, perhaps even more so than appendicitis, and the wide variance in its seriousness calls for the closest study and the greatest care in classification. In its pathology, too, gall bladder disease closely follows the pathology of appendicitis. The same changes take place step by step, and in both, at any stage, there is always the ever present danger of an acute exacerbation that will in a few hours place the patient beyond medical or surgical aid.

The first step in the progressive pathologic condition is usually catarrhal inflammation, due to the irritation of stones or infection of the bile. Then an interstitial inflammation, and a pericholecystitis follows, resulting in an adhesive local peritonitis causing adhesions between the gall bladder and the neighboring viscera. Finally, contraction of the gall bladder making traction on the adherent viscera and causing obstruction of the bile ducts, partial obstruction of the duodenum or the transverse colon,

and a host of other symptoms in which the part played etiologically by the gall bladder is often entirely overlooked. Hand in hand with these changes go the effects of extension of the inflammation along the interior of the bile ducts; obstruction of the bile stream through inflammatory tumefaction of the ducts and the grave results of cholangitis and pancreatic inflammation.

Going back to the similarity of gall bladder inflammation and appendicitis, the stones play the same part as the fecal concretions—causing ulceration and strictures of the ducts.

The progress of gall bladder disease is not usually, we believe, a steady onward march, but a succession of exacerbations and periods of latency. The fact, however, must not be overlooked that the individual exacerbations may be so slight that the disease is not even suspected until the advanced stages are reached.

It were well if all cases of gall bladder disease had this slow progression, but unfortunately at any stage a sudden crisis may develop of the utmost gravity, though an acute gangrenous cholecystitis, a pericholecystic abscess, or perforative peritonitis again reminding us of the pathology of appendicitis.

Perhaps as useful a classification of the symptoms of chronic cholecystitis as any, is the division of the symptoms into three groups.

First.—Those caused by the presence of stones and extension of the inflammation along the interior of the ducts; second, the symptoms due to the pericholecystitis, and third, the symptoms of cholangitis.

This classification is to a great extent arbitrary and all its divisions are blended in a broad pathological picture; but their separation is useful in our efforts to determine the stage reached in the disease and the exact lesion present.

The stones, if they remain in the gall bladder, are practically innocuous and are rather the result of the inflammation than the cause, or perhaps they may be better considered as going hand in hand with the disease, sometimes preceding, sometimes following the inflammation. Their presence in the ducts is a more serious affair, as here they furnish the nidus for strictures and by their bulk aid in the obstruction of the bile current. Practically all modern writers have abandoned the theory of mechanical obstruction due to the wandering of a stone for the more reasonable one of inflammatory tumefaction which explains the conditions found at the autopsy and the operating table in a much more satisfactory manner.

The symptoms caused by a catarrhal inflammation of the gall bladder and ducts vary widely in different cases. In some, where the consequent swelling of the mucosa is not sufficient to seriously impede the flow of bile, the only symptoms are a slight enlargement of the gall bladder with a little tenderness in that region, a slight elevation of temperature and a very moderate feeling of malaise and anorexia.

In many cases the occurrence of these mild attacks are the only indication of a gall bladder disease that is progressing steadily, and when operated upon on account of an acute exacerbation or intercurrent disease, we are surprised to find a condi-

*Read before Southern Surgical and Gynecological Association, Richmond, Va., November 10th, 1901.

tion of the gall bladder much more advanced than the duration or severity of the symptoms had led us to believe.

In other of the catarrhal cases only a little more severe grade of inflammation will produce the most alarming symptoms. The lumen of the cystic duct may be obstructed and severe gall stone colic occasioned, the inflammation may obstruct the common or hepatic duct and a marked grade of jaundice develop and yet the causative pathological process be in reality but little more severe than in a case of mere "biliousness."

The symptoms of pericholecystitis are most confusing and difficult of diagnosis. Adhesions to the duodenum often in the consequent contractions so obstruct its lumen that a dilatation of the stomach results. Adhesions to the transverse colon or other parts of the intestines may cause symptoms of intestinal indigestion, and adhesions to the stomach may very closely simulate gastric ulcer.

If in cases with these complications the individual acute exacerbations of inflammation have not been marked, it is only with the greatest acumen that we can arrive at the true nature of the trouble.

There is no doubt that a large percentage of the cases of chronic dyspepsia and intestinal indigestion are caused by the adhesions of cholecystitis and appendicitis, and no chronic case of this nature should be passed without a careful consideration of these two conditions.

Of the chronic symptoms of gall bladder disease none are more serious than those of cholangitis. The obstruction of the bile ducts by an infectious inflammation permits of a spread of the infection up to the smaller ducts of the liver, and produces a marked cachexia and a very serious form of hematogenous jaundice as well as the other manifestations of hepatic infection.

Gall bladder disease is a progressive process with very little tendency to self-limitation. There are perhaps a few cases of spontaneous cure by the discharge of all the stones and a subsidence of this inflammation; but in these cases, if there has been a pericholecystitis with adhesions to the surrounding viscera, symptoms due to these adhesions will persist without even the slightest sign of gall bladder disease. This point is very important in the causation of dilated stomach and other intestinal troubles, and, as said before, should never be lost sight of.

The progress of gall bladder disease is, however, remarkably slow in many instances, an individual may have a slowly progressing gall bladder disease extending over the course of his whole life, which never at any time causes more than a few days indisposition at irregular and often widely separated intervals. Yet in other cases a few days, or even hours, may be sufficient to terminate his life.

Gall stone disease was formerly divided into the infectious cases and those in which the symptoms were caused by the mechanical action of the stone. This classification is not correct, to our minds, for we believe that all the cases are infectious in their nature. Not that a gall bladder once infected always remains so, but that each exacerbation is due to an infection which even the slightest enteritis is

sufficient to light up in the already damaged gall bladder.

Again returning to our analogy between gall stone disease and appendicitis, we can divide the symptoms into those which are occasioned by pericholecystitis and those caused by defective drainage. The symptoms of pericholecystitis are those occasioned by the adhesions in great measure, and freeing the adhesion will relieve them, but the prevention of their reappearance lies with their cause, the defective drainage of the gall bladder and liver. So no matter what the nature of the symptoms, their cure lies in securing free hepatic and cystic drainage.

The flow of bile is so free that unless this is interfered with, the serious infection of the gall bladder, or more particularly the liver, is hard to conceive. Therefore, our success in the treatment of gall stone disease depends upon our ability to establish and maintain free drainage.

The waters of the Sprudel Spring at Carlsbad have long had an enviable reputation for the cure of gall bladder troubles, but we believe that no medicinal water is able to restore a damaged gall bladder to normal. What is accomplished is the freeing from infection of the hepatic drains, and by thus reducing inflammatory tumefaction to make room enough for the establishment of free drainage. Yet the pathological lesions are still present and ready at the slightest infection again to show themselves as a continual menace to life.

If we are able to diagnose gall bladder disease in its earliest stages before any marked anatomical changes have occurred; then temporizing and Carlsbad are indicated, but if the case first comes to our notice in the late stages when adhesion, contraction and strictures have made groundless the hope that nature will restore to normal the drainage system of the liver, then temporizing is dangerous.

The mortality of operations for gall stones lies not to the charge of the operation, but to the time at which it is done. Any operation performed upon a patient suffering from severe jaundice and an infective cholangitis is sure to have a high mortality, and the only way to avoid this is to operate early before the patient has developed these conditions.

Gall bladder surgery ought not to be relegated to a "last resort" procedure, but should be done at the time when the chances of recovery are best. The "last resort" surgery in all departments is the cause of the majority of unsuccessful operations. The widespread conviction that a surgeon is to be called in as a last resort is a great detriment both to the science of surgery and to the patient. How many deaths from appendicitis, cancer, sarcoma, gall stone disease and many other conditions are due to this relegation of the surgeon to the role of a "last resort."

In an operation for gall bladder disease, if there is any marked change in the gall bladder, it is better to remove it. This applies especially to the cases operated upon early in the disease, for this procedure insures a freedom from this trouble in

the future, and adds very little to the gravity of the operation.

The gall bladder is an organ of very little function in the human race; this is proved both by the result of its removal and by the cases in which stones have completely filled it, yet without symptoms.

The day is not yet, but we believe that experience will in the future show us that the removal of the gall bladder is nearly as necessary an adjunct to the operation for gall stones as is the removal of the appendix in appendicitis.

In the early cases removal of the gall bladder does not render the operation more formidable, but less so, for it prevents many an embarrassing case of biliary fistula and assures us that we have removed the seat of the beginning of nearly all cases of defective hepatic drainage.

In advanced cases with cholangitis it is essential to freely open and drain the bile ducts, for in the free escape of the infected bile lies our only hope for the cure of the condition. Then, too, gall stones are often met with in the ducts and a complete operation cannot be done without their removal.

A STUDY OF THE INITIAL SYMPTOMS IN 100 RECENT CASES OF SMALLPOX.*

By WILLIAM M. WELCH, M. D.,

of Philadelphia.

Physician in Charge of the Municipal Hospital of Philadelphia,
and JAY F. SCHAMBERG, M. D.,

of Philadelphia.

Professor of Diseases of the Skin in the Philadelphia Polyclinic;
Assistant Attending Physician to the Municipal Hospital

An important factor in the limitation of the spread of contagious diseases is their detection at the earliest possible moment. The initial stage of variola is characterized by a group of symptoms constituting a syndrome of great diagnostic import. Whilst it would be hazardous to base a diagnosis upon the initial manifestations alone; nevertheless the complex of symptoms is often sufficiently characteristic to excite a strong suspicion and lead to isolation of the patient and vaccination of exposed individuals, especially when smallpox is prevalent. It should not be forgotten that whilst smallpox is most contagious during the pustular and desiccative stages, the disease may be transmitted even during the invasive period.

After slight malaise the symptoms of smallpox commonly appear suddenly and often with considerable violence. Some patients complain of vague general pains, fatigue and loss of appetite during the latter days of the period of incubation.

The earliest symptom is most frequently a chill. This may be severe enough to be accompanied by chattering of the teeth or it may consist of a succession of creepy sensations scarcely sufficient to attract the patient's attention. Synchronously with the chill or immediately following it the fever appears. The temperature on the first day often rises to 103° or 104° F. and on the second and third day, with perhaps the exception of slight morning remissions, it rises still higher, frequently reaching 105°

and in some cases even 107°. The elevation of temperature is usually sudden; in but few diseases does it rise so quickly from the normal to a high degree. Even in varioloid the early symptoms are not infrequently equally severe, although occasionally they are so mild as to escape attention. But the eruption of unmodified smallpox never appears without being preceded by a well marked invasive stage.

While the fever continues, the skin, of course, is hot and sometimes dry, though more frequently covered by a moderate perspiration. The pulse is full, tense and rapid; its frequency generally corresponds with the temperature curve. In adults it may vary between 100 and 130 while in children it not infrequently reaches 160. The respirations are almost always increased in frequency, especially when the temperature is excessively high. Prostration is often extreme, being out of all proportion to the length of the illness. Strong and robust patients are frequently unable to stand without support, and when in the upright position soon become pale and liable to be attacked by vertigo or syncope. Thirst is great, the lips and tongue are parched and dry, and there is complete loss of appetite. Constipation is common. The tongue is usually coated with a thick yellowish covering and the breath is heavy and offensive. According to some authors the odor from the body of a patient at this stage of the disease is so peculiar and distinctive as to make it possible for the diagnosis of smallpox to be made by this symptom alone. We must confess that our olfactories have not acquired this degree of acuteness.

Irritability of the stomach is a very frequent manifestation. Occasionally the first symptom noted by the patient is severe and persistent vomiting. In such cases the disease has on more than one occasion been regarded as gastritis. The vomiting often continues for two or three days. It is apt to be accompanied by marked tenderness of the epigastrium. The irritability usually ceases when the eruption appears, and when it continues longer, it should be viewed with some solicitude. Especially in hemorrhagic smallpox is this symptom, together with pain in the pit of the stomach, apt to be distressing and prominent. Nausea and gagging are present in some cases, without actual emesis.

Headache is the most prominent among the early nervous symptoms. It usually follows shortly after the chill, but in a certain proportion of cases it precedes it, being not infrequently the earliest evidence of illness. Its intensity varies greatly corresponding in a measure with the height of the febrile action. At times it is so excruciating as to cause even self-restrained individuals to cry aloud. The face is often flushed, the carotids visibly pulsating. Restlessness and sleeplessness are common symptoms during this stage. When the temperature is high, delirium is prone to supervene. This usually takes the form of talkative incoherence, although some patients become quite violent. Coma is a rare exception in children. Convulsions are very common among children, more so perhaps in this disease than in any other of the exanthemata.

Pain in the back is a symptom so commonly observed that it is believed to be of special diagnostic value. It is not as constant as some of the other

*Read before the Medical Section of the College of Physicians, December 9, 1901.

symptoms, yet it occurs in more than one half of the cases. In perhaps one third of the cases it is sufficiently severe to cause the patient to volunteer information concerning it. Its diagnostic import, therefore, is due rather to its infrequency in the other acute infectious diseases, than to its constancy in smallpox. The lumbar and sacral regions are the parts to which the pain is usually referred, although it may extend to the dorsal region. As a rule it is more severe in unmodified smallpox than in varioloid, yet this rule is subject to many exceptions. In hemorrhagic cases the pain is often of an excruciating violence. Lumbar pain is more constantly seen among female than male patients, owing to the fact that the menstrual function is very liable to be excited by the initial illness of smallpox, causing the menses to appear out of their regular period. Pregnant women are exceedingly liable to suffer from abortion or premature delivery. The pain in the back owing to these causes is given greater prominence, therefore, in women.

General aches and pains are frequently complained of, appearing at the same time as the headache and backache. These may occur anywhere, but are usually referred to the lower extremities, particularly about the knees. The soreness of the general muscular system may lead to confusion of diagnosis with "la grippe". Vertigo, which is particularly manifest upon the patients assuming the erect position, is a common early symptom. It is often well marked in mild cases, for these patients are more apt to rise from their beds. Syncopal attacks may occur in weak individuals.

Peculiar prodromal rashes often make their appearance during the initial illness. Where they develop it is usually upon the second day of the invasive fever. They disappear ordinarily in from 24 to 48 hours. The frequency of these rashes appears to vary in different epidemics. During the wide spread and malignant epidemics of 1871-1872 they were very common. We have observed quite a few of these eruptions during the past months, although they are apt to fade before the patients are received at the hospital. The most common type is that resembling measles, with which disease, indeed, it is liable to be confounded. The eruption has a rather irregular distribution, being at times generalized and at other times limited to certain regions of the body. It moreover differs from the eruption of measles in that the rash is not elevated above the level of the skin and therefore scarcely appreciable to the finger passed over it. Its ephemeral character is also a differentiating feature. This roseola variolosa, as it has been designated, has a close analogue in the roseola vaccinosa which occasionally appears about 8 or 10 days after vaccination. The scarlatiniform type is, in our experience, rather less common than the morbilliform eruption. It, too, is inconstant in its distribution and extent, and equally evanescent. A third form of prodromal rash is the purpuric or hemorrhagic variety. This consists of closely aggregated, pin point to pin head sized petechiae which are in such close juxtaposition as to produce the impression of a diffuse redness. This type has a predilection for the lower portion of the abdomen, the groins, the inner aspects of the thighs and occasionally the axillae and lateral surfaces of the chest.

These eruptions are of diagnostic importance, for in association with classic initial symptoms, they afford strong presumptive evidence of smallpox. Prodromal rashes are more common in cases of varioloid than in unmodified smallpox.

One hundred patients recently admitted to the Municipal Hospital were closely interrogated as to the character of their initial symptoms. There was no attempt at selection of any particular type of smallpox. The number includes 28 cases of confluent smallpox, 15 patients with very profuse and semi-confluent eruptions, 29 eruptions of moderate severity, and 29 cases of mild varioloid. Of this series of 100 patients twenty-two died. Headache was the most constant of the initial symptoms. The various symptoms were present in the following percentages: Headache 86%; chills or chilliness 78%; backache 70%; vertigo 57%; vomiting 55%, with nausea in 10% more of cases.

In some of these cases the symptoms were of marked severity, whilst in others they were extremely mild. An effort was made to determine the earliest symptom observed by the various patients. It is recognized that some inaccuracy must arise from an attempt to chronologically arrange the symptoms from the histories given by the patients.

Chills were the first symptom in 35 cases.

Headache was the first symptom in 26 cases.

Backache was the first symptom in 16 cases.

Vomiting was the first symptom in 9 cases.

General aches and pains were the first symptom in 7 cases.

Vertigo was the first symptom in 2 cases.

In but two patients out of the hundred was there complete absence of initial illness. These occurred in a man 26 years, with a very mild varioloid, and in a colored woman aged 27, with an eruption of moderate severity. Upon close inquiry this patient admitted merely experiencing fatigue upon the day preceding the eruption. It is possible that some negative histories of this character may be due to poor memory and poor powers of observation on the part of the patient.

In the severe cases the initial illness was always well marked, although the classic symptoms were not invariably present. A man of 55 years who had a fatal confluent attack had merely as prodromes a severe chill, fever and prostration; headache, backache, vertigo and vomiting were absent. A male patient, 29 years of age, with an eruption of moderate severity, experienced during the initial stage, fever, repeated vomiting and pain in the stomach, the other symptoms being absent. On the other hand quite a number of patients with very mild eruptions gave a perfect history of the initial classic syndrome. A young woman of twenty years, for instance, with only three or four lesions on the face and a few upon the arms and hands, experienced at the outset of the disease headache, backache, repeated vomiting, severe chills, vertigo and aching in the legs.

The duration of the initial stage of smallpox is commonly 48 to 72 hours. It is rarely less, but it may be somewhat prolonged. Some text-books state that the temperature falls upon the appearance of the eruption. This statement requires qualification being true only in a general way. In our experience

in unmodified smallpox there is usually no decided remission in the fever until the second or third, and sometimes not until the fourth day of the eruption.

In conclusion we desire to call attention to the fact that in a large percentage of the cases of smallpox admitted to the Hospital during this year, the initial symptoms were interpreted by the physicians previously in attendance as the early manifestations of typhoid fever.

OPERATIVE TREATMENT OF BLADDER DESCENT AND SACCULATION.*

By GEORGE ERETY SHOEMAKER, M. D.,
of Philadelphia.

Gynecologist to the Presbyterian & Methodist Hospitals, Philadelphia.

Displacement of the bladder in the female may take place in several directions,—forward, upward, backward, laterally, and downward. Only in the downward direction is sacculation and imperfect evacuation liable to occur with any frequency, but its secondary effects in the causation of disease of the bladder are very important. The writer has seen but one case of pathological *forward* dislocation, in which instance what was really a hernia of the bladder occurred when the organ was full, owing to an extraordinary separation of the recti muscles in front of the abdomen, associated with a large ventral hernia. Here pressure of the hernia was required before satisfactory urination could occur. The *upward* displacements are caused by the growth of tumors, which may drag an adherent bladder, base and all, entirely out of the pelvis and spread it over the anterior abdominal wall. This is the variety usually caused by fibromata of the uterus. Irritation of the bladder follows, but seldom retention or cystitis from residual urine, as drainage is good from below. Tumors may develop in the true pelvis entirely below the bladder attachments, pushing as they grow the base of the bladder, with the uterus, out of the pelvis and compressing the urethra against the pubic bone. This is a more serious condition than where the bladder is pulled out from above.

A very troublesome case of the writer's, unique in his experience, was a multilocular cystoma with thick fleshy walls, probably a cystosarcoma. The pelvic basin was floored over with absolutely rigid new tissue in which cysts developed. One followed the line of least resistance and grew downward into the vagina, displacing the uterus above the pubic bone, partially shutting off the urethra by pressure against the pubis, so that catheterization was frequently necessary and there was much residual urine. This had resulted in cystitis and secondary nephritis. The tumor was attacked above and the solid portion proved to be absolutely irremovable. Relief was given by drainage of cystic portions of the tumor from below, which cured the bladder, and for a year and a half has made the patient fairly comfortable. The prognosis is, of course, ultimately unfavorable, though the patient is now doing well.

The *backward* displacements generally involve the fundus of the bladder and do not greatly affect the base; consequently less harm is done by interference

with drainage, though much distress may be caused. Some well marked instances have been observed by the writer when operating for encysted collections in the lower abdomen. When the pus lies outside the tubes, ovaries, and broad ligaments in certain forms of pelvic abscess, such as the tubercular, or when Nature is making an effort to dispose of a large blood mass after the rupture of an extrauterine pregnancy, the bladder fundus may become densely adherent to large and small bowel and by shrinkage of adhesions or other mechanical processes may be drawn well backward over the top of the uterine fundus. Such a condition is referred to in the report of a case of extrauterine pregnancy by the writer. *Annals of Surgery*, August, 1901.

Operative treatment involves the careful separation of the bladder from its normal attachments and the surgical management of the primary lesions. The *lateral* displacements are of little moment and are generally due to tumors. None of the above described forms call for treatment directed to the bladder condition primarily. An occasional fibroma of the uterus will require removal, more because it grows under the bladder attachments and so creates trouble, than because of its size or other features.

There remain for consideration the *downward* displacements of the bladder. Some of these are associated with procidentia or prolapse of the uterus

FIG. 1. Hypertrophied and torn cervix with bladder and vagina protrudes much more when patient is standing. Bladder cannot be fully emptied till reduced. Woman aged 41 years. Tonnuculum shown in centre of cervix uteri at lower edge of bladder. Catheter in urethra. Parts foreshortened to less than half natural size. Following operations done at one sitting: (a) Curettage. (b) Hypertrophied stripped out and amputated. (c) Median part of vaginal wall excised over cystocele and edges united. (d) Perineum repaired. (e) Two sub-peritoneal fibroid nodules excised (rubber gloves) from uterus and ventro-suspension done. Pulse at end of operations was 78. Highest pulse during convalescence was 52. In feeble patients the abdominal operation should be done at a later day.

* Read before the Medical Society of the State of Pennsylvania, September, 26, 1901.

and some occur when the uterine body is in situ. I have seen a large cystocele protruding from the vulva, when the uterus was held well up by pregnancy. Nearly all are originally associated with injuries to the pelvic outlet, usually occurring during labor, but the extensive subsequent displacements are due to the slow action of gravity, to straining, and to intra-abdominal pressure. In certain cases of uterine prolapse nearly the whole bladder and all of its base may be pressed outside the vulva. Again there may be more bladder descent than the location of the neck of the uterus would account for, as the bladder attachment has been peeled off, as it were, from the cervix, so that when a sound is put into the bladder, its tip appears almost at the external os. Such a condition requires special care to avoid wounding the bladder when it is to be separated from the uterus. Operations from above the pubis, such as those upon the round ligaments or by uterine suspension, have little immediate or no permanent effect upon the bladder position, if unsupported by other measures. In uterine procidentia the bladder descent is only a feature of the general condition of hernia through the pelvic outlet. The plan usually adopted for its cure by the writer involves several operative procedures, which may be thus enumerated. They may all be done at one sitting, if the patient can withstand either for an hour and a half. First, curetting the uterus. Then stripping out the hypertrophied cervix for one or two inches from bladder in front, from peritoneum behind, and from the broad ligaments at the sides; thorough ligation of the lower lateral uterine blood supply to bring about involution of the uterus; amputation of the cervix at a point regulated by the amount of tissue hypertrophy; attaching the vagina higher up to the uterus; taking in all slack in the anterior vaginal wall; thorough repair of the perineum, with special care to pick up the lateral fasciae. As a final step the abdomen is opened and the uterus suspended. It is firmly attached to the anterior abdominal wall in women beyond the child-bearing age. In young women a light attachment is made well in front of the plane of the cornua. This is the most satisfactory series of operations yet devised, and, if properly performed, rarely fails to cure the procidentia and to hold up the bladder as well. In well marked cases no one of these procedures can well be omitted, though probably the suspension can be first withheld as the cases lessen in severity.

The point to which it is especially desired to call attention is the method of taking up the redundant anterior vaginal wall and supporting the bladder. It is applicable whether there is descent of the uterus or not. The methods advocated by Sims and by Emmett of denuding various shaped areas on the anterior vaginal wall have been abandoned as too superficial and as not securing a sufficiently firm support from the lateral fascia. The method of Stoltz, which involves an oval denudation and a purse-string suture, is considered objectionable, because superficial and likely to take up as much slack in an antero-posterior direction as from side to side; though in some instances where there is increase in length of the anterior vaginal wall this must be overcome by the method of suturing. The normal

attachment of the anterior vaginal wall to the pelvic fasciae is mainly at the sides, the attachment to the bladder along the median line being by loose areolar tissue which can be readily separated by the knife handle. The best method is to cut out completely all of the anterior vaginal wall down to the loose areolar tissue underlying the bladder. Inspection will show where the greatest stretching has taken place. A free incision is made directly down to the bladder wall in the median line, extending from the cervix forward as far as any widening has occurred. With the knife handle and a few snips of the scissors the bladder is then peeled off the vagina freely right and left, few vessels requiring temporary clamping, usually none. The flaps are then

FIG. 2. Operation on anterior vaginal wall to support bladder. The cervix has been amputated and is not in sight. Vaginal wall is shown stripped from the right half of the cystocele. The flap drawn down off to the patient's right will be cut away entire, and the other half of the cystocele uncovered in same way back to dotted line or beyond. Flaps are to be so cut away that remaining portions of vaginal wall will just meet when drawn from opposite sides to the median line.

trimmed away on both sides with the scissors until, when their edges are brought together in the median line, all redundant tissue has disappeared. The opening may be oval, or it may be broader near the cervix than at any other point, according to the location of the greatest relaxation. Two or three continuous rows of fine catgut are inserted and buried one over the other, running from before backward in the cellular tissue underlying the bladder, or in the wall of that organ. They serve to obliterate dead space and firmly unite all portions of the wound surface except the cut vaginal edges. These are best held together by a continuous fine silk suture, which alone pierces the vaginal mucous membrane. When finished, the direction of all these rows

FIG. 3. The flaps have been cut away. One antero-posterior row of continuous catgut suture has been placed in cellular tissue, obliterating part of the denuded area. Needle shown continuing second row of buried suture.

of sutures is from before backward. All bleeding is stopped by the suturing and no ligatures are re-

FIG. 4. Vaginal flaps have been finally united with fine silk over three buried rows of catgut. Line of suture three inches long. Sims' speculum is in vagina, catheter in urethra. The next step is to be perineal repair.

quired. Primary union is always obtained, as the operation is done under a continuous stream of water, and only instruments are brought in contact with the wound. Where there is much separation of the whole vagina from the pelvic fasciae, the greatest care must be taken in operating on the posterior vaginal wall and perineum to catch fascia in the stitches. The operation in these cases must always include very thorough perineal repair, the method of Emmett being preferred.

The method as here outlined commends itself because of its ease of execution and certainty of results. With whom it originated I do not know. It is almost always done as one of a series of operations performed at a single sitting, simply because descent of the bladder and anterior wall of the vagina are almost always accompanied by other lesions, such as lacerated cervix, relaxed outlet, subinvolution and descent of the uterus.

The result of thus indirectly restoring the bladder to its proper place in the pelvis is soon seen in the improvement in the irritability of the organ. Drainage becomes more complete and the tendency to urine decomposition disappears. Another symptom cured is the slight incontinence of urine, as when coughing or sneezing occurs. Where well-developed cystitis exists, a cure by the usual methods is made possible.

A number of cases have been operated upon by this method in the past two years—some twenty-five in all. There was usually present much distress due to bladder tenesmus, burning, frequent urination, imperfect evacuation. In some urination could only be accomplished after using the hand to replace the bladder. Several had serious interference with sleep. The results have been very satisfactory as regards anatomical cures and the cessation of symptoms.

ON THE VALUE OF THE RECTAL TEMPERATURE IN PULMONARY TUBERCULOSIS.*

of Cotswold, England.

By J. C. BRAINE-HARTNELL, M. R. C. S., Eng., L. R. C. P.
(Lond.)

Resident Physician to the Cotswold Sanatorium

No one can deny that a true knowledge of the amount of pyrexia in a given case of pulmonary tuberculosis is of the greatest importance, as it is, firstly, to a great extent the most reliable indication of the amount of active mischief going on in the lungs; and, secondly, one of the most important of data in giving a prognosis.

At the present time there is a great difference of opinion as to where the temperature should be taken—in the mouth, in the axilla, or in the rectum. The vast majority of medical men still hold to the time-honored custom of taking an oral or an axillary temperature, but a few are more inclined to follow the plan carried out by Walther at Nordrach and to insist upon the superior value of the rectal temperature. The rectal temperature either gives important results and is, therefore, well worth the extra trouble and annoyance which it may cause patients, or it is a mere fad and unworthy of acceptance at

*From advance Sheets furnished by our representative at the Congress on Tuberculosis, London.

†The charts referred to in this article have been unavoidably omitted. They are not essential to an understanding of the paper.

the hands of the profession. The object of this paper is to endeavor to show that the rectal temperature is of grave importance, and that it is well-nigh imperative in cases of pulmonary tuberculosis, especially when patients are living in the open air all day long.

The esthetic reason for not taking a rectal temperature, which is sometimes put forward, should not, we think, be allowed to bias our judgment when we are simply acting in the interest of our patients. It is surely a self-evident fact that if we are to control a patient's actions for the whole day and to regulate his walks entirely by the temperature chart, this temperature should be as free from error as possible. I believe that this is to be found in the rectum. It has been known for many years that the temperature in pulmonary tuberculosis may be apyrexial if taken in the mouth or in the axilla. Without denying for one minute the occasional occurrence of active disease with apyrexia, I nevertheless believe that apyrexia is far less common than is generally held, and that many cases apparently apyrexial when tested in the mouth or axilla show, on the contrary, distinct pyrexia when the thermometer is placed in the rectum.

The first three charts are the records of the oral temperature in three different patients, all of whom had active disease going on, though the charts give no indication of the same. Chart I. is taken from a patient with disease in both lungs and very active mischief at the left apex. Physical examination revealed softening and rapid breaking down, but the chart here shown denotes no rise in the temperature; in fact, for the whole fortnight, as shown, the temperature never rose above normal. Chart II, is from a case with abundant physical signs of consolidation in both upper lobes with a cavity at the left apex. The temperature on two occasions in the course of a fortnight rose only to 99° F. Chart III. records the temperatures of a patient of excitable temperament with active disease at the apex and at the base. Here again during a whole fortnight there was no rise of temperature above the normal.

The question now arises, what is the normal rectal temperature and what limits may be allowed in tuberculosis when exercise is being taken? I consider the temperature of a healthy man when taken in the rectum should be normal or subnormal in the early morning—97.8° or 97.6° is a good morning temperature. After breakfast the temperature will rise to 99° or rather more, and exercise will have the effect of raising it a few points further. In the evening the temperature should again fall to normal. Exercise and food raise the temperature about one degree Fahrenheit. Wunderlich gives the average temperature for the twenty-four hours thus:—When taken in the the axilla, 98.6°; taken in the mouth from 98.78° to 98.96°; and in the rectum, from 99.14° to 99.5°. Guttman again gives the average temperature for the twenty-four hours when taken in the axilla as being from 98.6° to 99.14°. (See Chart IV.) As regards the limits allowed, I think that the temperature should be normal in the morning, before walking is permitted. Certainly if any exercise is taken, it should be the very slightest, and then only on the level for, say,

ten minutes at a time. A rectal temperature which is continually 99° in the morning, even though it keeps under 100° during the whole day, indicates activity and contra-indicates exercise, I think, and if rest be persevered in, these temperatures almost invariably in the long run come down to normal. It is in these very cases that the rectal temperature is so important, as in very many the oral temperature is below normal, and if so guided, we are not likely to allow our patients to take exercise to the extent that we should, if we followed the oral reading. Chart IV. indicates what a rectal temperature should be in a patient who is doing well and is walking several miles a day. In this case there was disease in the left lung of fibro-caseous type and early laryngeal disease. The temperature after exercise was generally under 100°, and it dropped to under 99° if no exercise was taken. This is not an isolated case; in the cases of all patients who do really well, a chart similar to this may be expected to be found. Of course there are exceptions. The sanatorium treatment of tuberculosis demands individualization in every particular, especially in feeding and in exercise, because if a patient is in other respects doing well, there is no reason to restrict his walks if his temperature should rise to 101°. It may be idiosyncrasy or due to undue nervous, excitement. Chart V. indicates this very well. The patient, who was exceedingly nervous, used to worry during the whole of his walk about his temperature lest he should be too high; in fact, he even went so far as to take his temperature during his walk if a suitable opportunity arose, with the result that it was almost always 101° or thereabouts. When sent out with a companion so as to divert his thoughts from himself, the temperature was frequently almost a degree lower, clearly showing that the rise was simply due to nervousness. Again, I am acquainted with a typically healthy man whose rectal temperature is always over 100° after exercise, and between 101° and 102° after a ride on horseback. There are cases in which one must individualize. The height to which the temperature rises after exercise is not, in my opinion, of great importance provided that it drops directly the recumbent position is assumed. It is of the utmost importance that the temperature be taken directly after exercise, as a delay of fifteen minutes may cause the difference of one degree, and all observes who do not insist upon this, will be led to believe that muscular exertion does not raise the temperature to any extent.

I wish now to show the value of the rectal temperature in tuberculosis. I cannot speak of other diseases, because I have had no experience with them, but I have heard Dr. Cayley say that he has seen no advantage from this method in enteric fever, and this is only what might be expected for reasons that I shall state presently. There is no doubt at all in my mind that in many cases of tuberculosis there is often no resemblance between the temperature taken in the mouth or in the axilla and that in the rectum. On the other hand, I acknowledge that in other cases there is little or no difference between the oral and rectal temperatures, though why this should be I cannot at present explain. This much I know, it is in the lower ranges that we find the greatest discrepancy and in the higher ranges the

greatest resemblance. Thus in Chart VI., that of a patient with early infiltration of the upper lobe of the left side, there is a great difference between the two records; in some records there is almost four degrees of difference, the rectal temperature rising after exertion and the oral falling as much as two degrees. On the development, however, of an acute caseous tuberculosis of the lower lobe on the left side, the temperature rose in the rectum to 104.2° and in the mouth to 103.6° , and during the whole time that the temperature kept up; there was very little difference between the oral and rectal temperatures, but when with a subsidence of the acute symptoms the pyrexia diminished, the difference between the rectal and oral temperatures was as marked as ever. Chart VIII. is the record from a female patient who was kept in bed for fourteen days consecutively with the result that no comparison between the two temperatures can be traced. The rectal record denotes active mischief, but it would be difficult to demonstrate this from the oral record or even to diagnose tuberculosis unless one be led to do so by the subnormality of the temperature. Chart IX. gives the temperature of a patient with infiltration at both apices. This shows a typically good rectal record, being normal morning and evening and with a rise on exertion to under 100° . The oral record is typical of nothing. Chart X. shows great dissimilarity between the rectal and the oral records, the rectal in many instances rising, while the oral is falling to a corresponding degree. Chart XI. shows regularity of temperature, but always two degrees of difference between the rectal and the oral after exercise. Chart XII. gives the temperatures of a patient with considerable disease at both apices, and Chart XIII. those of a man, aged thirty-six years, with fibro-caseous tuberculosis of the left lung. Charts XIV. and XV. show the dissimilarity between the oral and rectal temperatures in the cases of two different patients. I also think that a glance at Charts XVI., XVII., and XVIII. will show how unreliable the axillary temperatures may be in some cases. The rectal record in each instance shows very strongly the activity of the disease, whilst the axillary record would mask any progress that the disease might make.

All the above records have been carefully taken for at least five minutes, the regulation time, and in most cases with new tested thermometers. I trust that by these charts I have been able to show the value of the rectal temperature. I think that mistakes are bound to be made in apportioning exercise unless the temperature is taken in this way. It is a very common experience to hear patients say that they have taken their temperature regularly at home for some weeks, and that they have no pyrexia, and yet when the rectal temperature is taken the thermometer in almost every case reveals a degree of pyrexia more or less marked.

Walther of Nordrach, as is well known, is very emphatic upon the importance of the rectal temperature, and so are all his followers. I fail to see how any man who has given this method a fair trial in tuberculosis could ever rely on any other; in fact, I am always afraid of being misled by an oral temperature—I mistrust it; but with a rectal tem-

perature, on the other hand, I see exactly what degree of activity is going on, feel sure of my ground, and can be decided in the matter of exercise. With many patients it must mean all the difference between rest and exercise, progressive disease or convalescence. Exercise is one of the most important and yet one of the most difficult points to be decided; on that to a great extent hangs the great issue at stake. More patients probably come to grief through over-exercise than through anything else; it is to my mind the secret of the open-air treatment, the *crux* of the whole matter, when to allow exercise, and how much. If we made it a cardinal rule, and I most assuredly do so, that pyrexial patients must have no exercise, then surely we must know when we have to deal with pyrexia, and need not grope self-complacently in the dark with an oral temperature, buoying ourselves and our patients up with the false idea that there is no fever, and therefore that all is going well, while all the time there is pyrexia, there is actual disease going on, and yet we know it not. It is so easy to take an oral temperature and to shut our eyes to the rectal, easy for the physician, and gratifying for the patients, because with a low temperature the treatment is not so irksome or so monotonous, and patients think that they are doing well, which is half the battle, but they sorely resent being kept at rest for slight degrees of pyrexia as shown by the rectal record.

In conclusion, I think: (1) that in many cases the oral and axillary temperature records are untrustworthy; (2) that in a few cases there is very little difference between the rectal record and the oral record; (3) that the greatest discrepancy is found in the lower range of the temperature and conversely the greatest similitude in the higher ranges; (4) that the rectal temperature gives in almost every case a truer idea of the amount of pyrexia; and (5) that if we wish to do ourselves, our patients, and our treatment justice we should insist upon taking the temperature in the rectum.

HALLUCINATIONS: THEIR PATHOGENESIS, CLINICAL IMPORT AND MEDICO-LEGAL VALUE.*

By J. LEONARD CORNING, M. D., LL. D.,

of New York.

Hallucinations are among the most interesting phenomena that confront the alienist; and some understanding of their nature and significance is certainly indispensable to every physician. They are among the most common manifestations of insanity, but are also found in those otherwise apparently sane. They may be evoked, too, under certain circumstances by suggestion and by the use of various drugs. The word itself has been greatly abused by writers, both lay and professional. Sometimes it has been applied to illusion, more commonly, however, and more flagrantly to delusions. The last misapplication is frequently encountered in works of fiction, whose authors, bent upon the achievement of sensational effects, chill the spines of their readers at the expense of truth. Nor is this the worst of it; many—and supposedly competent—

* Read at the Semi-annual meeting of the Medical Society of the State of New York, October 15th 1901.

writers on psychiatry—I recall at this moment one particularly flagrant instance of it—have used the term in such an impossible fashion as to place ones mind, at the very outset of study, in an utterly false attitude towards the whole subject of mental diseases.

It would be a great assistance, could we tell in terms of causation, of simple physiology, precisely what happens in the brain when an hallucination is induced. This, unfortunately, is not satisfactorily to be done, in the present state of knowledge, save in a purely inferential way. The most we can do, now, is to analyze the phenomenon itself, in the light of current psychology, and frame our definition accordingly, leaving to a future, and perhaps more perfect, cerebral physiology, the task of completely unravelling the knot.

Bearing in mind, then, that a true, a normal, sensory perception requires something external, something outside of the cerebral ganglia, and usually outside of the organism itself for its initiation, we may say at once that an hallucination, in the strict sense of the word, takes its rise in the ganglia, is due to something—an excitation, in the language of common speech—having its seat in the gray matter of the hemispheres, and probably in those parts of the cortex which are active in normal perception.

Further, and casually, it is said by some (1) that "the centres aroused by incoming peripheral currents are probably identical with the centres used in mere imagination."

The bearing of this dictum upon the morbid physiology of hallucinations is obvious. By provisionally accepting it, the mind is set on the way at once to a reasonable conception of the mechanical elements rendering possible the participation of the imagination in the genesis of hallucinations, and more especially of those instigated by suggestion.

To return again to the original thread of the argument, a true sensory perception presupposes as a *sine qua non* physiological stimulation of the sensory nerves. No such stimulation is, however, necessary to the genesis of an hallucination, which arises in consciousness with all the vividness, all the verisimilitude of a true preception, in the complete absence of a normal sensory provocation. Those who are subject to hallucinations—of sight, for examples—may be acutely aware, may bear vividly in consciousness visual images, which have no counterpart in reality. The like applies to all the other senses.

There are several other interesting facts that might here be set down; but I venture to believe the bent of thought established by what has been said sufficient to warrant the intelligent framing of a definition, a definition explicit enough, so far as the manifestation is concerned, to enable one to recognize and intelligently interpret the phenomenon whenever and wherever encountered.

An hallucination may be defined then as a phenomenon which—in the absence of physiological incitement through the peripheral nerves—looms in consciousness with all the qualitative and intensive characters of a true sense-impression.

Deriving its being from within instead of from

without; dispensing entirely with the physiological offices of the peripheral nerves; bearing no resemblance to the external, the objective reality of the moment; yet, looming in the consciousness of the subject with all the characters of sense reality—such a phenomenon is, in the last analysis, nothing more than a kind of perceptive counterfeit, a vivid imitation of a sense-impression, deriving its elements, however, entirely from hoarded sense-memories—to speak graphically—and bearing, therefore, no relation whatever to the external reality of the moment.

In its nature, then—irrespective of all questions of immediate incitement—this counterfeit sense impression, this hallucination is central, while the true, the physiological sense impression is peripheral in its origin.

It follows as a self-evident corollary that those who have never seen can never—be they sane or insane—suffer from a visual hallucination; there are absolutely no visual memories to draw upon. The same principle is applicable to the other senses. Where the sensory loss has occurred long after birth—years perhaps—the principle does not hold, however, with the same force.

The resemblance between the hallucinatory phenomena of dreams and the hallucinations of the insane has elicited a good deal of interest among psychologists and alienists alike. This interest has something more than a purely academic justification.

Thus Heerman¹ who has investigated the phenomena of dreaming in the blind, found that visual sensations and ideas were entirely absent from the dreams of those who had lost their sight previous to the fifth year. His conclusions in this regard were based upon the careful study of fourteen cases.

The interesting conclusions of Heerman have been confirmed by Jastrow.² Of thirty-two persons who became blind before the fifth year not one saw in dreams. On the other hand, of twenty persons who became blind after the seventh year all had dream vision. It is evident, therefore, that the period between the fifth and seventh year is the critical one, in so far as the hoarding by the memory of visual impressions is concerned. When one considers the essential similarity between dreams and hallucinations, the bearing of these observations upon the genesis of hallucinations is obvious. If the sensory centres, instead of being educated by the constant reception of sensations shrivel, functionally speaking, for lack of such stimulation, there can, of course, be no revival of sensory memories or ideas which simply do not exist. Physiologically, these are interesting data; clinically, they are hardly less so; legally—in cases of alleged insanity in persons suffering from a sensory defect, particularly of sight or hearing—they may at any time become so.

Fascinating as the study of hallucinations is in the sane—in those assumed—erroneously, I think—

1. "Beobachtungen und Betrachtungen ueber die Traeume der Blinden," Monatschrift fuer Medicin, etc., Leipzig, 1838.

2. Jastrow, "Dreams of the Blind," Princeton Review, July, 1888.

to be in an otherwise perfectly normal mental condition, the length and rather casual nature of the present outgiving precludes it, save in a purely incidental way, save as it bears on the analysis of the phenomenon itself. With this reservation, let us confine ourselves to hallucinations as they arise in the insane. For the purpose of convenient discussion, hallucinations may be divided into primary and secondary;—the first, those excited by an irritation—*not physiological stimulation*—of some nerve of special sense or of its cortical termination; the second, those evoked by a dissociated idiational process. Hallucinations following middle ear disease or cerebral exhaustion are instances of the primary variety; those found in delusional insanity, or much of it, of the second.

While it is probably true that persistent brooding on a long-existent hallucination of primary origin may ultimately eventuate in the mental alienation of the subject, it is none the less true that in the great majority of mental affections the hallucinations are secondary to derangement of thought, either conscious or subconscious. But this fact detracts not at all from the importance of the hallucination itself, but, on the contrary, emphasizes it. How often, indeed, does it happen that the declaration of an hallucination is the first symptom to arouse obtuse relatives or friends to the serious mental condition of the subject. Brought, moreover, through such a warning under the observation of a competent examiner, how characteristic, in most instances, is the attitude of the subject towards the strange phenomenon which has stolen into consciousness! Creature as it usually is of his morbid mood and ideation, and partaking of their qualities, he will usually convince you by his language that he believes in its reality, logical and even sensory proofs to the contrary notwithstanding. Here is the dividing wall between primary so-called sane hallucinations, of whose spuriousness the subject becomes usually fully aware, either through his own uninvolved senses or through the arguments of others—especially in the beginning—and those of secondary origin, those arising as a sequence of pre-existent morbid ideation.

A proper understanding of the psychological relations herein implied is of assistance in the clinical examination; is valuable in framing the prognosis, and may, under certain circumstances, rise to supreme importance in a court of law. Among all hallucinations of the insane, those of hearing are the most common by far. Ringing, whistling, rushing and other indefinite noises are common to acute insanity, especially melancholia and the toxic insanities. In systematized delusional states voices are heard and externalized by the subject—voices uttering words, sentences, or carrying on protracted conversations.

Sometimes, however, the voices are not referred to the environment by the subject, are not externalized—so-called “psycho-motor” hallucinations. These have been attentively studied by Legros, but, in my opinion—as so often happens in neurological and psychiatric matters—he has over-classified them.

Hallucinations of sight, while relatively infre-

quent in common idiopathic insanity, are sometimes present in hysteria, and certain forms of epilepsy. They are exceedingly characteristic of poisoning by various drugs—mineral and vegetable, and of alcoholism;—in short of all toxic derangement of cerebral function. Of the impossibility of their occurrence in those born blind, or in those deprived of sight at a very early stage, mention has already been made.

Rarer are hallucinations of smell and taste. Even when they exist, it is often difficult if not impossible to determine whether they are primary or secondary—whether due to the incitement of gastro-intestinal derangement or to the suggestive sway of erroneous ideas. Like the hallucinations of sight, they are rather distinctive accompaniments of alcoholism and other toxic psychoses, of epilepsy and of systematized insanity.

Tactile hallucinations, false sensations of pain and hallucinations of the muscular sense possess a uniquely disagreeable interest to the alienist, because of the hypochondriacal and persecutory ideas that are readily built upon them. Various allegations of sexual violence—castration by men, obscene outrage by women; the assertion that they are beset by insects, so that the patient may disrobe in the ward of the hospital, or, if at large, on the public street; the belief that they are insidiously attacked by electricity, or other hidden agency are familiar illustrations.

In concluding this rather hasty sketch, I cannot refrain from entering a protest against the habit of regarding hallucinations as compatible with perfect cerebral health. Nor, on the other hand, is there the least evidence to warrant one in looking upon these phenomena as a distinct pathological entity. They are but parts—albeit integral and important—or a more general, a more basal cerebral mischief; and as such are to be both considered and managed with the whole.

TREATMENT OF CERTAIN PURULENT CONDITIONS OF THE ANTRUM OF HIGHMORE THROUGH THE NATURAL OPENINGS.

By NORVAL H. PIERCE, M. D.,
of Chicago.

The subject of this paper was chosen, first, because it is apparent that the ostium and accessory openings into the antrum of Highmore have not been used with the frequency they should be in the diagnosis and treatment of empyema; second, in order to make public the excellent results the writer has achieved in the treatment of certain purulent conditions of the sinus maxillare through the natural openings. Before proceeding to the chief part of this essay, it may not be amiss to take advantage of this excellent anatomical preparation from Dr. John W. Murphy's interesting collection to make a few prefatory remarks on the parts involved. The hiatus semilunaris lies in the middle meatus. In order to see this, we raise the middle turbinated body and now behold a rounded eminence, the bulla ethmoidalis, which contains the aperture of the middle ethmoidal cells. Below this is the infundi-

bulum which we may trace upwards and forwards to the opening of the frontal sinus. Its lower extremity leads to the sinus maxillare which receives the openings of the anterior ethmoidal cells and the ostium maxillare. The form and size of the ostium maxillare varies greatly. Most frequently it is an elliptical slit; it may be round or kidney shaped. The smallest ostium Zuckerkandl has seen had a diameter of 3 mm., the largest 19 mm. It was absent in only two of his enormous collection of skulls. Beneath this is found what Zuckerkandl denominates the accessory openings into the maxillary sinus. These accessory openings are pictured also in Henle's "Handbuch der Anatomie" and in Cruveilhier's and Sappi's anatomical works. They usually occur bilaterally, and they may be placed in any position in the middle meatus, but they are most frequently found in the regions of the hiatus semilunaris; they are oval or round in form with sharply cut edges and vary in size from a millet grain to a lentil; occasionally they are still larger. Giraldis believes that these openings are the result of pathological processes, because they are not found in young individuals. Zuckerkandl confirms this view inasmuch as he has observed rarefaction of the mucous membrane at points corresponding to these accessory openings. The importance of a knowledge of the existence of these openings must be clear to all who have to do with the treatment of disease of the maxillary sinus. According to Zuckerkandl, these openings were found in 10% of heads which he examined in his anatomical investigations. Hartmann believes that these openings are found more frequently in persons suffering from sinusitis. We can see how readily the ostium in the specimen which I hold in my hand may be reached by passing a properly bent probe through the anterior nares along the middle meatus. In washing out the sinus I use Moritz Schmidt's canula; this is attached to a bulb syringe which in turn is connected with a gal-

lon percolator jar. The apparatus may be held by an assistant during the process of irrigation or may

be suspended by an iron standard at the level of the patient's head. The amount of force of the current is regulated by pressure on the bulb of the syringe. It is unnecessary to say that a solution of cocaine and suprarenal capsule is used in order to contract and anasthetize the parts. It is best applied by means of a cotton carrier, the point of which is bent so as to enter well into the sulcus. Causes which preclude catheterization of the ostium maxillare are: narrow nasal chambers, deviations and spurs of the septum, polypi, hypertrophies, localized hyperplasia, synechia, osteoprytes about the region of the hiatus and an inaccessible ostium. During introduction of the canula the patient's head is inclined somewhat backward. When the canula is in place the patient's head is bent forward in the median line and the solution from the nose is received in a receptacle held beneath the patient's chin. The canula is introduced under illumination with crook directed upward. When the point arrives opposite to the middle of the middle turbinated body, the instrument is gently insinuated into the middle meatus, and the opening into the antrum felt for. When the instrument passes into the ostium or an accessory opening, sight and touch make us aware of the fact. It is my experience that in many cases of antral disease the ostium or an accessory opening may be found without the aid of vision as easily as the opening of the Eustachian tube. With the aid of illumination and anterior rhinoscopy the procedure becomes much easier. Exploration of the ostium maxillare is by no means a recent device. The dentist Jourdin in 1765 employed this method to ascertain the patulane of the ostium without illumination, depending entirely on the sense of touch. When the canula is in the sinus we have the choice between aspiration, inflation and rinsing the cavity. In the diagnosis of antral disease all of these procedures may be of value, but the latter procedure is the most important, inasmuch as the exudate may be small in quantity or very thick and only appear in the washing. All fluids used in washing should be sterile and bland. For diagnostic purposes sterilized Thiersch's solution is the most acceptable. We will frequently observe after such a washing the entire disappearance of the symptoms of an acute empyema, or they will be greatly diminished. Solutions which I have used in the treatment of maxillary sinusitis are: Thiersch's solution, solution of bicarbonate of soda, 2.5% carbolic acid solution, saturated solution of boracic acid, aceto-tartrate of aluminum (1 ounce of the saturated aqueous solution to 2 quarts of sterilized water). It is needless to say that these irrigations can be curative only in uncomplicated empyemas, though cases of dental origin have been reported where healing has taken place, notwithstanding the fact that the suspicious tooth remained. It is necessary in all cases to exclude all hindrances to healing, such as empyemas of neighboring sinuses, especially that of the frontal and ethmoidal. Polypi and hyperplasias or diseased teeth should receive the necessary attention.

One disadvantage of this method of treating disease of the maxillary antrum is that it necessitates a visit from or to the physician every time the antrum is irrigated. Very rarely do we find a patient who can find the opening himself, though I have

seen such an instance. In most acute and in many chronic inflammations, however, the diseased conditions are overcome after surprisingly few treatments. The following cases will illustrate the results obtained:

CASE I.—M. R., male, banker, aet. 39, sanguinous nervous temperament, was seized with a fever, rhinitis and pains in the head three days before I saw him. At the time he consulted me his temperature was 101.3°F.; the pain was localized to the right side of the face and he was in a highly nervous state from loss of sleep. He complained of sensitiveness of the upper teeth on the right side. The discharge was muco-purulent and much more profuse on the right side. Transillumination gave a marked right infraorbital shadow. The mucosa of the nose was greatly swollen. After thorough cocaineization muco-pus could be seen coming from the region of the hiatus. The canula was introduced with ease into an accessory opening. Purulent mucus in abundance came away in the Tiersch's solution, followed by clumps of thick brownish material. The patient experienced immediate relief and that night slept well for the first time since the beginning of the attack. Irrigations were continued daily, and the solution came away perfectly clear after the fifth treatment.

CASE II.—A medical student, male, aet. 23. Had attack of grippe beginning ten days before I saw him. Temperature ranged during this time from 100° to 102.5°F. He suffered from severe pain in the frontal and temporal regions, photophobia, lachrymation and great depression. There was profuse discharge from both sides which possessed a disagreeable odor. Both cheeks were slightly edematous, and pressure over them elicited expressions of pain. The patient gave a history of a similar attack about a year before. After application of suprarenal capsule and cocaine, both antra were irrigated through natural openings. Muco-pus came away from both. Headache, lachrymation, photophobia were relieved almost immediately. The distressing discharge which with the headache had kept the patient awake was lessened so that he slept. His recovery was continuous and at the end of six days complete. About two weeks later he came to my office complaining of slight tenderness over the left anterior antrum and increase of discharge from that side which seemed to have an odor. Irrigation revealed a small quantity of thick yellowish pus, which disappeared after the tenth irrigation. It is not unusual to observe relapses in these cases. Indeed, it is probable that in many cases the acute inflammation is but an accentuation of a subacute or chronic process of so slight a character as to produce little or no disorder.

CASE III.—S. K., female, married, aet. 29, complained of discharge and offensive odor from nose. The discharge was especially annoying at night as it ran back into the throat and caused cough; she suffered from recurrent attacks of neuralgic pain in the right side of face. Inspection revealed slight atrophy of both inferior turbinated bodies and the presence of thick muco-pus in both chambers. Transillumination gave right infraorbital shadow, canulization slightly difficult. Irrigation brought away about 2 drachms of thick yellowish matter. Iodoglycerine with vibratory massage applied to the mucosa of the nose. Patient employed irrigation by means of gravity douche twice daily at home. The nasal symptoms improved immediately. After about a month the solutions used in irrigations of the antrum came away perfectly clear. The discharge from the nose was reduced to a minimum. The neuralgic pains and odor had disappeared and the patient's appearance and general health had greatly improved. Probably in many cases of antral disease the absorption of septic material by the mucosa of the antrum causes a low grade of pyemic poisoning.

CASE IV.—B. K., merchant, aet. 38, married, complained of discharge into throat at night which awakened him and caused cough, he had similar attacks several times in past winter. Examination revealed tenacious muco-pus in the left middle meatus which during removal adhered to region of hiatus. Left infraorbital shadow on transillumination. Irrigation through opening in middle meatus revealed muco-pus. Operation was advised but refused. The irrigations through the natural openings were carried on daily for three months at which time the solution came away perfectly clear. He was kept under observation for six months without relapse occurring. Here we have a chronic

sinusitis cured by irrigation through the natural opening. Relapses, however, are common. Therefore the patient should be kept under observation for a long time. Cases might be multiplied, but that is unnecessary for our purpose, above quotations from my records being sufficient to show what may be done. It should be understood that not all cases may be treated through the natural openings, and that not all cases which may be reached through such openings will recover without further surgical interference.

In conclusion I would say:

1. That there is strong evidence to warrant the belief that in diseased antra accessory openings are more frequently found than in healthy antra.
2. That in a certain number of cases the ostium may be used to irrigate the antrum.
3. That we should in all cases whether for diagnosis or treatment try for the ostium or accessory openings before resorting to surgical puncture, whether through the inferior or middle meatus, the canine fossa or alveolar process.
4. That it is of no importance whether the opening through which we irrigate be the ostium or an accessory opening.

A CASE OF MORPHINE POISONING; SUCCESSFUL EMPLOYMENT OF COCAINE AS AN ANTIDOTE.

By ALBERT C. BARNES, M. D.
of Philadelphia.

The case herewith reported has many points of practical and scientific interest. 1. It illustrates the absorption of toxic quantities of morphine in an unusual manner. 2. It is, as far as the writer knows, the first case on record of the use of cocaine antidotal to morphine. 3. It offered an excellent opportunity of a detailed study of not only the toxicologic action of both morphine and cocaine, but illustrated clearly the antagonism of the physiologic activities of these two alkaloids.

The history of the case is as follows:

Girl, aged 17, employed in the laboratory of a firm of manufacturing chemists, was engaged in molding finely powdered morphine sulphate into hypodermic tablets. About two hours after beginning work the patient's companions, engaged at the same work, noticed that her mental powers became obtunded, her physical movements less, and that she acted in a dazed and peculiar manner. Shortly after the appearance of these symptoms, the patient's head dropped forward on her arms and it was found upon investigation that she was unconscious. The writer was called to see her within an hour after the development of unconsciousness, when from the history, and existing symptoms and physical signs it was recognized as a case of morphine poisoning. Absorption of morphine had probably taken place from the upper respiratory mucous membrane. Unconsciousness was profound; violent shakings, loud noises, etc., failed to elicit anything but most transitory—second or two duration—signs of mental life. The respiration, when first seen, was six to eight per minute; the individual inspirations were very deep. Later the respiratory movements became shallower and irregular and, still later, periodically shallow and irregular (Cheyne-Stokes type). At one time there was complete cessation of voluntary respiratory movements which necessitated artificial stimulation to respiration by means of alternate rhythmic contraction of the patient's chest, slapping the face with towels saturated with ice water, etc. During this period of respiratory stillstand her face was dark, cyanotic and covered with profuse perspiration.

The depression of the cardiac functions was almost equally pronounced. The individual heart beats, counted by direct auscultation of the chest, registered, at various stages of the poisoning, sixteen, twelve, and eight, respec-

tively per minute. The blood-pressure, estimated by the volume of the pulse, was apparently normal. The characteristic "pin-point" pupils were present; later, however, during the stage of respiratory cessation, the pupil became less contracted; this phenomenon is to be explained by the asphyxia.

Even from the start the case seemed very unfavorable; the occurrence of cessation of respiration and the marked cardiac centric depression were extremely ominous signs.

The usual well-known restoratives were applied before the writer was called. The patient was kept on her feet, compelled to exercise voluntary efforts at walking to and fro in the room, was given repeated strong decoctions of coffee, her face was frequently dashed with water, slapped with wet towels, etc. These procedures are of course useful adjunctive ones, but are unreliable as life-saving methods in severe forms of opium poisoning. The question to be answered, and answered promptly, was, what remedy, which could be administered hypodermically, is strongly and primarily stimulant to the central nervous system—the cerebrum, cerebellum, and the medulla with its contained cardiac respiratory and vaso-motor centres?

Atropine was not employed, because the pharmacological action of atropine is not, contrary to the accepted teachings, such as would indicate its use as an antidote to morphine. The elaborate studies of metabolism under morphine and atropine recently made by Professor Reichert, which, however, were not published until after the occurrence of the writer's case, shed much light upon the respective influence of morphine and atropine and show why they should not be used antidotal to each other.

At the time of the occurrence of this case the suggestion that cocaine be used as an antidote to morphine had never been made; nor are there, as far as the writer knows, any cases of cocaine-treated morphine poisoning on record. Cocaine was employed in this case because its primary physiologic activity is that of a descending stimulation, i. e., it first stimulates the cerebrum, then in succession, the cerebellum, medulla and spinal cord; in the case of morphine poisoning under discussion all of the functions of these parts of the central nervous system were profoundly depressed—in fact almost abrogated. Cocaine stimulates the respiratory centres, hence, accelerates respiratory movements. It stimulates the heart and vessels by direct action and also, by a specific effect upon the accelerator mechanism, produces increased heart activity. Cocaine produces rise of body temperature while morphine causes a fall of temperature. Moreover, the metabolic changes caused by cocaine are also directly opposite to those produced by morphine. It is therefore evident that the primary effects of toxic doses of cocaine are directly antagonistic to the late effects of toxic doses of morphine.

For this reason the writer's patient was given one-half grain of cocaine hydrochlorate, hypodermically; moreover this first injection was given at a time when the patient was apparently moribund. Marked improvement was not noticeable, so that a second injection of one-half grain of cocaine was given in one half hour. The effects of cocaine were plainly evident ten minutes after the second injection. The pulse and respiration became more rapid, and the patient showed signs of returning consciousness. However, there was not enough improvement to indicate that the stimulation had been sufficient, and it was therefore deemed advisable to give a third injection of cocaine. Accordingly, one quarter grain of

cocaine hydrochlorate was administered, with the result that within ten minutes the patient became conscious, the respiration and pulse (recorded at five minutes intervals) increased to 20, 46 and 80, respectively, per minute. It would have been ideal if these conditions had continued; but within a half hour after the third injection of cocaine the patient was garrulous, partially delirious, her heart beats registered 180 per minute, her respirations were quick, short and jerky, and she had tonic and clonic convulsive movements of the arms and legs. She had received *in toto* one and one quarter grains of cocaine. The case was now one of the first stage cocaine poisoning, but inasmuch as the morphine already in the patient's system would probably antagonize the development of dangerous convulsions, no fear of this danger was entertained. However, the later effects of toxic doses of cocaine consist of depression of all the functions primarily stimulated and this, added to the morphine depression, would most likely prove fatal. This depression did not ensue to sufficient extent to endanger life. The first convulsive effects of the cocaine passed away in the course of an hour and the patient, as far as consciousness, respiratory and cardiac activity were concerned, remained apparently normal for several hours. One half grain of elaterium was given in order to help remove both poisons from the system. Four hours after the last injection of cocaine the patient again showed symptoms of stupor with slow pulse and respiration, but these were successfully combated by strong coffee, forced voluntary movements in the open air, etc. She was under observation from 11 A. M., to 5 P. M., and at the latter hour at her own request she was removed to St. Agnes Hospital. Subsequent inquiry revealed that she recovered entirely from the effects of the poisons, but developed a condition resembling "typhoid fever" which necessitated her remaining in the hospital for five weeks. A study of her nitrogen metabolism during this period would have been most interesting and very likely productive of some new and important facts.

Inasmuch as this patient's life was unquestionably saved by cocaine, and as this latter remedy is the most rational physiological antagonist to morphine, it should find more general employment as an antidote. However, care must be exercised that the antidote be not given in too great quantities; in regard to this latter point the above mentioned case would seem to indicate that one-half grain of cocaine hydrochlorate may be given at half-hour intervals until consciousness returns and the respiratory and cardiac functions are sufficiently aroused. In this case, the stimulation was even more accentuated and extended to the spinal cord, producing convulsive movements.

Spontaneous Non-traumatic Fracture of the Ribs.—Chelmonski (*Gazeta Lekarska*, May 12, 1901) observed 13 cases of fracture of the lower ribs produced by muscular contraction. 8 were cases of tuberculosis and 5 of cachexia. According to Prszevoski, the facility with which the bones fracture in such cases is due to osteoporosis. [A. R.]

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended December 13, 1901.

JOURNAL DES PRATICIENS.

August 31, 1901. (15mc. Année, No. 35.)

1. Scrofulous Bronchitis in Children. A. BRETON.

1.—By scrofulous bronchitis Breton means that form of chronic bronchitis of childhood, tenacious, recurring superficial, and of long duration, which remains unaffected by treatment. It is seen from one to seven years of age, as a rule, though it has been found in children of eleven. It is most common in city children. Improper feeding, bad hygiene, too much clothing, too many sweets, irregular bowel movements, pertussis, etc. may all predispose to scrofulous bronchitis, as do alcohol, syphilis, and tuberculosis in the parents. The condition may develop from a coryza, diarrhea, or with teething, in winter or summer. It is commonly seen in either tubercular or rachitic children, with cervical adenitis, scoliosis, conjunctivitis, chronic rhinitis, etc. The lymph-glands are enlarged all over the body, there is no pain, a few rales being the only symptom. Occasionally there is some fever, with expectoration. Dyspeptic symptoms may appear. Laryngismus stridulus follows frequently, or emphysema, while phthisis may develop; or the chest may remain undeveloped. Mentally and physically these children are backward. The prognosis is unfavorable for the future development of the child; the diagnosis difficult, especially the differentiation from phthisis. Prophylactically hygiene, exercise, etc., are of use. A change of air, diet, the removal of existent adenoids, are beneficial. Cod liver oil, the iodides, etc., should be given. Graduated gymnastics may aid greatly during recovery from scrofulous bronchitis. [M. O.]

September 14, 1901. (15mc. Année, No. 37.)

1. Abscess of the Subcutaneous Tissue of the Prepuce, due to Gonococci. ALEXANDER RENAULT.

2. The Prophylaxis of Tuberculosis in the Country. QUELME.

3. Massage. KRIKORTZ.

5.—A man of 42 contracted gonorrhea and was cured in six weeks. Then, as he imbibed freely, the discharge reappeared two weeks later, followed by cystitis. An entire month elapsed before an abscess was discovered in the subcutaneous tissue of the prepuce. Pus from this abscess was full of gonococci. Such a condition, occurring so long after the primary attack of gonorrhea, and so far from the urethra, is extremely rare. [M. O.]

2.—In order that the people living in the country may benefit by the recent advances made in the treatment of consumption, Quelme believes that new methods should be taught to the country physicians. Tuberculosis to many of them means approaching death for the patient, and no means are undertaken to stop the progress of the disease. Besides, they must be shown that phthisis is contagious, and how to prevent this contagion. Quelme concludes that the people in the country should be made to understand that the term tuberculosis means but the beginning of phthisis; that it is contagious; and that a physician should be consulted early in every case. [M. O.]

3.—Physiology has shown that muscular movements aid the venous circulation in propelling the blood toward the right ventricle, and thus it is that **methodic exercise** is of service in heart disease. Rapid, automatic movements act as a sedative to the heart, and are of use in the functional heart troubles, as arrhythmia, irregular pulse, or unstable vaso-motor innervation. Passive, circumductive movements have the same effect. Slow, inhibitory movements increase arterial pressure and act as a tonic to the heart. They are useful, therefore, in hypostole, and in some cases of dilatation of the heart. Abdominal massage and forced expiration reduce arterial pressure, also; while forced inspiration raises it. Massage of the abdomen and legs often acts as a diuretic. While harm may be done by ill-advised massage in heart disease, well regulated, it will give satisfactory results. [M. O.]

\$3.00 PER ANNUM

An Official Report on Food Adulteration.—One of the most extended investigations into the use of preservatives and coloring matters in foods and beverages has just been concluded in England by the publication of a government blue-book, containing full reports of testimony taken by a departmental committee and presented to Parliament. The work of the committee began in July 1899, and closed, as far as taking testimony was concerned, in May, 1900. Seventy-eight persons comprising physicians, chemists, pharmacists, factors, and purveyors were examined at considerable length and with much care and discrimination. The report fills five hundred closely printed pages. The information presented includes statements of actual practices in regard to food adulteration with the views of experts as to the probable effect of such practices. As might be expected, differences of opinion on the latter question are to be noted often, but the committee seems to have so controlled its work as to secure a fair representation of competent authorities and check the exploitation of eccentric or selfish views.

Great attention was given to the additions to milk and milk products. On this point the experience of the Aylesbury Dairy Company which has a very large business in the west end of London is instructive. This company finds it necessary to use some coloring matter in milk during much of the year. The managers are not desirous of doing this, but whenever the color is omitted, complaints begin to come in that the milk is too pale and is not pure. On the other hand, the company has been able to collect milk from farms many miles from London and distribute it over a considerable area without using preservatives and without dissatisfying its customers.

The extended use of boric acid and borax (usually in mixture, under the name of "boron" preservative) is clearly indicated. The principal foods so preserved are meats, milk and butter.

Sodium benzoate now so much used in the United States for preserving jams, jellies and other package foods has apparently not made much headway in England, as salicylic acid is still reported in large

use. The question of the use of borates in butter is one of worldwide importance, for a mixture of borax and boric acid is now used very largely as a substitute for salt. The quantity of preservative is usually about eight ounces to the hundred pounds, that is 0.5 per cent. By this use the amount of salt may be much diminished which may be regarded as a sanitary gain, whether, however, a net gain or not cannot be positively stated.

While the medical witnesses were mainly in agreement concerning the necessity of restricting the use of preservatives, there were marked differences as to the specific toxic effect of these substances in full dose. Thus one experienced hospital physician stated that boric acid is likely to produce serious dyspepsia; another apparently equally experienced witness had seen no trouble arise from the free use of the substance. The experiments of Tunnicliffe and Rosenheim as to the effect of boric acid and formaldehyde when administered with the food of children (noted a few months ago in this journal) failed to show any injurious action.

The following are the conclusions of the committee, which will, in all probability, be of considerable influence on the methods and rulings in the United States. The conclusions seem to be conservative in the best sense of that word. Dr. Tunnicliffe dissents from the prohibition of copper coloring in vegetables and appends a special paragraph in which he states that he finds no evidence that the small amount of copper can produce disease.

That the use of formaldehyde or formalin, or preparations thereof, in foods or drinks be absolutely prohibited, and that salicylic acid be not used in a greater proportion than 1 gr. per pint in liquid food and 1 gr. per pound in solid food. Its presence in all cases to be declared.

That the use of any preservative or coloring matter whatever in milk offered for sale in the United Kingdom be constituted an offence under the Sale of Food and Drugs Acts.

That the only preservative which it shall be lawful to use in cream be boric acid or mixtures of boric acid and borax, and in amount not exceeding 0.25 per cent. expressed as boric acid. The amount of

such preservative to be notified by a label upon the vessel.

That the only preservative permitted to be used in butter and margarine be boric acid or mixtures of boric acid and borax, to be used in proportions not exceeding 0.5 per cent. expressed as boric acid.

That in the case of all dietetic preparations intended for the use of invalids or infants chemical preservatives of all kinds be prohibited.

That the use of copper salts in the so-called greening of preserved foods be prohibited.

That means be provided either by the establishment of a separate Court of Reference or by the imposition of more direct obligation on the local Government Board to exercise supervision over the use of preservatives and coloring matters in foods, and to prepare schedules of such as may be considered inimical to the public health.

The Open Air Treatment of Tuberculosis in Germany.—The Imperial Health Office at Berlin has just published a statement showing remarkable success in Germany with the open air treatment. In the Spring of 1901 there were sixty institutions in the empire with a capacity for five thousand patients devoted to this class of cases. Of the number admitted from the beginning of 1899 to the middle of 1900, there were 5059 male and 1214 female patients. Nearly half were between the ages of 20 and 30 years. The report takes up the social condition of the patients, the influence of occupation, heredity, duration of the disease before admission to an institution, the duration of treatment and the success of the treatment in general. In 56 per cent. the social conditions were favorable, in 31 per cent. they were moderately good, and in 12 per cent. they were bad owing to poor housing and insufficient food. In half the patients the origin of the disease was alleged to be due to the continuous inhalation of dust involved in their employment; there were 182 cases due to metal dust; 129 from stone, coal or glass dust; 116 cases from wood dust; 111 cases from wool dust and 126 cases from the effects of various kinds of dust. Smoky workshops and rooms filled with chemical gases had an injurious effect on 81 persons. In 253 cases the disease was ascribed to a sedentary occupation connected with the keeping of the body in a bent position and living in damp rooms; 313 cases were the alleged results of weakening incidents, such as heavy night work with insufficient nourishment, irregular manner of living, excesses, accidents etc. It is interesting to note that in twelve cases the disease is said to have originated from infection in institutions and hospitals for consumptives or through other professional inter-

course with tuberculous patients. It is probable that 2177 or 34.7 per cent. were directly infected, or had become tuberculous by infection in the family. In just one half the cases the disease had existed for less than one year before admission to an institution.

The average duration of treatment in an institution was 92 days. At Dannenfels, St. Blasien, Grabowsee, Reiboldsgrün, Harlaching and Albertsberg the treatment extended from 100 to 202 days.

The results reported are remarkable. Out of 6108 cases 67.3 per cent. were perfectly fitted to pursue their former occupation; 7.1 per cent. were quite able to earn a living in a different vocation; 14.6 per cent. were partly able to earn a living and 11 per cent. were unfitted for work. It is stated by Frank H. Mason, U. S. Consul-General at Berlin (Report to the Surgeon-General of the U. S. Marine Hospital Service) that 87.7 per cent. were discharged as cured or improved and this remarkably good result is attributed to the careful selection of cases suitable for treatment in the institutions.

Shall We Heat Our Street Cars?—There has been considerable criticism in the daily press of late on account of the failure of the railroad companies to heat the street cars. It has been urged that motives of economy have led to the refusal of the railroad authorities to make these cars more comfortable; while, on the other hand, the companies assert that they believe it is preferable for the health of the passengers not to heat the cars. The sentiment of the press, as a whole, has been in favor of heating the cars, and it has been urged that in travelling in cold cars passengers have been thoroughly chilled, and that many cases of sickness, especially attacks of pneumonia, have resulted from this. Others have pointed out that smallpox is favored by a low temperature, and that riding in cold cars exposes one unnecessarily to the risk of this infection. In our opinion, whatever the motives of the railroad companies may be in refusing to supply heat in the cars, they have decidedly the better of the argument on scientific grounds. It has been stated by many authorities that the great prevalence of catarrhal conditions in this country is due in part to heating our houses to a degree quite unnecessary, and subjecting the inmates to sudden changes of temperature on exposure to the outside temperature. It is no doubt true that riding in cold street cars is uncomfortable, but in looking back a few years to the time when our cars were heated generally, we recall that travel was scarcely more comfortable, if at all so. When the car doors were closed the temperature rose to an uncomfortable point; when they were opened to

permit the ingress or egress of passengers the temperature dropped many degrees, and it is scarcely open to doubt that those sudden falls of temperature of such intensity are far more injurious than an equable temperature, however low. When no heat is used in the cars, the temperature within approximates the temperature without; the constant opening and shutting of the car doors, while it allows draughts, is nevertheless far less harmful in our opinion than a drop of perhaps 20 degrees, which would occur under similar circumstances if the cars were heated. A point which our people have still to learn is, that the more rational manner of living consists in accommodating oneself by the proper amount of clothing to the temperature which prevails. Hygienic science has much to exact from those who have charge of public conveyances, but we are of the opinion that cold ears, when it is necessary that frequent stops be made, are far less likely to produce ill health among the passengers than travel in heated conveyances.

The Report of the Surgeon-General of the Navy.—Surgeon-General Van Reyden's annual report is a voluminous document of more than 300 pages, and, covering as it does the operations of the United States Navy for a year, it contains much interesting reading. Perhaps the most important parts of it for the future student are the accounts of the operations in foreign lands, and the official report of President McKinley's case.

Only 34 deaths are reported among the sailors and marines who were engaged in the Chinese expedition. Such diseases as occurred were mostly due to the insanitary condition of the country and the unfavorable effects of the climate. Taken in conjunction with the favorable report of Surgeon General Sternberg of the Army, the satisfactory conclusion can be drawn that our Government has shown remarkable efficiency in looking after the welfare of our troops on duty in foreign countries.

The official report of President McKinley's case by Dr. Rixey is largely a repetition of the report, already published, of the attending surgeons and physicians. It is supplementary in the sense that it goes more fully into detail. It is in fact a complete diary of the case, giving every bulletin as published and every minute detail of the clinical history. In this sense it is the most valuable report of the case extant, and leaves nothing to be desired as a paper for future reference.

Dr. Van Reyden's annual report is too lengthy for complete review here. We may, however, in general terms, commend its wealth of information and the value of the many special reports from medical offi-

cers on duty in various foreign stations. Many of these are contributions to our medical knowledge that reflect credit on their writers and add materially to our medical literature. They remind us that we are reaping some advantages from being a "world power" if only in the breadth of view and opportunity for study which this enlarged activity confers.

The Remuneration of President McKinley's Doctors.—We notice that this subject is being discussed in some of the newspapers, and we trust it will be taken up by Congress at an early date and the accounts satisfactorily adjusted. Congress surely does not need to be reminded that these services were rendered to Mr. McKinley not as an ordinary citizen but as President of the United States. The obligation is a national one and should not be a charge against the martyred President's estate. In the case of President Garfield, this obligation was recognized by Congress, but if our memory serves us, there were some unnecessary discussion and some rather unseemly haggling over the settlement. It is not the part of outsiders to determine the value of these services or to suggest the size of the fees, but it is evident that these latter should be proportioned to the eminence of the patient, the importance of the services, the standing of the attendants, and the responsibility of the case. It is not inappropriate or indelicate to call attention to the fact that the mere risks to professional reputations involved in such a momentous and critical case are certainly as great as, if not greater than, any risks assumed by any professional men in any other circumstances whatever. From the legitimate business standpoint, such risks are not among those which physicians and surgeons can afford to assume for mere sentiment or should be called upon to meet without ample compensation. The medical conduct of the lamented President's case was conspicuously free from selfish, jealous and unworthy motives. The physicians and surgeons performed a grave public duty, without a taint of self-seeking or of vain-glory. It is appropriate now that they should be well remunerated by the American people.

The Scientists and the Poets.—Professor William L. Poteat, in *The Popular Science Monthly*, contributes an instructive study of the great Latin poet, Lucretius, who wrote a poem in which he forecast the doctrine of evolution, and who, although he lived two thousand years ago, had the spirit but not the methods of modern science. Professor Poteat takes pains to point out that the union of the scientific and poetical genius, so conspicuous in Lucre-

tius, is not so rare as it is sometimes, on superficial grounds, claimed to be. He reminds us that Tyndall and Huxley had been known occasionally to drop into verse. On the other hand the poet Goethe was said to be more proud of his scientific achievements than of "Faust". Of poets of the first rank who have maintained an interest in science, Tennyson was a striking example. "He studied medicine until he imagined that he had all the diseases set out in the books". It is interesting to us moderns to know that Lucretius, who died in 54 B. C., left a description of the great epidemic of plague in Athens, and that this description forms part of his poem. In the opinion of a competent critic he has given the history of this tremendous pestilence with the accuracy of an historian and the genius of a poet.

The Westphal-Piltz Pupillary Phenomenon.—

Among the endless array of reflexes, but few can be considered as diagnostic without accompanying clinical substantiation, and still fewer are *prima facie* evidence of any one disease. We do, however, find many which are valuable diagnostic adjuncts, and further observations may yet accord the Westphal-Piltz pupillary phenomenon a recognized position among the reflexes that are available for diagnosis. This reflex, described by Westphal and Piltz within a month of each other, consists of a contraction of the pupil, when the orbicularis palpebrarum is contracted energetically. It has been claimed that this phenomenon is most easily detected in medium sized pupils and in those that are immobile or extremely sluggish to light stimulus. Westphal found it present in cases of general paresis, and it was in a case of paretic dementia with typical Argyll-Robertson pupil, that Piltz first observed it. The phenomenon, as claimed by Piltz, disappears under homatropin mydriasis, which Wundt considers a physiological manifestation. In order to preclude any possible interference with the experiments by drug mydriasis, Fritz Schanz recently elicited the reflex in an incurable case of internal ophthalmoplegia, which led him to conclude that the pupillary contraction is due to the mechanical effect caused by the energetic contraction of the orbicularis. Furthermore, he attributes this mechanical impediment to a subnormal innervation of the iris, as evidenced by the coexisting loss of light reflex. As originally claimed by Westphal, the condition is present in most cases of reflex iridoplegia, and also in pupils not reacting to light but in which the convergence reaction is still preserved. Westphal and others attribute the phenomenon also to the

mechanical interference, but they believe it due to an increase mechanical determination of blood to the eyeball and especially to the iris, causing stagnation with subsequent motion of the pupil. While reflexes are pouring into the diagnostic armamentarium in great numbers, there seems to be an increased and justifiable skepticism arising among the more conservative, so that it may not be long before a newly described reflex must be supported by the strongest clinical evidence, before it is accorded a recognized and permanent position in diagnosis.

If Mr. Carnegie's gift to the nation carries with it any promise or prospect of enlarging the field of medical research, we shall of course feel duly grateful to him. Even a part of the income of ten million dollars, judiciously expended, would do something toward advancing this country on her destined way to become the foremost nation in the world of medical science. We have always contended that the genius of the American people—so inventive, so practical and so energetic—was just as well adapted to excel in original medical research as it has already shown itself to be in the mechanical arts. After all, much of medical research has become a higher form of the mechanical arts.

The season is suggestive of good will to everybody—if not peace on earth. It is gratifying to note that the hospitals and homes reap their full share from the benevolence that rules at Christmas-tide. What with evergreens and holly, some of the hospital wards acquire a home-like and holiday appearance that is good to look upon. The decorative scheme may even include a Christmas tree—an object which no person is ever too ill or too old to regard with indifference. Such decorations may not be strictly antiseptic—especially after they have stood for a week—but they have their wholesome influence nevertheless.

Current Comment.

THE CENSUS OF FRANCE.

France's census makes gloomy reading for that country's well wishers. According to "figures," there has been a renewal of collapse, and a writer in the *Figaro* points out that in French families there have been more bereavements than joyous births. France has lost 26,000 lives. For centuries France was preponderant in the world because her population was the most dense; to-day the outlook is terrifying, for the remedies suggested to the Senate by M. Piot and others are good intentions wasted. This census mathematically confirms M. Emile Zola's amazing statistics.—*The Boston Herald*.

EIGHTEENTH CENTURY REMEDIES FOR CANCER.

With regard to an annotation which recently appeared upon the traditional and medieval therapeutics of the violet a correspondent has written to us pointing out that

when the medicinal powers of the violet were most believed in it was never considered to be a cure for cancer. "The sovereign charm," he writes, "for that worst of human ills was the morel, a species of fungus said to be of tallow origin. Human milk, too, honey, and now bread, were ingredients in the plasters laid by forgotten leeches upon growths most probably non-cancerous, but suspected of malignancy in their action or developments. The human milk is, of course, a manifest survival of tribal cannibalistic ideas. It was still recommended among the ingredients of a 'precious medicine' which 'will bring forth a cancer, and pluck it up by the roots' in a popular chapbook of the date 1791. It is curious to note, when tracing the evolution of a recipe from such a book as this through such works as Sendall's MS. of the Commonwealth era to the early writers in Henslow's book, how persistently the mere ritual of the so-called cure survives when the components of the emplastrum or pill have changed half a dozen times. Morel gives place to the white of an egg, and both are now merged in a decoction of violet leaves, but the milk 'of one that hath been a mayde and hath given birth to a knave' is recommended at the dawn of the nineteenth century, while the directions as to the use of lint, a form of bandage rarely, if ever, mentioned in chapbooks, survive from the days of Rufus to the opening years of a new era of enlightenment. The ancient belief was that the lint or cloth, laid upon the growth, would bring it away 'in the morning.' 'In the morning thou shalt find the Cancer lead on the said plaister. This is most true. I copied this out of an old written book.' Nowadays there is no talk of growths being brought away in the night, but none the less the lint is used and the symptoms of the disease are recorded as vanishing in 14 days."—*The Lancet*.

CYCLING AND ITS ABUSE.

The curse of cycling, as of course with many other modes of exercise, is the tendency to carry it to excess. A striking and pitiable example of this human failing has been recently given in Madison Square Garden, where, for a week, a number of men toiled round and round that hall for hours at a stretch, making a spectacle of themselves, and like the gladiators of old, providing the inhabitants of New York with a Roman holiday. The brutalizing effect of contests of this nature was recognized years ago, and laws were passed which seemed to minimize the severity of long-distance races. Notwithstanding this legislation, the men who raced the past week appear to have suffered from the strain as much, if not more, as did the men who pedaled for the same period two years ago. Utterly exhausted, worn out in body and mind, several were forced to retire many hours before the stipulated time for the contest to end. Those who stayed to the finish were kept going by stimulants and drugs, which imparted to them sufficient fictitious strength to endure through their appointed task. Needless to say that such tests of endurance are useless, foolish, and even criminal. No good object is obtained by bicycle riding of this description, and it tends to bring the exercise into disrepute. Some of the men who played tricks with their constitutions in Madison Square Garden will suffer from the effects of their foolishness for years, perhaps for life. The heart is almost certain to be affected injuriously, and the strain put upon the nervous system is more than likely to sap the vitality of any but the strongest constitution. Medical journals everywhere should protest against bicycle riding—in itself a healthy exercise—being thus so grossly abused.—*The Medical Record*.

A DOCTOR IN AN IMPORTANT OFFICE.

Hardly second in interest to the medical profession is the office of the street cleaning commissioner. Doubtless true is this in the present instance, for the new appointee is himself a physician, Dr. John McGaw Woodbury. We need not point out the close connection between cleanliness of the streets and a normal sanitary condition of the city. In the army Dr. Woodbury has won an enviable reputation for executive ability, a prime essential in a street cleaning commissioner, and if there was to be found a worthy successor to the lamented Colonel Waring, we have every reason to hope that it is Dr. Woodbury. Many of our people have despaired of ever finding a second Waring, but we

believe Dr. Woodbury will prove himself such a man. Dr. Low is deserving of special credit for having exercised such rare discrimination in the appointment.—*The New York Medical Journal*.

CHRISTMAS FOR A PATIENT.

The clinic before several hundred students at the Jefferson Medical College a few days ago terminated in a species of donation party for one of the patients, in order to make a brighter Christmas for the sufferer. A little girl had been treated for some deformity of her feet due to an accident, and at length an operation had been performed. Although the operation was successful and healed nicely, nevertheless it did not restore to the sufferer the use of her feet, and the Professor stated to the class that the little girl would never walk again. "I saw some of you young men dispensing small change rather freely a few days ago," said the Professor to the several hundred young men in the amphitheatre about him. "Suppose you contribute a little toward making Christmas more joyful for this little girl." The response was prompt and generous. Showers of coins rained into the open centre of the structure, and when collected a tidy sum was realized. It doesn't take much to make happiness for some one about you. Try it. —*The Evening Telegraph*.

Correspondence.

MOSQUITOES AND YELLOW FEVER.

By GEORGE E. BEYER, M. D., of New Orleans, La.
To the Editor of the Philadelphia Medical Journal.

In an article in your valuable Journal of October 19, 1901, entitled "Mosquitoes and Yellow Fever," I saw myself quoted in two instances, which, however, lead me to think that these sentences of mine have been somewhat misunderstood, especially if they are quoted to disprove the possibility or rather ability of transmission of disease by these insects.

It is perfectly true that I could not lengthen the life of any of my mosquitoes in captivity beyond 22 days, but it must be borne in mind that my observations were confined to spring and summer and consequently to a period of full insect activity, but they have no reference to hibernation. Dr. Reed's experiments, quoted also in the above article, were all made during midwinter, and at a time when even in the tropical climate of Cuba these insects are forced to enter into a semi-hibernation. It may be by reason that the thermal or other conditions are not exactly suitable for the adults themselves or for the development of the eggs and larvae. I am sure, however, that in freedom, Dr. Reed's 71 day mosquitoes would have survived until such a time when the deposit of their eggs would have also engendered the further development of the larvae. Upon these same thermal conditions, which control the adult mosquitoes, depend, no doubt, the ability of the insect to transmit the disease, (yellow fever), and, instead of requiring an incubation of twelve days or more in midwinter, a much shorter period may be necessary during midsummer, as, for instance, quite recently demonstrated in New Orleans, when a period of seven days was found sufficient for the mosquitoes to convey the disease. It is quite true that *Stegomyia fasciata* have, in our section, at least, their winter quarters about the middle of April, sometimes earlier, sometimes later. This, however, can in my opinion not affect the ability of mosquitoes as disease transmitters. An infected mosquito may hibernate, and with it naturally the parasite which it harbors, as was amply proven by Reed's and Carroll's experiments. If, then, it should feast upon some hapless victim after emerging from its winter-retreat in April, the chances may be that the foundations for an epidemic have been laid then and there. But, on the other hand, as mosquitoes are not as plentiful about that time, no further infection of other mosquitoes may occur, and the patient either recovers or dies as the case may be. Such sporadic cases, unless too pronounced, are usually diagnosed as anything else but the true disease.

In fact, by reading over the entire article, and for that matter the one of August 3, 1901, as well, I feel convinced that the writer on mosquitoes and yellow fever has under-

taken too much in his endeavor to contradict facts by unreliable traditions and time-worn theories.

For such stories as, for instance, the one about the recurrence of yellow fever on board the U. S. S. Plymouth in 1879, are no longer tenable if confronted with facts elicited by modern and ever progressive scientific research.

REPORT OF A CASE OF RETAINED PLACENTA WITH ECLAMPTIC CONVULSIONS.

By JOSEPH W. LACKEY, M. D., Durango, Col.

Mary C., age 22, primipara, was confined at 8 P. M. She did not intend having an attendant until four hours later the placenta had not come, and she was having convulsions. When I arrived at 12 o'clock I found her flowing considerably; pulse weak and intermittent; cold sweats, and having convulsions every 15 or 20 minutes. She called it a chill, but did not feel cold. No pains. Her perineum was torn to the third degree.

I tried to start the expulsion of the placenta by hot drinks, whiskey, strychnia by hypodermic, and Crede method, but her convulsions kept getting worse; severe, so at 12.45 I gave chloroform, sterilized vagina and my hands, went into the uterus and loosened the attached portion with my fingers and then by traction on cord and compression of the fundus it came. I then sewed up the laceration with chromicized catgut. Her convulsions continued at intervals of about fifteen minutes until 2 P. M., when she went to sleep from an hypodermic of morphia I had given.

She did not lose consciousness, nor have any pains during convulsions. They would last about two minutes, tonic in character, but not typical eclamptic.

Next day urine showed trace of albumin, no sugar, sp. gr. 1025. Acid reaction, but loaded with acid phosphates. Microscopic examination showed calcium oxalate crystals and debris. She made a good recovery.

Puerperal convulsions may be (1) eclamptic, (2) hysterical, (3) epileptic, or (4) some cerebral lesion, which last three are to be regarded simply as accidental complications. The eclampsia is fortunately a tolerably rare event, its estimated frequency is about once in five hundred pregnancies. The mortality is about 32 per cent.

Usual symptoms: The attacks resemble those of epilepsy, the cry being absent, eyes wide open and fixed, pupil contracts, later may dilate. Convulsive twitchings start in all the muscles of the face. These convulsions extend to the muscles of the body generally, movements as a rule are more pronounced in the upper extremities. The convulsions are tonic and clonic. The face becomes cyanosed, breathing irregular, stertorous, pulse intermittent; if severe they become comatose.

As to the etiology and pathology of this condition, there is much diversity of opinion. Since Braum's work was published in 1857, the term eclampsia and uremia have come to be regarded as synonymous by the majority of practitioners.

Treatment is first preventive and of the attack itself. Preventive in albuminuric patients: ward off attacks of indigestion; keep them warm. If there is edema, a strict milk diet, drink plenty of the natural alkaline waters, such as Vichy, Seltzer, Lithia water, etc.; mild diuretics, and the skin should be made to aid the kidneys; also free catharsis. The attack itself. First, induction of premature labor, venesection is very useful here. Narcotics and anesthetics, saline enemata, intravenous infusions of normal salt solution.

Reviews.

Anesthetics and Their Administration, a Text-Book for Medical and Dental Practitioners and Students, by Frederic W. Hewitt, M. A., M. D., Cantab.; Anesthetist to His Majesty the King; Anesthetist and Instructor in Anesthetics at the London Hospital; Late Anesthetist at Charing Cross Hospital and the Dental Hospital of London. London: Macmillan & Co., Limited; New York: The MacMillan Company, 1901. Price, \$4.00.

This book is one which commends itself to all surgeons, and which should be studied by everyone who considers himself, or who is considered by others, an anesthetist. Its field of usefulness, however, is not confined to these

two classes of medical men, but also includes medical students and those who only occasionally administer an anesthetic. It is written by one who has devoted all of his professional life to the study and administration of anesthetics; his experience has been extensive and his book presents both the theoretical and the practical side of the subject in an authoritative manner. This second edition differs greatly from the first and is particularly enlarged by the addition of chapters on the history of anesthesia and the experimental physiology of the subject. The matter is remarkably well systematized so that reference to both facts and figures is made easy.

We are pleased to see that Hewitt gives the credit for the first use of ether anesthesia for the distinct purpose of producing insensibility to pain during a surgical operation to Crawford Long, of Georgia. Due credit is also ascribed to Morton, Wells, and Jackson. Chapters VI and VII are devoted to "Special Considerations in the Selection of Anesthetics and Methods" and contain matter of the utmost importance to every medical man. Especial attention is called to the various postures during anesthesia, a matter which should be given more consideration than is usually allowed it.

This work comes to us at a time when the subject with which it deals is being extensively studied in both this country and abroad, and we feel that the time has come when medical men generally should be better informed regarding the properties and the method of the administration of anesthetics. Hewitt's book may be considered a complete treatise on the subject, dealing as it does in a most thorough manner with every detail. [J. H. G.]

Annual Report of the Smithsonian Institution, 1900. Washington, D. C.

The Smithsonian Institution does more for the promotion of science in America, than any other single body, and it does it in a most rational and satisfactory way. Of course there are men interested in some particular small line who will be irritated at it because their particular small line is not given undue prominence, and there are others who, on account of their own failure to accomplish original and scientific work in spite of advantages and opportunities, prefer to condemn all other persons occupied in scientific pursuits, in order to minimize their own defects. But an examination of the annual report of the Institution from year to year is sufficient to convince anyone of the truth of our initial statement. This report consists essentially of the account of the business sessions of the Board of Regents and of the reports of the Committees and officials of the Institution, but it has been the custom to add, as an appendix, original papers, abstracts of papers, and reports of experiments which cover the general field of science and indicate the progress of events, and these papers are selected partly with the idea of instructing the ordinary non-scientific. They are chosen with rare skill, and there is hardly one of them which cannot be read with interest by any intelligent person. For instance, we find in the present number such popular articles as an account of the Zeppelin air ship, of Liquid Hydrogen, by James Dewar, of the Photography of Sound Waves, by R. W. Wood, of Unsuspected Radiations, by Prince Kropotkin, of the Restoration of Extinct Animals by Frederick A. Lucas, of Nature Pictures by Radcliffe Dugmore, of a Notable Advance of Color Photography, the latter illustrated by reproductions of the plate in various stages, and in its final form. We must say that the last stage is somewhat disappointing, and entirely too chromo-like. More popular articles are "Through Africa from Cape to Cairo," by Ewart Grogan; The "Yermak" Ice-breaker, by Vice-Admiral Makaroff; and a character study of a beaver, by Radcliffe Dugmore, and one which has a sort of moral quality: "The Loot of the Imperial Summer Palace at Peking," by Count D'Hérissou. The report also includes some valuable accounts of the progress of science in its various branches, such as astronomy, aeronautics, chemistry, geology, physics, electricity, psychiatry, and as a tribute to the increasingly scientific character of medicine, on the progress of medicine itself. There is also an article on the century's great men of science, by Charles S. Pierce, and two interesting articles on Huxley. Of course most of these articles

are due to the initiation of the new century. Of distinct medical interest are the articles on malaria, and on the transmission of yellow fever by mosquitoes, both by General George M. Sternberg. "One of the most interesting sections of the preliminary part is the report of the Superintendent of the National Zoological Park. An energetic effort is being made to complete a collection of American animals, and in many cases this has been successful. We note the acquisition of a Philippine deer, apparently the only animal from our new possessions, and of one buffalo calf, which was born in the Park; a very small result for a herd of ten. The total number of animals resident at the Park on the 30th of June, 1900, was 839. [J. S.]

The Medical News Visiting List for 1902. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 100 pages of blanks. The 60-patient Perpetual consists of 256 pages of blanks. Each style in one wallet-shaped book, with pocket, pencil and rubber. Seal Grain Leather, \$1.25. Thumb-letter Index, 25 cents extra. Philadelphia and New York: Lea Brothers & Co., Publishers.

The Medical News Visiting List for 1902 shows the usual well known concise additions upon methods of keeping physicians' accounts, thermometric scales, ordinary weights and measures, the metric system, examination of the urine, dose tables and therapeutic remedies. Besides this, many excellent points are taken up. It is sure to be as useful as it has always been. [J. L. S.]

Principles of Surgery, by N. Senn, Ph. D., LL. D. Third Edition, thoroughly revised. Philadelphia and Chicago: F. A. Davis, Publisher, 1901.

This third edition of Senn's Principles of Surgery brings the able work up to date. Besides many noticeable changes in the former chapters, he has seen fit to add two entirely new chapters, one on "Degeneration" and the other on "Blastomycetie Dermatitis." The former of these new chapters follows that on "Regenerations" and precedes that on "Inflammation." It has to deal in a brief but comprehensive manner with atrophy, cloudy swelling, and fatty, mucoid, colloid, waxy, and amyloid degeneration. The portion of this work devoted to "Suppuration in Large Cavities" in which the author deals with brain abscess, empyema, suppurative pericarditis, etc., is both scientific and practical, presenting the most rational reasoning and the most reliable treatment. Considerable space is devoted to a discussion of "Hydrophobia" and its treatment. Senn is a strong advocate of Pasteur's prophylactic inoculations employed in the various Pasteur Institutes. A number of chapters are devoted to a most careful consideration of surgical tuberculosis. All the forms of this disease and their treatments are most comprehensively presented. It is this portion of the book which we consider most valuable. Anyone wishing information on the various surgical phases of tuberculosis will not be disappointed in consulting this work. This criticism, however, does not apply to what is written on tuberculosis of the kidney, the reader being struck with the small amount of space given to this subject. The discussion of tuberculous tendo-vaginitis takes up more than five pages, while renal tuberculosis is only allowed one-half a page.

Senn is to be commended, not only for what he says, but for the way in which he says it, his descriptions always being most comprehensive. We feel that this book is one which deserves to occupy the place won by former editions. [J. H. G.]

A Case of Primary Cancer of the Bronchus.—Sadovskii (*Medycyna*, May 26, June 2, 1901) describes a case of the above affection in a physician, 39 years old. During life the clinical picture resembled closely tuberculosis and pleurisy. The pus found in the pleural cavity, however, was due to perforation of the bronchus. [A. R.]

American News and Notes.

PHILADELPHIA AND PENNSYLVANIA NEWS.

Philadelphia County Medical Society.—Dr. Lewis S. McMurry, of Louisville, Ky., read by invitation a paper on "The Shock of Abdominal Operations" before the Philadelphia County Medical Society on Wednesday, December 18th. After the meeting a reception was tendered Dr. McMurry at the University Club.

Ashley Bars Osteopathic Vaccinations.—Three hundred children of Ashley, Pa., may be turned out of the borough schools, because they were vaccinated by osteopaths. A number of students of the School of Osteopathy vaccinated hundreds of the poorer children, because their charges were less than those of the physicians. The School Board holds that the osteopaths have no legal standing, and that their certificates of successful vaccination are invalid.

Society Meeting Next Week.—The only society to meet next week, at the College of Physicians, Philadelphia, will be the Obstetrical Society, on Thursday evening, January 2, 1902, at 8.15 P. M.

Diphtheria at Wayne, Pa.—Dr. R. L. Pitfield, assistant bacteriologist to the State Board of Health, said that there have been fourteen patients with diphtheria at Wayne, all having been served with milk from one farm. One of the persons who did the milking is known to have had a suspicious sore throat a month ago, and it is possible that the infection may have arisen in this way.

Smallpox in Philadelphia.—Despite the continued cold weather, which is admitted as favorable to the spread of smallpox, only 76 cases of the disease were reported up to noon, December 21. This is 49 less than the previous week when 125 cases were reported. The disease is still practically confined to the wards where the outbreak is epidemic. There were 10 deaths from the disease during the week, two more than recorded last week. For the year, 1,041 cases of smallpox have been reported, with 137 deaths. There are now 363 residents of the city ill with smallpox.

Philadelphia Hospital.—The Finance Committee of City Councils has given the Department of Charities and Correction \$80,000 for a pavilion for consumptives at the Philadelphia Hospital, though the other new buildings asked for were disallowed. A new item of \$4000 for electrical apparatus for treating patients in the hospital was granted. Dr. Shoemaker proposes to erect eight pavilions, the framework to be of steel with walls of glass. The five hundred patients will be divided among the pavilions according to the stage of the disease. Practical isolation for each person will be effected by a system of ventilation and the constant generation of ozone. There will be static electric batteries in all pavilions. These reinvigorate the air and destroy the germs of tuberculosis, with which it is constantly infected by patients. They generate ozone rapidly. The new Children's Building will be erected on the ground owned by the city abutting on the University of Pennsylvania property, where now stands the Museum of Science and Art of that institution. This was decided upon at a meeting of the Board of Charities and Correction held December 20. The University had requested the city to cease work upon the building started a week ago, on the ground that the close proximity of the two buildings would be detrimental to both, and suggested that the city choose another site. Provost Harrison, of the University, offered to pay for the work already done by the city if the site were changed.

NEW YORK AND NEW JERSEY.

Stony Wold Sanatorium.—Five lots in Township Ten of the old military tract in Franklin county, N. Y., have been purchased by the Stony Wold Sanatorium as a site for its institution. The project for the establishment of this sanatorium has for its object the furnishing of a temporary home for dependent young women who are threatened with pulmonary diseases. The property was purchased from Arthur G. Leonard and Benton Turner, of Plattsburg. A nominal consideration only was paid Mr. Turner, he virtually donating his property. The tract is about 1,000 acres in extent and includes the Kushaqua Hotel property,

which will be utilized for the present. It also includes Round Lake, well known for its beauty.

Fordham Hospital Quarantined.—A patient with smallpox, discovered after he had been in the Fordham Hospital four days, has caused the revaccination of all the inmates of the institution, which has been quarantined for the next three weeks.

Dr. John McGaw Woodbury, Seth Low's street cleaning commissioner, is a graduate of Princeton and the Bellevue Medical College, and has studied the problem of garbage and waste disposal in all the great capitals of Europe. If he isn't a worthy successor of Col. Waring, all the appearances are deceptive.—*Boston Herald*.

Insane Asylums Overcrowded.—At the 29th annual meeting of the New York State Charity Aid Association, held December 19, the reports of the various State Insane Asylums showed that all the institutions were overcrowded, some containing 500 more inmates than they should accommodate.

The New Lying-in Hospital, the gift of J. Pierpont Morgan, will soon be ready for occupancy, and the annual report, just issued, shows conclusively the need of such an institution and its extensive field of help for the poor. The hospital is for the benefit of those who are unable to pay for medical attendance, and for whom the Department of Charities makes inadequate provision in this class of cases. There were last year 50,228 births in the borough of Manhattan, of which 24,917 were reported by physicians and 25,311 by midwives.

WESTERN STATES.

The Michigan State Board.—The State Medical Board of Michigan wishes to make it easy for a physician to be transferred from one State to another. As it is now, States have different requirements, some maintaining a higher standard than others. A meeting will be held in Chicago, some time in January, of the executive officers of the State Medical Boards of Wisconsin, Illinois, Indiana, Ohio, and Michigan, to form a nucleus of the western central States to discuss reciprocity. The Michigan law already provides for reciprocity, admitting such physicians from other States as are considered qualified. There are now 1587 duly registered physicians in Michigan.

The Health of Chicago.—Influenza, closely followed by pneumonia, leads the list of diseases reported in Chicago, Ill. While smallpox is spreading throughout Illinois, only six cases have occurred in the city of Chicago since October 1st, after an interval of entire freedom from the disease since August 12. Not one of these six patients, three of whom were imported from Rochester, Ill., and the other three of whom developed from them, had ever been vaccinated. The death rate remains low.

A Death From the Plague in Utah.—The Public Health Report of November 22 notes one death (page 2732) from bubonic plague at Salt Lake City, Utah. It will be interesting to know the source of infection in this case.—*Occidental Medical Times*.

Criminals to Aid Science.—Instead of hanging or electrocuting the criminals of the country, Dr. W. B. Fletcher, a physician of Indianapolis, Ind., suggests confining them in government hospitals where, in the cause of the advancement of medical science and the ultimate good of humanity, they can be subjected to probably fatal experiments that will lead to a broader knowledge of human anatomy. He believes that a criminal should not die as an example, but as a sacrifice; that the miserable life should go out for the benefit of mankind. Drs. W. N. Wishard and Albert F. Sterne also believe that the condemned criminal should be given into the hands of the experimenters, and not only will the letter of the law be satisfied, but humanity will likewise be lastingly benefited.

The Barron County Medical Society met at Cumberland, Wis., December 11, and a number of interesting papers were read and discussed. Some of the prominent physicians in the State and nearly all of those in the county were present. An exhibit of X-ray work was given and officers were elected for the ensuing year.

Western Reserve University.—The Rockefeller Institute for Medical Research, which has at its disposal the income of \$200,000 given by John D. Rockefeller, has allotted \$500 for this year to the Medical department of Western Reserve University. Under direction of the Professor of

Pathology W. T. Howard, Jr., this sum will be expended in the pathological laboratory in pursuing a research into the relation of the *bacillus mucosus capsulatus* to the infectious diseases. Dr. Roger G. Perkins, a fellow of the Rockefeller Institute, will conduct the research.

Medical College for Utah.—Prominent medical men of Salt Lake City and other of Utah's larger towns are projecting a medical school to be located at Salt Lake City. Considering the remoteness of Utah from the greater centers, and the great population which looks to Salt Lake City, a new medical school seems a wise move.

Wealthy Aliens Barred by Immigration Law.—In answer to a hypothetical question propounded by the Oceanic Steamship Company, whether or not an alien afflicted with consumption, traveling first-class and of ample means, might be allowed to land in this country, Commissioner of Immigration North, of San Francisco, has decided that such an immigrant is not entitled to admission.

Milwaukee Medical Society.—Steps to perfect the organization of the Milwaukee Medical Society were taken at a meeting December 18. The association was incorporated some time ago. Dr. Bartlett presided. A committee was appointed to draft a constitution and by-laws.

Leland Stanford University.—Mrs. Jane L. Stanford transferred to Leland Stanford, Jr., University by deed, bonds, stock and real estate valued at \$30,000,000, the largest single gift ever bestowed on any institution of learning. This gift places Stanford in first financial rank among the great universities of the world, and will enable it to carry out many projected plans. Leland Stanford, Jr., University stands today as one of the great educational institutions west of the Mississippi. With the University of California, it ranks in efficiency and scope with Michigan, Chicago, Pennsylvania and Cornell Universities.

A Case of Glanders.—Because of the rarity of such cases, the death of a woman in Oakland, Cal., from glanders contracted from a horse, has caused no little comment among medical men. Since Oakland had a Health Department and records have been kept of the causes of death, no such case has come to the notice of the authorities. About 10 years ago, however, a Portuguese vegetable farmer who was living near Temescal, outside the city limits, died from this disease.

Wisconsin State Medical Board.—Gov. La Follette on December 7th appointed Drs. J. R. Currens, of Two Rivers, J. V. Stevens, of Jefferson, and F. A. Forsbeck, of Milwaukee, as members of the State Board of Medical Examiners. All are reappointments except that of Dr. Stevens, who was formerly a member of the Board. Secretary H. M. Ludwig, of Richland Center, retires. The appointments are for four years.

Smallpox and Scarlet Fever.—Smallpox and scarlet fever are fast becoming epidemic in Chilton, Wis. Two more members of the Schabel family, which has been under quarantine with smallpox for some time, are ill: a bartender at Egerer's saloon is quarantined, and smallpox has broken out in the family of a miller. Three families are quarantined with scarlet fever. In many of the surrounding towns smallpox is raging to an appalling extent. The schools will probably be closed on account of the prevalence of these diseases.

St. Anthony's Hospital Laboratory, Denver.—A thoroughly equipped chemical, pathological and bacteriological laboratory has been established in connection with St. Anthony's Hospital. Physicians desiring to perfect themselves in this line of work may arrange for a private course of instruction. Dr. C. E. Cooper, recently at Johns Hopkins, is director of the laboratory. Prof. Philip Hill-kowitz, Prof. Edward Curtis Hill and Dr. George Henry Stover will have general supervision of the laboratory.

A New Antiseptic.—Dr. Novy and Professor Freer, of the University of Michigan, announced several months ago that they had made an antiseptic that cured guinea pigs inoculated with intestinal diseases. The preparation was styled benzozone. During last week five medical students have been the subjects of an experiment. They were not allowed to eat anything, and were to drink only sterilized milk. Each day the students went to the laboratory, took doses of benzozone, and drank milk. Repeated chemical analyses showed a total destruction of intestinal poisons. The next step will be to try the preparation on an actual case of disease in the human body.

The Rocky Mountain Industrial Sanatorium has furnished us the following data. The expenses are from \$35 to \$10 a month. A good table is furnished, as patients with tuberculosis cannot improve without nourishing food. Outdoor tent life is the policy of the institution, a method causing patients to improve quickly. The climate favors such a life and the sanatorium is protected from the north and west winds. The institution is not conducted for profit nor is it purely charitable, but is run upon the cooperative plan. The work is all performed by patients except the cooking, which is done by an expert in perfect health. There have been 27 patients in the institution since it first started, of which 13 paid, 11 were wholly self-supporting, and 3 partially self-supporting. The amount of compensation allowed will depend upon the strength and ability of the patient, as well as his competency in certain industries. The property consists of 10 acres under cultivation, while more land in the vicinity can be purchased as the institution develops. There are accommodations for a few more patients if properly recommended by the Advisory Board.

SOUTHERN STATES.

State Aid for the Insane.—The most important matter considered at the monthly meeting of the managers of the Springfield State Hospital, Maryland, held December 11, was a plan to have the State provide for the care and maintenance of the insane. Dr. Clarke, superintendent of the hospital, stated that there were 405 patients in the institution, filling both groups of buildings; and he believed that new buildings would soon be necessary. The most urgent need is a cottage for female epileptics, who are now kept with the other insane. As other similar institutions in the State are also overcrowded, some action looking to an increased accommodation for the insane of the State will probably be taken by the next Legislature. Dr. Clarke suggested that a slight increase in the tax rate be made, of about three cents, to provide for the indigent insane.

A Ruling in Osteopathy.—Judge Samuel E. Greene, of the criminal court in Birmingham, Ala., December 14, decided that osteopathy is the practice of medicine and any person engaging in the same in Alabama can be forced to procure a license for practicing medicine. His decision was based on the dictionary definition of the word medicine, which is the science which relates to the cure, prevention or alleviation of disease. The defendant claimed that osteopathy was not the practice of medicine, as no drugs were used.

To Combat Consumption.—Dr. John S. Fulton, secretary of the Maryland State Board of Health, called upon the Governor in compliance with a resolution passed at the last meeting of the State Board of Health in reference to State aid in the prevention and care of tuberculosis. The State Board is of the opinion that material benefits will accrue to the Commonwealth from the treatment of tuberculosis in its earlier stages in State institutions, and that the time is ripe for the State to begin sanatorium treatment. The Governor realized the importance of combating this particular disease and held the very broad view that if a particular malady exceeded all others in its power to destroy wage-earning capacity, such a malady should be prevented, whether the cost fall upon private resources or public funds.

Diphtheria in Delaware.—Two cases of diphtheria have developed in a family in Clayton, Del., and the house has been quarantined by the Board of Health. The disease had been prevalent in the town for several weeks, but was supposed to have been completely eradicated.

Army Medical Staff.—Surgeon General Sternberg said, in reference to that part of the speech of Dr. Chas. A. L. Reed, the retiring president of the American Medical Association, at Marion, Ohio, December 10, which alleged an inability to fill vacancies in the army medical corps, that Dr. Reed was misinformed with reference to the filling of vacancies in the medical corps of the army. The corps was increased by Congress at its last session by the addition of two colonels, two lieutenant colonels, ten majors and 115 assistant surgeons. This increase was out of proportion and in the absence of additional legislation would make promotions very slow for the fifty or sixty assistant surgeons at the foot of the list. But about eighty of the vacancies

created by the reorganization act have been filled during the present year, and a considerable number of applications are now on file. Up to the present time the failure to provide for more officers of the higher grades has not deterred young men from seeking admission to the medical corps of the army.

The Tri-State Medical Association met in Cumberland, Md., December 19. Papers were read by Drs. F. W. Stewart, of Pittsburg, I. N. Love, of New York; F. C. Johnson, of Pittsburg, Christopher Columbus Jacobs, of Frostburg, and A. F. Spelcher, of Elk Lick, Pa.

The Johns Hopkins Hospital Medical Society met December 16. Among the papers read was one upon the distribution of mosquitoes about Baltimore, by Drs. L. K. Hirschberg and S. C. Dohme, who related the results of their researches on mosquitoes, covering many weeks of patient work in and around Baltimore. They found the malarial mosquito larvae first on June 20 and the number of them was too great to count. They were found at Sparrows Point, where malaria is always present, until the end of October. They were found living in the Chesapeake bay, Patapasco river, marshes, pools, brooks, lakes and in old water logs. The little larvae which develop into the malarial mosquitoes were frequently captured as they tried to hide beneath seaweeds and bullrushes. They were also captured in water collected in boxes, basins, flower pots and tin cans. The culex mosquito, which does not cause malaria, was caught frequently with the anopheles. Fish, which have always been thought to eat the mosquito larvae, were seen living in the same streams with anopheles larvae. After heavy rains the anopheles larvae became much more numerous. When they placed anopheles larvae in an aquarium containing fish, the larvae were all quickly eaten by the fish. The color of anopheles larvae is usually black, but not always. They are most easily found at the edges of the brooks. They always move tail first as they wriggle about, but they take their food through the mouth while at rest on the surface of the water. In all they captured the larvae which cause malaria from 100 different places in and around Baltimore. They advise that ponds, swamps, and marshes be filled in where practicable. Slow-running streams should be banked. A few ounces of petroleum cast upon the water will free it from mosquitoes for two weeks. All patients with malaria should be protected by mosquito nets to keep them from infecting nearby mosquitoes, which in turn bite other persons. All cases of malaria should be reported to the health authorities. Houses should be built mosquito proof. Bedsteads should never be made without a patent adjustable mosquito canopy. This is especially important where mosquitoes prevail. Mosquito curtains should never touch the floor, but slide in grooves at the side of the bed.

MISCELLANY.

Syphilis in Morocco.—Raynaud says that syphilis is very common in Morocco, even far inland. The patient is kept in a dark room for 40 days, without eating meat, olives, or salted food. He is given unleavened bread and sarsaparilla. He is also sent to a spring near Fez, where bathing in the sulphurous waters is advised. Here thousands of natives are seen, and it is not uncommon to hear of others who have visited the baths for the treatment of syphilitic ulcerations.—*Le Caducée*.

Yellow Fever in Colombia.—Yellow fever is still epidemic at Buenaventura. Many deaths occur daily, especially among the government troops.

A New Treatment for Hysteria.—An attack of hysteria simulating unconsciousness in a woman may be stopped, by someone taking a pair of scissors and regretfully announcing that he will have to cut all the patient's hair off in order to make applications to her head. It is doubtful whether this bluff has ever been known to fail.—*Modern Medicine*.

An Old Indian Remedy.—An English physician has aroused discussion by an assertion that he has discovered a cancer cure in the leaves of the violet. Whether right or wrong, it is interesting to note that to the American Indian the violet cure is as old as his people. When bitten

by a snake the Indian binds across the wound a poultice of crushed violet leaves. Bruised wild violet leaves will relieve the pain of the sting of wasps, bees or any other poisonous insect. The Iroquois Indian of to-day compounds an ointment, of which the violet is an essential portion, which is described as being a rare remedy in vicious eruptions including cancerous growths.

Doctors in Madagascar.—The French have begun to carry out a great work of humanity in Madagascar. The Governor General several years ago established a school of medicine and a hospital. The medical school has already turned out fifteen native physicians competent to practice medicine. The Governor has therefore decreed that all branches of the medical service in the island shall be consolidated, and that hospitals similar to the one in Antananarivo, where 125 sick persons may be accommodated at one time, and where free medical service is dispensed to applicants numbering 100 to 150 a day, shall be established in the larger towns. Many natives trained for medical service will travel from one village to another distributing medicines and treating the ill. Particular attention will be given to the care of children, as the mortality among infants is actually 40 per cent. of the total deaths. Pamphlets are now being printed in the Malagasy language giving rules of hygiene. It is hoped that the measures which are taken to improve the health of the people will result in rapid increase of the population, which now numbers 2,500,000.

The Dietetic Role of the Microbe.—Kijanitzin asserts that animals placed in sterilized air emaciate and die in a few days. The injurious effects persist after removal from the sterile air. In breathing ordinary air the microbes inhaled are devoured by the leukocytes, and from them ferments extracted that are necessary to promote normal oxygenation. If the microbe supply is cut off, the ferments disappear from the blood, leukomaines accumulate and death finally ensues.

The Act of Dying.—The popular idea that the act of dying is painful often causes fear of death. But death from even the most painful disease is usually preceded by a period of cessation from suffering and partial or complete insensibility, resembling falling asleep, or the pleasant gradual unconsciousness caused by an anesthetic. The common phrase, "death agony," is not warranted by what occurs in natural death. When death is due to heart failure or syncope, it is sudden and painless, perhaps pleasant. Death by decapitation or electricity is only a momentary shock, hardly felt. Death by poisoning varies in painfulness according to the poison employed. Arsenic, strychnine, carbolic and mineral acids, corrosive sublimate, tartar emetic and other metallic poisons, inflict slow and torturing death.

The Influence of Color on Mosquitoes.—Osborne Browne has said that mosquitoes seek dark places to retreat into and believes that on this account walls and furniture should be light in color. To fight mosquitoes he thinks that one should pay attention to details, screen windows and doors, open the house to sunshine and fresh air, brush ceilings, corners, and behind furniture daily, put all dark clothes away, kerosene the tanks, keep natives (on the Gold Coast) at a distance, paint houses white, use a good net hung within poles of the bed, thrown up during the day and personally tucked under the mattress at night, use light-colored clothes, and avoid late dinners with friends. He does not believe that upturning the earth frees resting spores.—*The Journal of Tropical Medicine.*

America is the country that has the most lady doctors. The first was Elizabeth Blackwell, who graduated as physician in 1849. Three years later there were six in Philadelphia. In 1889 there were 3,000 lady doctors in the United States; in 1896 there were 4,555, and now there are probably 6,000, some of whom have very lucrative practices.—*Health.*

The Human Voice.—Eighteen miles is said to be the longest distance on record at which a man's voice has been heard. This occurred in the Grand Canon of the Colorado, where the voice of a man shouting "Bob" at one end was plainly heard at the other end, eighteen miles away. Dr. Young records that at Gibraltar the human voice has been heard at a distance of ten miles.

Notes.—Hong Kong is being fumigated in anticipation of the next visit of the plague.—There are 28 pounds of blood in the body of an average grown-up person, and at each pulsation the heart moves 10 pounds.—It is a curious fact that a negro has never been known to tame an elephant or any wild animal.—Rice, raw eggs, and venison are the easiest to digest. At the other end of the scale are pork, cabbage, and hard-boiled eggs, which take four hours to digest.—Antiseptic preparations may easily be forced into wood by causing them to follow the lines taken by its sap, otherwise it is exceedingly difficult to fully impregnate the wood with them.—Tall men, as a rule, have bodies out of proportion to their limbs, that is, smaller than they ought to be, with the natural result that they are unable to bear the same amount of fatigue as men more harmoniously proportioned.—A white disc a foot across can be seen with the naked eye at a distance of 17,250 feet.—Greenland is one of the very few countries where infectious diseases are unknown.

Coffee After Dinner.—It is difficult to give an adequate reason for this practice. One explanation is that coffee tends to neutralize the effect of alcohol which may have been consumed. The practice of taking cheese at the close of a meal is justified on the ground that it aids the secretion of gastric juice and thus favors digestion. This is probably correct, for a morsel of old cheese causes an increased flow both of saliva and of gastric juice. But the coffee question can hardly be solved on a like basis. Instead of favoring digestion, both tea and coffee retard it. Sir William Roberts questions whether this delaying effect on digestion may not after all be a beneficial feature. He argues that the perfection of cooking tends to present us with our food in a condition which favors not merely rapid digestion but too quick assimilation.

Japanese Life.—The Japanese do not use milk, cows being almost unknown in Japan. Milk, an animal product, falls under the condemnation which excludes everything that has pertained to life from the list of articles used for food. Animals taken in the chase are excepted, as are fish. The Japanese mother nurses her own child, continuing sometimes up to the sixth year, though other food is given in addition after the first or second year. The main food of the Japanese mother consists of rice, fish, shell-fish, and seaweed. Wine or alcoholic products are never used. Medical men think that the large use of the products of the sea is the reason why rachitis is unknown. Of course, the Japanese know nothing about butter, cream, cheese, etc., but they make an excellent substitute from a bean, rich not only in oil, but also in nitrogenous elements. Yet consumption is common among the upper classes in Japan. Mountaineers are, however, exempt from tuberculosis. The Japanese are a small people, smallness with them being a race characteristic.

Obituary.—Dr. John H. Sears, at Waco, Texas, December 4, aged 75 years.—Dr. William J. Van Eman, at Leavenworth, Kan., December 9, aged 52 years.—Dr. John E. Heers, at Danby, N. Y., December 5, aged 61 years.—Dr. Edward H. Zier, at Minneapolis, Minn., December 9, aged 44 years.—Dr. Peter Austin, at Carrollton, Mo., December 7.—Dr. Simeon J. Shaw, at Great Bend, Kan., December 10.—Dr. M. S. Stahl, at Guthrie, Ill., December 7, aged 75 years.—Dr. Timothy D. Wadsworth, at Warehouse Point, Conn., December 17, aged 64 years.—Dr. James K. H. Jacobs, at Centerville, Md., December 18, aged 45 years.—Dr. C. Otto Ficht, at Montclair, N. J., December 18, aged 83 years.—Dr. W. E. Bowman, at Elkhart, Ind., December 18.—Dr. George B. Henshaw, at New Rochelle, Mass., December 19, aged 34 years.—Dr. George Bayles, at Orange, N. J., December 20, aged 65 years.

GREAT BRITAIN, ETC.

Increase of Longevity.—According to the annual report of the Medical Officer of London, the average of life is increasing in the metropolis. During the last ten years the average mortality has been more than five per cent. less than in the previous decade. The average number of deaths from consumption in each year from 1890 to 1899 was 8,532. Last year the number was 8,030. Deaths from bronchitis decreased from 10,226 to 8,699. The main increases in disease have been in cancer, pneumonia and apoplexy. In view of recent experiments to find a cure for

cancer, there is additional significance in the figures showing the increase in London in the annual deaths from this disease from 3,800 to 4,261.

Poisoning From Dutch Cheese.—A number of cases have recently been reported in and near London of toxic symptoms following the ingestion of Dutch cheese. A number of the cases have been traced to one particular consignment of cheeses which reached London in October last. No deaths have occurred.

Colwyn Isolation Hospital.—The Colwyn Bay Urban District Council, Wales, will soon erect an isolation hospital at a cost of \$30,000. The buildings will consist of two ward pavilions, accommodating 16 patients each, and an administration building.

Smallpox in London.—On December 9, 199 cases of smallpox were actually under treatment in London. An expert view is that sixty cases of smallpox in London can be traced to one individual.

Queen's College, Belfast.—Professor J. Symington has been appointed registrar of Queen's College, Belfast, in the place of Dr. J. M. Purser, who recently resigned.

Obituary.—Dr. John Warren Edger, the oldest member of the English medical profession, has just died at Monk-seaton. He was 98 years old, took his degree in 1828, and practiced until a few years ago in Kirby Stephen. On November 20, Dr. Jenkin Lloyd, a graduate of Glasgow University, died at the Bethesda. He was 48 years old. On November 30, Henry Piers, Deputy Inspector-General of Hospitals and Fleets, a graduate of Guy's Hospital, died in Burnham, Somerset, in his 84th year. Dr. William Doblo, a graduate of the University of Edinburgh, died recently in Keighley, in his 67th year.

CONTINENTAL EUROPE.

The Depopulation of France.—The last two censuses in France have brought home with increasing force the fact that this country, owing to depopulation, is losing rank among the nations. It matters not that England, if things go on as at present, will also have to face the problem of depopulation. In the Senate, M. Bernard and M. Piot moved a resolution asking the government to appoint a commission to make a general investigation of the question of depopulation. France, at the opening of the Nineteenth century, was the most compact national group in Europe, with 25,000,000 inhabitants, Germany had but 15,000,000 and England 12,000,000. To-day France has a population of 38,000,000, Germany has 56,000,000 and England 41,000,000. Italy, Austria, Switzerland and Belgium have increased at the same rate. Compared with her neighbors, France is declining morally, financially, economically, and as a military power. The example of Germany, England, and Italy showed that numbers had something to do with a nation's standing. The decline in the French birth rate was due to several causes, chiefly the selfish desire of the French middle classes, who wish to have few children in order to bring them up to a more prosperous condition and leave them more money. The peasants in France are just as averse to large families as the middle classes. Continuing, the speaker said that depopulation could be arrested in two ways, by reducing the death rate, particularly among infants, and by legislation to increase the birth-rate. He was in favor of encouraging large families and of discouraging single persons. Legislation might be made an efficient weapon by a severe tax on single persons. M. Bernard did not say whether spinsters ought to be taxed equally with bachelors.

A Physician's Idea.—Dr. von Jirus, professor in the Bohemian University Medical School in Prague, whose death has been announced recently, had no faith in the lasting fashions of modern man's attire, for he bequeathed \$40,000 to the Bohemian National Museum, upon condition that his clothes be packed in cases hermetically sealed, to be opened in 200 years, that people of that time may see how foolishly we dressed in the twentieth century.

The Disease Purveying Mosquito.—The mosquito is going to be made responsible for leprosy also. Dr. Blanchard stated at the Paris Academy of Medicine that leprosy "could be transmitted by mosquitoes" and Dr. Chante-messe remarked that "leprosy was caught generally at night." "Other vermin," it is said, are the carriers of

"Malta fever," relapsing fever, typhoid, and perhaps several skin diseases.

Austrian Mortality Statistics.—Professor Gerhardt, of Vienna, directed attention, in a recent lecture, to the fact that within the last twenty years mortality has decreased from thirty-two to twenty-nine a thousand in Austria, and from twenty-one to eighteen in England.

Typhoid Fever on Railway Trains.—Precautions are about to be inaugurated by the Prussian state railway authorities to prevent the spread of typhoid fever. Practically every station will be turned into a quarantine and every station master made a health officer. In addition to orders to maintain scrupulous cleanliness throughout depot premises, the station masters are instructed to furnish the physician, who will henceforth accompany every through train, a detailed report of any typhoid fever cases in their town or any symptoms of possible cases. If fever conditions are found to exist, the station master must furnish freshly boiled water for the use of passengers and the train crews. He must also maintain tanks of sterilized water conspicuously marked for the use of the travelling public. The regular stationary drinking fountains must be sealed up until the town has been declared free from fever.

Koch's Theory Not Credited.—A new case of transference of animal tuberculosis to man is attracting the attention of the Berlin medical profession. A butcher was operated upon for lupus of the hand at the Berlin University clinic December 16. Dr. Erich Lexer expressly emphasized this case as contrary to Dr. Koch's theory.

To Grow Tall.—Dr. Springer, of Paris, has a method to make one grow tall. This is to apply static and faradic electricity to the knee-joints daily in connection with massage, night and morning. He binds the joints in compresses saturated with salt water each evening, and puts his patient upon a diet of cereals to promote the growth of cartilage.

The Deepest Well in the World.—The deepest of all borings is at Parnsdrowitz, near Ratibor, in Silesia, where the Prussian Government sunk a well 2,003.34 metres below the surface (nearly 6,573 feet). The upper part of the well is lined. Observations of temperature have been made, giving practically the same results as those obtained in the well of Schadebach, near by, which is only 256 metres less deep.

French in Scandinavia.—In January last the *Vordiskt Medicinskt Archiv*, which has always been printed in the French language, appeared in German, because it was less expensive to translate articles from the Scandinavian into German than into French. The official translators have consented to lower their prices, and it is announced that from next August the periodical will again appear in French.

Death of Dr. Kowalewski.—On November 22 Dr. Alexander Kowalewski, professor of zoology, died in St. Petersburg. He was a member of the St. Petersburg Academy of Sciences, and foreign correspondent of the Paris Academy of Sciences.

A Case of Fracture of the Skull Undiagnosed During Life.—Rendu and Geraudel report the case of a man of 46, with aphasia and cerebral confusion, without paralysis. His gait was ataxic. As there was no history, a possible diagnosis of syphilitic arteritis or tuberculous meningitis was made. Later his wife arrived and stated that he had fallen heavily. No traumatism was visible upon his shaven scalp, nor were there other signs of fracture. Lumbar puncture gave a few mononuclear lymphocytes, just like those seen in tuberculous meningitis. Ptosis and oculomotor paralysis appeared before death. The autopsy showed fracture of the right parietal bone, with hemorrhages between the fracture and dura, and on the opposite side of the brain, and hemorrhagic softening following the contusion. Rendu and Geraudel call attention to the fact that the cellular elements found in the cerebro-spinal fluid were the main cause of the faulty diagnosis. (*Bulletins et Memoires de la Société des Hôpitaux de Paris*, July 11, 1901. No. 24.) [M. O.]

The Latest Literature.

BRITISH MEDICAL JOURNAL.

December 7, 1901.

1. A Clinical Lecture on Delayed Union, Non-Union and Mal-Union of Fractures. A. H. TUBBY.
2. Colles's Fracture and its Treatment.

JOSEPH GRIFFITHS.

3. A Case in Which, After Erasion of a Tuberculous Elbow, a Thin Gold Plate was Buried in the Joint for Two Months. C. B. KEETLEY.
4. An Oblique Pelvis Associated with a Congenital Dislocation of the Hip Joint. LLEWELLYN PHILLIPS.
5. An Outbreak of Epidemic Catarrhal Jaundice in Derbyshire. HERBERT PECK.

1.—In a lecture on **delayed union, non-union and mal-union of fractures**, Tubby points out that in addition to the length of time which has elapsed after the occurrence of a fracture, delayed union may be distinguished from non-union by the presence in the former of loss of voluntary movement accompanied by pain on passive motion; absence of pain with voluntary motion means non-union. The causes of delayed union are: imperfect immobilization due to splints wrongly or loosely applied; the position of the fracture, the proximal fragment in fracture of the upper part of the femur, for instance, being specially difficult to control; the interposition of muscle, ligament, or synovial membrane between the osseous segments; lack of nutrition from tight bandaging; and general causes, as anemia howsoever produced, syphilis, rickets, phosphaturia, pregnancy and scurvy. Senility, locomotor ataxia, and poliomyelitis, although predisposing to osseous lesions, do not interfere with the subsequent repair. The treatment of delayed union is to improve the general health, secure perfect immobilization, and to wait. The injection of irritating fluids, acupuncture, setons, electrolysis, subcutaneous section of the callus, and rubbing the ends of the bones together are mentioned to be condemned. The various forms of bone-joining through an incision are to be employed if non-union appears inevitable and if the operation be not dangerous. The mortality for pseudoarthrosis of the femur is 20%; apparatus may make the patient's life bearable without operation. Violent union, excluding that following fractures in the upper third of the femur and in the middle of the humerus, should be very rare, as it is usually the result of inefficient treatment. Slight cases may be benefited by the use of apparatus, severe cases require operation. [F. T. S.]

2.—From a study of **Colles's fracture** in the cadaver, Griffiths concludes that the most efficient method of reduction consists of complete flexion of the wrist; this position of the wrist is maintained by strapping the forearm and hand to a metallic splint very similar to that devised by Lewis. [F. T. S.]

3.—Keetley details the history of a case of **tuberculosis of the elbow joint** which was treated by erasion of the articular structures. One month later the joint was reopened and the lower end of the humerus covered with gold plate with the idea of securing motion; 8 weeks later the plate was removed, although it had caused no irritation. Four years after the operation the motions of the joint are painless and limited only to a slight extent in extension. [F. T. S.]

4.—Phillips describes a specimen of **congenital dislocation of the hip** which he obtained from the cadaver of an adult female. The head of the femur had disappeared, a portion of the eburnated neck of the bone entering into the articulation. There was a joint capsule, and the lower and anterior acetabular surface was covered by fibrous tissue; the neck of the femur articulates with eburnated area, the result of a flattening of the upper rim of the acetabulum. The pelvis is markedly asymmetrical, the normal half being better developed. [F. T. S.]

5.—Peck reports an outbreak of **epidemic catarrhal jaundice** which occurred in Derbyshire. He saw 69 cases, which, he believes, represents quite half the cases that occurred up to the time of writing. The onset of the disease was usually gradual; there was almost always abdominal pain, and cramps in the calves of the legs occurred in many cases; after a variable period the patient vomited;

diarrhea was only occasionally present; the temperature was between 100° and 101.5° F.; a distinct rigor occurred in several cases, and there was a history of chilliness and shivering in all; jaundice usually came on a day or 2 after the vomiting; pruritis was a frequent symptom; tenderness of the liver was present in the majority of cases, but enlargement less frequently; the spleen was frequently found enlarged. There was one case of acute yellow atrophy which proved fatal. The author believes the disease to be icterus gravis or epidemic jaundice called Weil's disease. The incubation period is, perhaps, 6 or 7 days. The period of duration of the disease from exposure to infection to commencing recovery is about 10 or 12 days.

10. Duration of Residence in Sanatoria for Pulmonary Tuberculosis. THOMAS CAMPBELL.

1.—Morris delivered the presidential address before the Chelsea Clinical Society at the Central Institute of Preventive Medicine, on October 15, 1901, on **some war sequels**. In the South African War the number of medical cases far exceeded the number of surgical cases. The common medical diseases were enteric fever, dysentery, and diarrhea. He states that the spread of enteric fever was largely due to flies and violent wind storms which carried infected dust and finally drifted it into the food and drink. The author has had some personal experience with preventive inoculation for enteric fever, and he believes that the body after inoculation is rendered less susceptible but not entirely immune, and that if the disease is taken, it is modified, its severity lessened, and the mortality reduced. He has found a number of individuals who have suffered from phlebitis and thrombosis at some time during their illness of enteric fever. The left femoral vein was commonly affected. Cases of dysentery were very numerous and frequently the patient was left with some chronic intestinal disturbance. Malaria, which is said not to exist in South Africa, occurred in a number of individuals and seemed to be invoked by surgical operations in those who were apparently healthy, as well as those who were seriously ill. The infection must have been introduced into the system in India or elsewhere. Only a small number of diseases due to exposure, such as bronchitis, nephritis, and rheumatism, developed in the soldiers. Neurasthenia, he remarks, was seen very frequently and developed after evidence of privation, exhaustion, and mental strain. The wounds induced by bullets, he states, are far in excess of those produced by shells. Shell projectiles caused lacerated and contused wounds, varying in severity. Shell fire was not very dangerous to life. The South African War was the first war in which any extensive experience was obtained showing the results of modern small calibre magazine rifles firing with smokeless powder mantled bullets which travel with an enormous velocity. The wounds produced by these modern rifles are not less dangerous to life than those of older type, but on the whole, the wounds are clean cut, often perforate through soft parts and heal very frequently by first intention. The reason why suppuration does not occur in the wounds from modern bullet wounds is: "1. The small skin wound produced by the bullet makes it almost a subcutaneous one, the walls of the narrow track

fall together, and a small scab forms on the orifice, under which it heals rapidly; (2) the climate is most favorable; the air is dry and pure and aids the formation of a scab. Even the dust seems aseptic; (3) the early application of the first field dressing; (4) the healthy condition of the wounded; (5) the injury is an aseptic one; (6) the rarity with which foreign bodies were carried into the wound." The author then gives an account, illustrated by cases, of bullet wounds of the soft parts, bones, joints, nerves, and injuries of the spine. [F. J. K.]

2.—Buzzard reports three cases of family paralysis with a consideration of the pathology of this disease. The first occurred in a married woman between the ages of 35 and 40. Her father and mother died at the age of 73 and 75 respectively. Her mother was of nervous temperament. The patient presented no signs of hysteria or excitability. The parietic seizures from which she suffered dated back to early childhood. They varied in severity lasting for many hours or a day or two. During the attacks she is unable to move, and at times there is only a temporary or comparative disability. The author thinks that these seizures invariably commence during a period of rest, but generally follow physical exercise, such as walking, cycling, etc. They never occur during the actual performance of these exercises. A peculiar sinking sensation at the epigastrium marks the onset of the paralysis. In severe attacks she gradually becomes powerless to use any voluntary muscle, except those concerned in the movements of the face, eyes, lips and palate. At times even respiration is difficult. The paralysis passes off gradually, and several days may elapse before she recovers. The attacks were at one time as frequent as two per week. The intervals of their occurrence have gradually decreased. The patient has two sons, aged 13 and 11, respectively, who also suffer from these periodic attacks of paralysis. The attacks in each never last more than one or two hours, but occur with greater frequency than in the mother's case, and, as in her case, their occurrence follows previous exercises, and not unfrequently they come at night. The author made a careful examination of these boys and finds no evidence of any organic disease of the viscera or of the central or peripheral nervous system. The author has tried all methods of treatment without curing or even alleviating this disease. The author suggests that the action of the lymph on the muscular tissues may have some relation to the pathology of the paralysis. Muscular activity with increased production of lymph or by prolonged rest and decreased secretion or stagnation of the lymph circulation seem to act as causative factors. He reaches the following conclusions: (1) That a chemical of physical change in the muscle plasma alone is not only a possible, but the probable explanation of the loss of contractibility described in this disease. 2. That the important part played by the muscular system in the control of the lymph circulation points to an unstable condition of the latter or an abnormal, perhaps, toxic, constituent of the fluid itself as possible sources for the changes in the muscles. [F. J. K.]

3.—Harper discusses pure urea in the treatment of tuberculosis and reports a number of cases treated with this drug. The first case occurred in a married woman, 29 years of age, who came under observation of the author on July 11, 1901. She was pregnant. The patient had been ill for six months, complaining of dyspnea, attacks of hemoptysis, cough, loss of appetite, and during this period she had lost one and one-half stones in weight. The expectorated material contained tubercle bacilli. Urea was administered in 20 grain doses, three times a day, increasing the dose 10 grains every week, until 55 grain doses were reached. This treatment was given in addition to the regular routine measures, as regards food, exercise, etc. The patient responded to the treatment rapidly; her cough subsided, her appetite became better, and she gained flesh immediately. The cough disappeared and tubercle bacilli were not to be found in the sputum after a time. The second case occurred in a female, 32 years of age, who came under the observation of the author on July 8, 1901. Her illness began four months before this date with a cold, which was followed by headache, loss of flesh, and languor. Tubercle bacilli were found in the sputum and, upon physical examination, signs of infiltration were elicited over the right apex. The patient was given urea in increasing doses, until 50 grain

doses, three times a day, were reached. The urea treatment was combined with the usual measures. On August 16, 1901 the patient had gained 7 pounds in weight, was feeling quite well, and cough and sputum, and physical signs disappeared. The third case occurred in a man, 25 years of age, who came under observation on July 20, 1901. His illness dated back six months and began with pains in the left side. Cough was excessive, but there was little expectoration. Loss of flesh and fever were pronounced. Tubercle bacilli were found in the sputum and physical examination elicited signs of pleurisy on the left side. Increasing doses of urea were administered until the patient was taking 60 grain doses. Decided improvement followed within one month. After two months practically all evidence of pulmonary disease disappeared. The weight increased one stone. The fourth case occurred in a boy 22 months of age. The child had had occasional attacks of diarrhea and did not increase in weight during the first six months. Enlarged glands were found in the neck. The abdomen was round, hard and cushion like. The patient's temperature was 101°F. Urea flavored with glycerine and peppermint, in four grain doses, was administered three times a day. The dose was gradually increased to 10 grains. Within one month, the abdomen became soft, the child's weight increased five pounds and the enlarged glands disappeared. The fifth case occurred in a married man, 30 years of age, who came under observation on April 7, 1901. He had had tuberculous gland in the left side of the neck for seven years, and for four years he had been under medical treatment. The patient's father died of tuberculosis. The patient's thorax was narrow, his limbs long and his weight only 5 stones, two pounds. He was put on urea in increased doses until 60 grains were taken, three times daily. Rapidly the mass decreased in size and the patient gained 1½ stones in weight. In this case it appears that the urea had a specific effect upon the tuberculous gland. The sixth case was that of a female, aged 28 years, who came under observation 6½ years ago. There was a family history of tuberculosis. Two years before she came under the care of the author she had what appeared to be acute tuberculosis. The right lung was tuberculous throughout, with a marked cavity at the apex. The sputum was loaded with tubercle bacilli. For six years she was treated on the ordinary principles, receiving abundant nutritious food; cod-liver oil and iron were the medicines taken internally. She seemed to do better when partaking of much meat. She improved from year to year very slowly. More recently signs of tuberculosis in the right lung showed themselves. On June 15, 1901, urea was administered with happy results. The cough subsided, and expectoration disappeared. The patient gained 10 pounds. The seventh case occurred in a patient 20 years of age, who came under the care of the author about 10 years ago. She had had tuberculous disease of the spine when 18 months old and at the age of eight years lupus developed on both cheeks and gradually involved a part of the nose. The patient was treated on the ordinary lines for tuberculosis—abundance in nutritious animal food and cod-liver oil and arsenic internally. The ulcerations on the cheeks and nose did not heal for eight years. On July 17, 1901, urea was administered with the most satisfactory result. Healing rapidly began, and the patient gained 10 pounds in weight. The author emphasizes that urea, which he had prescribed for his patients for two and one-half years, is of decided value in the treatment of tuberculosis, and he thinks that urea exerts a specific action on tuberculosis, as mercury on a syphilitic node, salicylate of sodium in rheumatic fever, and potassium iodide in bronchial asthma. The urea which he has been employing is a synthetic product. Harper thinks that the most suitable cases for the administration of urea are the following: "(1) Circumscribed pulmonary tuberculosis of the lung, in which the sputum exhibits abundance of bacilli, and only a limited number of cocci; (2) enlarged tuberculous glands situated on any part of the body; (3) tuberculous pleurisy (here in my cases urea acted like magic); (4) tuberculous laryngitis; (5) lupus; (6) tuberculosis of the peritoneum with fluid in the peritoneal cavity; (7) hydrocephalus in children, (8) tabes mesenterica or carreau." Unsuitable cases are: "(1) Pulmonary tuberculosis in which cocci predominate, practically covering the whole field of the microscope, and the tubercle bacilli exhibit a short stumpy appearance, the typical Koch's bacillus being scanty; (2) acute

millary tuberculosis with a high temperature (103° F. or over); (3) gastritis; (4) the last stage of tuberculosis where the patient is dying; and (5) when the patient has a temperature of over 101°." The author believes that the whole problem of the treatment is based largely upon the immunity or natural resistance. Urea stimulates immunity or natural resistance. He thinks that the drift of medical opinion is to ignore the etiology of tuberculosis and to assume that every individual is vulnerable to tubercle bacilli. He believes that the organism in which the microbes thrive constitutes the main factor in the causation of disease. He contends that "if the color of the iris, a mole situated on a particular place on the body, or a distinctive family wrinkle on the brow, not to mention the grosser forms of heredity, such as supernumerary or webbed fingers, be transmitted from generation to generation, or if the bars on the wing of the wild pigeon remain the same through centuries, it is most likely that those who have withstood the assaults of the bacillus for generations possess within their tissues a protective." He is firm in his belief that urea gives the best results in tuberculosis when Koch's bacillus is the predominating microbe. Tuberculous patients can often consume large quantities of urea, as it seems to supply something that is lacking in the economy of these patients "who crave for it as the hungry for meat and the thirsty for water." [F. J. K.]

4.—Colbeck discusses "the pathogenesis of fibrous hyperplasia." He discusses the subject under the following headings: (1) Post inflammatory fibrosis; (2) so-called compensatory fibrosis, visceral cirrhosis and the like; (3) the fibrosis of mechanical congestion; and (4) senile fibrosis. The author holds that "the essential and fundamental element in the pathogenesis of fibrous hyperplasia is increased nutrition consequent on the partial or complete loss of the control that is normally exercised over the nutritive supplies to the fibrous tissue by the more highly specialized cells with which it is associated." [F. J. K.]

5.—Choksy discusses acute emphysematous gangrene. He mentions that this condition is of infrequent occurrence and few cases are recorded in medical literature. He states that Corner, Singer, and Welch believe that the specific microorganism exists in two forms, aerobic and anaerobic, the first being generally associated with the streptococcus pyogenes and staphylococcus and the second occurring in pure cultures. Three varieties of the anaerobic have been described. "(1) *Bacillus emphysematosus*; (2) *bacillus oedematis maligni*; and (3) *bacillus aerogenes capsulatus*." The author quotes Dr. Welch: "That by far the most common specific cause of emphysematous gangrene is the *bacillus aerogenes capsulatus* and that numerous organisms, described by other observers under different names, are to all intents and purposes either identical with it or that at least one of them is an aerobic bacillus, probably identical with Sanfellee's *bacillus pseudo-oedematis maligni* which is also capable of producing this affection, but with much less frequency than the *bacillus aerogenes capsulatus*." [F. J. K.]

6.—Warrington reports three cases of the peroneal type of muscular atrophy (Charcot-Marie-Tooth-Hoffmann) occurring in a family. The first case occurred in a healthy looking woman, 56 years of age. When about 7 years old, her ankles easily turned in, therefore she often suffered from sprains. At the time of this report the muscles of the thenar eminences and of the first interosseous space were wasted to a less extent than those of the hypothenar eminences. This deformity produced very little disability. No deformities were found in the upper extremities. The right foot was hollowed and inverted and somewhat dropped. The tendon of the tibialis anticus was prominent. The foot could not be everted on account of paralysis of the peroneal muscles, all other movements could be made. The same characteristics which were found in the muscles of the right foot, but less marked, were found in the left. The knee jerks were absent and the plantar reflexes gave the usual flexor response. Electrical reactions in the thenar eminences were absent. The interosseal muscles reacted slightly and no reaction was found in the peroneal group of muscles. The second case occurred in a man, 31 years of age, the son of the above patient. The foot on both sides could not be inverted and there was always a marked club-foot deformity. Decided wasting was

present in the front and outer sides of the legs. The calf muscles were well developed and the smaller muscles of the hands exhibited extreme wasting. Feeble knee jerks and absent plantar reflexes were elicited. Electrical reaction in the atrophied muscles was not obtained. The third case occurred in a man 30 years of age, a younger brother of the above patient. Since the age of twelve this patient noticed weakness of the ankles, and, sometime after, wasting of the balls of the thumbs. The muscles of the front and outer sides of the legs were atrophied. Only a moderate degree of power was present in the calf muscles. Only slight plantar reflexes could be obtained, but the knee jerks were distinct. Electrical reaction in the thenar eminences was present. The author states that these cases conform with the classical description of Charcot, Marie, Tooth and Hoffmann. [F. J. K.]

7.—Brunner discusses headaches of nasal origin. He thinks it is not very generally known that headaches are often due to disease of the nose. Nasal trouble is not in many cases the cause of headache, but aggravates already existing symptoms. In every case of chronic headache, the cause of which cannot be found and in which there are nasal symptoms, the nasal cavities should be carefully examined. He thinks that if this would be more generally carried into effect, many of the so-called incurable headaches would be relieved. Nasal headache is often of a neuralgic character. The headache may be chiefly supra-orbital or in the middle of the head, behind the eyes, and sometimes at the top or back of the head. It presents an intermittent character and is always worse in the morning. Headache due to eye strain is always better in the morning. Nasal obstruction sometimes gives rise to a diffuse headache. Frequently dizziness is a symptom of nasal disease. A diminished resistance to alcohol, coffee, tobacco, and mental excitement is often pronounced. Affections of the frontal sinus give rise to local pains which are increased by pressure and often radiate into the head. The author gives a report of five cases of headache associated with nasal disease. [F. J. K.]

8.—Braithwaite thinks excessive salt in the diet a probable factor in the causation of cancer. The following is the substance of his theory: "(1) That excess of salt in the diet is one of the four factors that originate the disease. This is the essential factor, but it is inoperative without at least one, or probably two, of the others. Excess of salt may arise from individual taste, or from much salt meat, or from too much ordinary meat, which of course involves much salt. The other factors are these: (2) an over-nourished condition of the body from more food and especially more meat than is required. This condition is rarely met with amongst out-of-door workers; (3) an impure condition of the body owing to non-use and non-oxidation of the food which has been taken. The amount may have been moderate or even small. The cells of the body in this condition are loaded with effete material. It obtains in old age; in persons who lead indolent, easy, and in-door lives; and locally in organs the active functions of which have ceased; (4) a fourth factor is some local irritant or stimulant, such as friction from a stem of a pipe or irritation from some microorganism of which no one is actually specific, or ovarian stimulation in the case of the breast. Of these the first must always be present, and probably, in some form, the fourth, and also in all either the second or the third, but not both of them. These factors being in existence, the disease may be started in perhaps some one epithelial cell or in a mass of cells, which grow individually larger and change the nature of their protoplasm, for a cancer cell will not stain congo red, whilst an epithelial cell takes the stain deeply. The cell becomes a different being with often more than one nucleus. It is itself the parasite, living and growing at the expense of the tissue around it, and contributing nothing to the common good." [F. J. K.]

9.—Hunter reports a case of asthenic bulbar paralysis. The patient, a man aged 58, was admitted to the Glasgow Royal Infirmary on December 18, 1899. He complained of difficulty in speaking and swallowing, and of an intermittent weakness of the extensor muscles of the neck, for two months previous to admission. The patient thought the carrying of heavy loads of books on his head on two successive days was responsible for the affection. After talking for awhile, defect in speech would come on, and, after a short rest, speaking was always fluent and dis-

thet. Intermittent difficulty in swallowing was present. The family history appeared to have no relation to his condition. The patient had been a soldier for 21 years. He has had several attacks of ague, one of which lasted 10 months. He had suffered from measles and scarlet fever in childhood, and throughout his life he has had hemorrhoids. On examination no evidence of paralysis of the facial muscles was found. Firm adhesion existed between the left tonsil and the postero-lateral part of the dorsum of the tongue. The character of his speech varied. At times articulation was imperfect. Weakness of the trapezius and possibly in the erector spinae muscles was present which produced a forward drooping of the head. The patellar reflexes were present, but ankle clonus and knee clonus were absent. Vision appeared normal, there was, however, slight paralysis of the right internal rectus. The patient gradually grew worse. He had a number of attacks of dyspnea, and the difficulty in swallowing became so urgent a symptom that it was necessary to introduce food into the stomach by means of a tube. Death occurred for an attack of dyspnea of five hours' duration. A microscopical examination of the pons, medulla, and cord, was made and they all seemed to be perfectly normal. The motor and sensory tracts did not show any signs of degeneration. The motor ganglion cells stained extremely well throughout the whole cord. The peripheral nerves were not examined microscopically. [F. J. K.]

10.—Campbell discusses the duration of residence in sanatoria for pulmonary tuberculosis. He is of the opinion that on the early recognition of tuberculosis in the lungs depends the duration of residence in the sanatorium. He thinks it is necessary that laboratories for the use of medical practitioners should be established, in order that sputum examinations may be made free of charge. There is also a need for the erection of a number of sanatoria to deal with cases in the earlier stages of the disease. The shortest period of treatment which will benefit a patient has been fixed by most physicians as not less than three months. When the physical signs have become pronounced, few cases will improve in not less than six months. He thinks that at the present time, a period of six months may be looked upon as a fair limit for residence in a sanatorium. [F. J. K.]

MEDICAL RECORD.

December 21, 1901.

1. The Cure of Chronic Bright's Disease by Operations. GEORGE M. EDEBOHLS.
2. An Improved Method for Introduction of the Stomach Tube. H. CRENSHAW.
3. Results of Osteotomies for the Correction of Genu Varum and Genu Valgum. HOMER GIBNEY.
4. A Method of Protecting the Perineum During Labor. L. E. NORFLEET.

1.—J. M. Edebohls discusses the operative cure of chronic Bright's disease. He presents a study of 18 patients treated surgically, all of whom were women, and whose ages varied between 19 and 45 years. Of these 18 patients with chronic Bright's disease; five had right chronic interstitial nephritis, four had left chronic interstitial nephritis; four had right and left chronic interstitial nephritis; two had right and left chronic parenchymatous nephritis; three had right and left chronic diffuse nephritis. Right nephropexy was performed upon four patients and bilateral nephropexy upon twelve. Extensive denudation of the kidney cortex, by stripping off the capsule proper, so as to lay bare about one-half of the surface of the kidney, was a feature of all these nephropexies. In three or four instances renal cysts of various sizes were punctured and evacuated prior to anchoring the kidney. Upon his last two patients he performed total excision of the renal capsule proper with the sole and specific object of bringing about a cure of chronic Bright's disease. There has been no mortality in his series. He believes that the condition was cured in eight of his cases, and that the operation causes the increased and adequately maintained blood supply of the kidney leading to gradual absorption of the interstitial or intertubular inflammatory products and exudates, thus freeing the

tubules and glomeruli from external compression, constriction, and distortion, and permitting the reestablishment in them of a normal circulation. [T. L. C.]

2.—H. Crenshaw suggests that the introduction of the stomach tube may be very much facilitated by freezing two or three inches of the extremity of the tube just prior to its introduction, the object being to secure slight temporary anesthesia of the fauces and pharynx by means of the cold rubber. He recommends spraying the extremity of the tube for a few minutes with ethyl chloride. [T. L. C.]

3.—Homer Gibney discusses the results of osteotomies for the correction of genu varum and genu valgum. A table is presented showing the result of the operation in 21 cases. The method employed has been that of subcutaneous osteotomy. The legs are prepared as for any surgical operation. An assistant grasps firmly the thigh, the knee is held in semiflexion over a sandbag for supracondylar osteotomy, and on either side of the site of operation, for tibial osteotomy in bow-leg; the small osteotome is then forcibly pushed through skin and soft parts to the bone parallel with long axis; the osteotome, then at apex of greatest deformity, placed transversely, and with a mallet is driven into the ivory-like cortex of the bone. By gradually manipulating the osteotome, a line semicircular is cut down to the medullary canal, where less resistance is appreciable; withdraw gently the osteotome, and place a pad of gauze over the small opening made by the insertion of the instrument, the partial or incomplete fracture is in many cases easily affected. Complete fracture is often performed. The wound is surgically dressed, and put up in position of over-correction in plaster of Paris, in nearly all instances encircling and hugging the pelvis snugly. At the expiration of two or three weeks, the dressing is cut down, position of limbs observed, and still further over-corrected, as in some instances it is necessary for the plaster of Paris to be re-applied. This, however, may be lighter than the first dressing. The apparatus is worn after the discontinuation of the plaster of Paris to prevent relapse. [T. L. C.]

MEDICAL NEWS.

December 21, 1901.

1. Report of the Committee of Seven on the Prophylaxis of Venereal Disease in New York City.
2. The Medical Society of the County of New York and Its Objects. FRANK VAN FLEET.
3. Three Points in the Treatment of the Deformities of Infantile Paralysis. JOHN LINCOLN PORTER.
4. Artificial Milks. LOUIS KOLPINSKI.
5. On the Biological Relationship of Proteids. P. A. LEVENE.

3.—J. L. Porter emphasizes three points in the treatment of infantile paralysis: "(1) The most efficient treatment of the deformities resulting from infantile paralysis is the preventive treatment. Thirty-five per cent. of the deformities of the lower extremities comes from infantile paralysis. A very large percentage of these cases could have been prevented if the treatment had been begun earlier. Treatment should be begun as soon as the extent of the paralysis is well defined, for it can generally be predicted what the resulting deformity will be; (2) every case of infantile paralytic deformity, however slight or severe, can be improved to some extent by appropriate treatment. This may be anything, from adjusting a small ankle brace to correcting club-foot, to an extensive tendon transplantation or to the production of an artificial ankylosis of a joint. The author described an apparatus to be used in a condition in which the anterior muscles of the thigh and leg are affected, but those of the calf are spared. A bearing point is made on the anterior surface of the thigh by means of a spring steel band which passes half around it, another is fixed in the same way just above the ankle, then the leather strap is passed just behind the tibia below the knee joint, and thus the tibia is drawn forward by tightening the strap. Sometimes this can be accomplished quite rapidly, at others it takes several weeks, the strap being drawn a little tighter every few days. The bands at

the thigh and ankle are completed by leather straps which buckle around the leg to hold the splint in place. At the knee a ring-catch joint is made so that the patient can sit down. When he rises to walk the ring drops over the projecting bar and fixes the knee stiff and holds it in the normal position. But when the head of the tibia is drawn forward into place the heel is lifted from the floor by the contraction of the tendo-Achillis and the extensor of the foot, so that the patient cannot place the foot flat, but usually has to step on the ball of the foot; (3) simple tenotomy of the shortened tendons in these cases is of great benefit aside from the release of tendon and improvement of function that results. If tenotomy of the tendo-Achillis is done and the foot dorso-flexed to a little more than a right angle and placed in plaster of Paris until healed, then with a stop-joint at the ankle the patient can walk with the leg and foot in normal position. [T. M. T.]

4.—L. Kolipinski gives the important points necessary to produce an artificial milk: (1) That it should approximately represent all of the component parts of the animal secretion; (2) the percentage of salt and water is of vital importance; (3) the product should be cheap, readily and rapidly prepared; (4) the ingredients should be easily obtainable, fresh and sterile and the mixture be palatable. He gives the following formula for such a milk: Extract of malt (sirupy), one teaspoonful; olive oil, one tablespoonful; roasted flour, two tablespoonfuls; one broken raw egg. Beat up in a bowl with a spoon or egg beater three to four minutes. Add while stirring a tumbler of pure cold water. Season with table salt. To be taken one or two hours after meals. In hot weather add crushed ice. [T. M. T.]

5.—P. A. Levene's experiments on the biological relationship of proteids is as follows: He immunized rabbits for about two months with milk and found that their sera formed precipitates with milk, casein, milk albumin and also with beef serum. The same serum will fail to form precipitates with the entire white of the egg, egg albumin, egg globulin, chicken serum and sheep hemoglobin. On the other hand he found that animals that received injections of the white of the egg for two months will form precipitates with egg albumin, egg globulin, the yolk of the egg, with chicken serum. No precipitates will be formed on the addition of the milk proteids, beef serum, nor of the different proteids of the latter, of guinea pig serum, nor of serum of a normal rabbit. The conclusion is that chemically different proteids derived from the same or closely related animals have the power of producing similar "precipitates" when injected into animals. This seems to show that human milk could be used for obtaining serum for the detection of human blood. [T. M. T.]

THE NEW YORK MEDICAL JOURNAL.

December 21, 1901. (Vol. LXXIV. No. 25).

1. The Correction of Deformities Following Osteitis of the Knee. WISNER R. TOWNSEND.
2. On the Feasibility and Management of a Hygienic Cure of Pulmonary Tuberculosis Outside of Closed Sanatoria. CHARLES L. MINOR.
3. The Treatment of Abortion. HELEN HUGHES.
4. Anygdalotomy Itash. EDGAR A. FORSYTH.

1.—W. R. Townsend states that osteitis of the knee either invades the upper end of the tibia or the lower end of the femur or both with or without destruction of the joints in about fifty per cent. It is a well-known fact if this condition is properly treated in the acute stage that all patients should recover with straight limbs. The amount of motion will vary, but the earlier treatment is begun, the more motion. Under the old method sixty per cent. recovered with motion; under the fixed plan seventy-six per cent. recovered with motion, while under the protective plan and the one used at the present day ninety-five per cent. were cured with motion at the knee. The author mentions the following deformities due to this disease: (1) Subluxation of the tibia; (2) all other deformities. All these may be present without ankylosis of the joint. Subluxation is usually present with deformity. Complete luxation rarely occurs. Forceful correction under anesthesia is advised for subluxation deformities. This is done by pressing the tibia forward as the leg is straightened and cutting the hamstring tendon when necessary. For the correction of the other deformities there are three methods

available: (1) Forceful correction; (2) osteotomy, linear or coniform; (3) excision. It will be found that a great many of these cases will be corrected by a forcible correction. If the hamstring tendon has to be cut, the external should always be divided through an open incision for fear of injury to the external popliteal nerve. The internal is cut by subcutaneous incision. After this the limb should be held for a considerable period, as it has a tendency to return. Osteotomy is preferred to an incision in all cases where the deformity is so great that the lower leg cannot be brought into a straight line with the upper, except in two classes: (1) Where the subluxation is extreme; (2) where the deformity is almost a right angle, complicated with subluxation. Excision has been discontinued by most surgeons in children, as the great majority of cases can be corrected by osteotomy. [T. M. T.]

2.—To be abstracted when concluded.

4.—E. A. Forsyth described a rash which follows the removal of the faucial and pharyngeal tonsils as follows: The rash generally appears on the second or third day after operation, and may be papular, roseolar or erythematous in type. It appears first on the neck, chest and abdomen, sometimes extending to the face or extremities, lasting two or three days, but may last as long as five. In some cases there is desquamation; in others itching. There is very little constitutional disturbance; slight fever. The author reports a case similar to the above. [T. M. T.]

1. A Discussion on the Relation Between Human and Bovine Tuberculosis, etc. A. D. BLACKADER.
2. On the Necessity for Special Study and Experience in Treating Children. FREDERICK A. PACKARD.
3. Notes on X-Light Radiable Windows in X-Light Tubes. WILLIAM ROLLINS.
4. The Formation of Cysts in the Faucial and Pharyngeal Tonsils. J. L. GOODALE.

1.—Blackader begins a discussion of the relation between human and bovine tuberculosis by a consideration of the most important literature since 1865. After reviewing the work of Villemin, Chauveau, Gerlach, Klebs, Orth, and a number of others, he concludes that the first part of Koch's statement that human tuberculosis differs from bovine and cannot be transmitted to cattle, is to be regarded as true only in a modified sense. He then refers to a number of cases in which the evidence points to the transmission of bovine tuberculosis to man. It is to be remembered that the pulmonary tissue is peculiarly susceptible to the growth and development of the tubercle bacillus; that generalization of the infection is a striking feature of tuberculosis in childhood, due probably to the activity of the lymphatic circulation and that the tubercle bacilli, gaining access to the body through the intestines, may be readily conveyed through the thoracic duct to the right side of the heart and thence directly to the lungs. With our present knowledge of the distribution of the tubercle bacillus from human sources, it is extremely probable, considering the way children are allowed to creep along the floor and the tendency they have to put everything into their mouths, that bacilli may be frequently introduced on their fingers or on their playthings. The ingestion of bovine bacilli conveyed in milk is, therefore, by no means the only source of intestinal infection. Much clinical and bacteriological work still remains to be accomplished before the latest statements of Koch can either be accepted or contradicted. [J. M. S.]

2.—Packard read a paper before the Suffolk District Medical Society, in October, on the necessity of special study and experience in treating children. He referred to a number of well-known points in which the diagnosis of disease in children is not susceptible to the ordinary rules applicable to adults. One or two points deserve special mention. He refers particularly to enlargement of the tracheobronchial lymph-nodes. Unilateral diminution in the loudness of the breath sounds, without evidence of material interposed between the lung and the chest-wall is a valu-

able sign of the enlargement of these structures when the presence of a foreign body in the bronchus of the affected side can be excluded, but the venous hum which is developed on the extreme extension of the head and which can be heard when the bell of the stethoscope is applied over the upper portion of the sternum is of greater importance. This is known as Eustace Smith's sign. It is sometimes absent even when this group of glands is enlarged. The possibility of the existence of a patent Meckel's diverticulum should always be borne in mind when a reddish, vascular growth, resembling granulation tissue, is found at the umbilicus. If such a structure were snared off, the intestinal contents might escape into the peritoneum with fatal result. In young babies the absence of Kernig's sign has no significance whatever in the diagnosis of meningitis. The recently described Babinski reflex is of but little value in children because of the fact that in perfectly healthy children irritation of the sole of the foot will cause a different character of reflex to appear in the same child almost with each succeeding stroke of the finger. The ease with which lumbar puncture can be performed in babies makes that procedure especially valuable to the pediatricist.

[J. M. S.]

3.—In treating skin lesions by the use of X-rays Rollins advises that a large opening be made in the non-radiable mask which should be covered by thin, transparent celluloid, gelatine or collodion held in place by rubber of other elastic cement. This transparent window can then be covered by some opaque paint up to the margins of the diseased area. As the condition yields to treatment and the area of disease becomes smaller, the painted area can be extended. [J. M. S.]

4.—Goodale reports 2 cases of cyst of the tonsil. He believes that these structures are produced by the adhesion of opposite sides of one of the crypts in the tonsil, so that the lining epithelium produces a secretion that distends the circumscribed cavity thus produced. [J. M. S.]

12. Smallpox and Vaccination, Etc. GEORGE DOCK.

1.—Hall discusses the evaluation of anthropometric data, giving an account of the old and new methods of obtaining data and the significance of the results. He draws the following conclusions: "1. The collection of anthropometric data is almost universal in the practice of medicine. In the case of certain special lines of work these data are of fundamental importance. 2. Anthropometric data have a potential value, but no practical value as such. Only through some process of evaluation can the potential value be made practical and form the basis of general conclusions. 3. That method of evaluation which involves the use of arithmetical average is both time wasting and inaccurate, while the method based on Quételet's median value is accurate, and is quickly and easily applied. 4. The median value is the

value represented by the median measurement of a series of measurements; that is, that measurement which has as many values above it as below it. 5. The above described method of evaluating anthropometric data should be of value to all surgeons, pathologists, physiologists, and psychologists; to medical examiners in schools, gymnasia, insurance companies, the army and the navy; and to criminologists, neurologists and anthropologists."

2.—Madden emphasizes the importance of education of the degenerate. He thinks that heridity, the most potent factor in determining the characteristics of the individual, will never be controlled by society through legislative enactment or otherwise, therefore degeneracy must be eliminated through education and change of environment.

[F. J. K.]

5.—J. Rawson Pennington, after referring to the character of hemorrhoids and the difficulties encountered oftentimes in their ligation and in the caustic treatment, describes a method of his own, which consists in eversion of the pile-bearing area and the removal of an elliptical piece of mucous membrane from each hemorrhoid, and then the complete removal of the tumor by dissection. The patient having been prepared in the usual way for the operation with a laxative and an enema, the sphincter is dilated and the rectum irrigated with bichloride solution of 1:3000, followed by normal salt solution. The hemorrhoids are everted by traction with a number of T-shaped forceps applied at the mucocutaneous juncture. During the removal of the hemorrhoids through the elliptical incision a stream of hot normal salt solution is allowed to flow over the wound. Any spurting vessels are caught with hemostats and twisted, the author never having found it necessary to apply a ligature. After the removal of the tumor the mucous membrane collapses and covers the denuded surface. Care should be taken in the operation not to cut the skin surface as it renders the post-operative stage much more painful. When the operation is completed a gauze tampon covered with rubber is introduced into the anus. The tampon is removed at the end of 48 hours and the bowels are opened. The author has employed this method in 138 cases, in 29 of which local anesthesia was employed. His article is illustrated with a number of cuts. [J. H. G.]

6.—C. E. Ruth, after referring to the anatomical structures concerned in fracture of the neck of the femur and to seventeen cases reported previously, in which he employed the treatment advised thirty years ago by T. J. Maxwell, add eight others to this number. In adjusting the fragments after a fracture of the neck of the femur the thigh should be flexed upon the abdomen to relax the psoas and the iliacus and prevent them from being caught between the fragments; vertical traction should then be made on the shaft of the femur while it stands at right angles to the trunk; adduction to the normal line, followed by extension of the long axis of the trunk should then be made. Buck's extension apparatus with elevation of the foot of the bed and elevation of the side of the bed upon which the injured limb lies, together with lateral extension of the upper portion of the femur, should now be carried out. Much is claimed for this treatment. It is said the patient is much more comfortable, can be much more easily bathed, and that it permits of a freer movement of the upper portion of the body and the well limb. Reference is made to a case in which this treatment was carried out in a patient 70 years of age. The patient died at the age of 90 and an examination of the bone postmortem showed perfect union to have taken place, the patient having enjoyed perfect use of the leg during the last twenty years. [J. H. G.]

12.—Dock arrives at the following conclusions in regard to the value of vaccination and particularly the advantages of using glycerine lymph. "(1) Glycerinated lymph properly raised and prepared offers less danger of septic infection than any other kind of vaccine virus, and, notwithstanding the disadvantage of slow drying, it is to be preferred to dry points as made at present; (2) the peculiar features of the vaccine vesicle as known since the days of Jenner are due to the specific virus; any marked variation from them must be looked upon as evidence of imperfect protection; (3) virus that produces an imperfect lesion should not be used, because, though it may induce immunity for a short time, may even prevent the taking of an active lymph inserted

soon after it, it is likely to obscure the real condition of the subject and set up an unfounded feeling of security; (4) a knowledge of the natural history of normal vaccinia is very desirable for the physician; (5) the vaccination histories of all cases of smallpox, varioloid and chickenpox should be ascertained and recorded as fully as possible; (6) makers of vaccine virus should give clear and explicit statements as to the quality of their products. The mere assertion of freedom from pyogenic germs covers only part of the case. Evidences of specific activity, as from use in the human being, should be given. For the makers, the results of variolous inoculations in vaccinated monkeys, as suggested by Copeman, would seem very useful and almost essential to the maintenance of a proper standard; (7) a government station for the making and testing of vaccine virus is highly desirable. This need not interfere with private enterprises, but, properly conducted, would be of great value to the latter; (8) public vaccinators should be trained for their work, and facilities should be given for others to study the methods and clinical features of vaccination."

[F. J. K.]

AMERICAN MEDICINE.

December 21, 1901.

1. Four Cases of Typhoid Cholecystitis; Two Followed by Gallstones. CHARLES G. STOCKTON.
2. A Case of Subcortical Glioma of the Lower Part of the Left Ascending Frontal Convolution Successfully Removed. JAMES STEWART.
3. Surgical Malposition of the Gallbladder.
E. D. FERGUSON.
4. The Question of Ovarian Pregnancy.
J. CLARENCE WEBSTER.
5. Blindness from Inhalation and Ingestion of Methyl Alcohol. H. V. WUERDEMANN.
6. Angoneurotic Edema; Report of a Case, etc.
BERNARD KOHN.
7. Alcohol and Insanity. ARTHUR S. HAMILTON.

1.—Charles G. Stockton and Albert T. Lytle report four cases of cholecystitis complicating typhoid fever. Two of the cases give evidence of the relation that exists between infectious cholecystitis and cholelithiasis. [T. L. C.]

2.—James Stewart reports a case of subcortical glioma of the lower part of the left ascending frontal convolution successfully removed. The case is interesting as being an instance of a successful removal of a subcortical growth, the location of which had been correctly made out six weeks previous to the operation. It shows that dysarthria and not aphasia is the characteristic form of speech disturbance met with in growths in this situation. There was a marked disorder in writing—an ataxia of writing, or what might be called dysgraphia. This was present without any weakness of the right hand, and was, therefore, not due to loss of power, but rather to disturbance of coordination. Following the operation there was a great improvement in articulation and writing. [T. L. C.]

3.—E. D. Ferguson reports three cases of surgical malposition of the gallbladder. He believes that these were due to developmental conditions. The relation of the peritoneal coat of the intestinal canal as it passes on to the gastrohepatic omentum is well known, as well as the important surgical mark known as Winslow's foramen. Though in its growth the liver falls to carry before it a complete envelop of peritoneum, the biliary ducts for present purposes may be considered as surrounded by that serous membrane, but as mesentery and omentum are but two

layers of this serous sac, outside of but still encircling certain organs, it is quite clear that in the fold extending from the intestine to the liver there may be not only protrusion of some portion of the liver from its serous envelop, but portions of the biliary ducts may be so developed as to extend beyond the omental fold and outside of the peritoneum. [T. L. C.]

4.—Webster gives an interesting, though brief, review of the case of ovarian pregnancy reported by Catherine van Tussenbroek, reported in 1899. He does not change his original opinion that ovarian pregnancy cannot exist, and in this move does not share with Lawson Tait, Berry Hart, Bland Sutton and others in their change of mind. He remarks that several conditions may simulate ovarian gestation, such as hematoma ovarii, pregnancy in an accessory tube, or pregnancy in an accessory fimbriated extremity, or in a diverticulum of the tube. While admitting that van Tussenbroek's specimen was one of exceeding interest, Webster holds that her work has not proved that there may be an exception to the statement made by him some years ago, namely, that the development of a fertilized ovum implies a genetic reaction, which results in decidual formation, and that the latter, being always present, implies a relationship of necessity. [W. A. N. D.]

5.—H. V. Würdemann reports a case of blindness following inhalation and ingestion of methyl alcohol. He reviews the literature of the subject and concludes that the indigestion of methyl alcohol will produce blindness of a characteristic type which is sudden and in most cases complete, which tends later to a partial or incomplete recovery. Without securing an authentic history and without observation for some weeks of a case or from one examination, it would not be possible to state that a certain case of blindness was or was not caused by methyl alcohol, as the ocular appearance, the state of vision, and the scotoma in the visual field are the same as in the other forms of toxic amblyopias. The prognosis might clear up the condition. [T. L. C.]

6.—Bernard Kohn reports a case of angioneurotic edema, and reviews the literature of 71 cases. He mentions the origin of the disease, and states it has been quite generally demonstrated that it is of nervous origin. Low temperature seems to have considerable influence in bringing on the attacks in the predisposed. The relation between angioneurotic edema and urticaria is discussed, as alcohol, trauma and malaria as causes. He states that the condition is a manifestation of the same angioneurotic state of the blood vessels in various tissues of the body, but there is difficulty in determining its exact nature. [T. L. C.]

7.—Arthur S. Hamilton presents a paper on alcohol and insanity. He discusses the influence of age, sex, civil conditions, occupation, as well as climate and races, and furnishes the symptoms of alcoholic insanity, disregarding delirium tremens (which is really the beginning of alcoholic insanity). Premonitory symptoms are rare, but at times there is unusual depression of spirits for a day or two, some headache, and an inability to sleep. Hallucinations of hearing are more common than those of sight. Delusions of persecution are frequent. Delusions of grandeur are not common. Delusions of marital infidelity are of frequent occurrence. Many of these cases become dangerous as a direct result of their hallucinations and delusions. Attempts at suicide are not infrequent. The most essential point of treatment is total abstinence, and seclusion in an institution of some kind is practically always necessary. [T. L. C.]

3. The Action, the Method of Use, and the Collateral Effects of Thiosinamin. F. JULIUSBERG.
4. On the Treatment of Rupture of the Liver (Conclusion). WILMS.
5. A Case of Poisoning with Ammonium Sulphide. A. HESS.

1.—The authors report a case of typhoidal suppuration in a very unusual situation—in the sheath of the right rectus abdominis. The man was admitted to the hospital on January 23d, and while entering convalescence, exhibited on the 8th of February, after a marked attack of cough, pain in the region of the rectus muscle, which in a few days was followed by the development of a mass the size of an egg, which was subsequently incised. About 150 cc. of pus were obtained from it, and pure cultures of the typhoid bacillus were found. Another mass developed on the other side in a similar position. This was not incised because it was already known that the other was caused by typhoid bacilli, and since local typhoid lesions of this kind often recover spontaneously, this second mass was left to itself, and it underwent spontaneous absorption. The patient recovered entirely. The bacilli isolated from the pus were virulent to animals, and they gave a marked agglutination reaction. The virulence, however, was not of high grade. The authors believe that there is a very definite relation between the local lesions produced by the typhoid bacillus, and the degenerative changes which take place in the muscles in typhoid fever, and which have been known for years. They think that the typhoid bacillus localizes itself in the areas which have undergone degeneration, and the fact that degeneration has occurred permits of the bacilli causing local suppurative lesions, when otherwise they, in all probability, would not occur. [D. L. E.]

2.—Kaminer gives a table of 50 cases exhibiting the influence of labor and pregnancy on phthisis. He opposes the view of Maragliano, that pregnancy should be interrupted because it interferes with the subsequent existence of a person who would probably become tuberculous. Kaminer considers this an unreasonably Spartan-like standpoint. He refers to 15 cases under his observation in which labor was artificially interrupted, and 2 in which the interruption occurred spontaneously. In 12% of these cases death occurred; in 30% there was a marked increase in the severity of the disease; and in 70% there was no change notable. In no cases was there any suggestion of a real cure. This is also strongly against Maragliano's belief that pregnancy should be artificially interrupted for the benefit of the patient. Kaminer believes that it does not aid the patient, indeed, is much more likely to make the condition worse, and at any rate any little aid given by this method is given only through the loss of the life of the child. In many instances he believes that one is justified in interrupting pregnancy, but that this is practically never one's definite duty and at any rate a decision cannot be reached by following a general law, but only by observing each case and reaching an individual opinion. He believes that the most important point is to prevent conception in phthisical subjects. [D. L. E.]

3.—Juliusberg has used thiosinamin in a series of cases, chiefly those in which there was marked scarring from lupus, keloids and similar conditions. He believes that he has observed most strikingly satisfactory results, particularly in keloids and scars resulting from lupus. He has also had excellent results from this drug in scleroderma, particularly when its use was associated with massage and elec-

tricity. He states that keloids and lupus scars have in several instances been practically entirely absorbed, and in scleroderma the board-like regions of skin have rapidly become soft and flexible. He uses the drug in a 10% water-and-glycerine solution, and states that injections of this solution are absolutely painless, while alcohol solutions are more or less painful. The dose which he used is about 1½ gr. every 2 days; he usually gave it between the shoulders. Two or three times this amount was given in some cases. Local applications of the drug in 10, 20, and 30% blisters were also used, and in many instances produced good results, but these local applications could not always be borne. No results were seen from using the drug in fresh lupus vulgaris, in cases of tabes dorsalis, and in mycosis fungoides; nor in a number of cases with so-called plastic induration of the corpora cavernosa penis. Some authors have claimed that the drug has an excellent effect upon tubercular tumors of the glands, and upon adhesions of the uterine adnexa, and various other conditions. [D. L. E.]

5.—The poisoning occurred as a result of the use of a capsule which the patient found in his room, and which he thought contained castor-oil. He broke open the capsule and swallowed the contents, when he at once had burning pain in the mouth, vomiting and diarrhea. The tongue was found to be white and was somewhat painful; he had some tenderness of the abdomen, but otherwise practically no symptoms and soon recovered entirely. It was found that the substance which he had swallowed was ammonium sulphide. The capsule containing this was intended to be used as a practical joke. When thrown against any hard substance near the object of the joke they would break and produce the unpleasant odor characteristic of ammonium sulphide. [D. L. E.]

11.—Schwenn reports an interesting case of paralysis agitans occurring in a young man, who in the course of 6 or 7 years died. The symptoms were exceedingly characteristic; he first suffered from writers cramp, then from tremor in the right arm, followed by tremor in the right leg, and then, in order, the left arm and left leg. The gait was not disturbed until the 5th year. At the end of 6 years all the symptoms were characteristic. There was propulsion, disturbances of gait, the pill-roller's tremor of the fingers, and towards the end of the disease tremor of the head and tongue. In the last two years he had occasional night sweats, slight paroxysms of fever, considerable albumin in the urine without casts. The speech was lost, and swallowing became impossible. The patient finally died of indurative pneumonia. At the necropsy the following changes were noted; atrophy of the brain with edema of the meninges, a mild form of endocarditis, and nervous system otherwise normal. Microscopical examination of the brain, cord and nerves, however, failed to show any pathological changes, not even the previously described

gentle disturbance in the blood vessels. In the muscles, however, there was multiplication of the nuclei of the fibres, without any other morbid alterations in them. Schwenn, however, believes that his case proves that paralysis agitans is chiefly the result of progressive alteration in the nutrition of the muscles, which gradually invades the total musculature of the body. He does not believe that the changes he describes can be the result of gentle changes or alterations in the muscular activity, and he thinks that the changes occasionally observed in the skin argue in favor of a peripheral seat of the disease. He explains the cessation of the tremor that follows apoplexy, by supposing the normal influences passing through the muscles of the body cease, and therefore the tremor, which is a perversion of activity, must cease also. [J. S.]

12.—Hirsch has performed a number of experiments with the sphygmomanometer of Basch, and the tonometer of Gärtner. The first consists essentially of a small button that can be pressed against an artery until the latter is occluded. Pressure is then gradually relaxed until a slight pulsation reappears, and the result read. The instrument of Gärtner consists of a small hollow rubber ring which is slipped over the finger, causing anemia of the peripheral phalanx. The pressure is then relaxed until the finger becomes red, when the amount of pressure exerted is read upon the scale, and the result recorded. In both instruments it is necessary to overcome the resistance of the arterial wall, and of the soft parts lying between the artery and the compressing part of the machine. A number of comparative measurements were made, and it was found that the 2 instruments did not agree very closely. In one half the cases the tonometer pressure was from 10 to 20 mm. lower than that of the sphygmomanometer. In one fifth of the cases the results were equal, and in the remaining cases the sphygmomanometer pressure exceeded that of the tonometer. He concludes that the tonometer does not show the absolute blood pressure, but this plus the pressure caused by the soft parts of the walls of the blood vessels. The results therefore are valuable comparatively for experiments made upon the same individual. He believes that Basch's sphygmomanometer is much more accurate. [J. S.]

13.—Burekhardt has investigated the blood pressure and the pulse in a number of cases of tuberculosis in Davos, under varying conditions of climate and treatment. The investigations were performed with Gärtner's tonometer, and were commenced by Professor Egger at Basle, before the patients departed for Davos. Within an hour after their arrival the measurements were taken, and for the following week 3 times daily; later at somewhat longer intervals. The results showed that in general a moderate rise in blood pressure occurred immediately upon their arrival in Davos, although this was by no means constant. This rise in blood pressure persisted throughout the entire stay. There was also an increase in the frequency of the pulse. As the result of his studies on various cases of phthisis, Burekhardt states that in the first stage blood pressure is normal; in the second stage it falls, and the pulse-rate increases, and this condition persists throughout the course of the disease. Hydrotherapeutic measures were also tested, and it was found that the cold douche caused a considerable increase in blood pressure in nearly all cases. An injection of cinchonic acid caused practically no alteration in the blood pressure. Exercise in the form of short walks produced either no alteration in blood pressure, or a temporary diminution. Hemoptysis produced an increase in the blood pressure in one case, which was transient, followed by a rapid decrease and death. It follows from these results that it is important in the treatment of pulmonary tuberculosis to increase the blood pressure. [J. S.]

14.—Franke describes certain symptoms that he finds almost invariably in influenza, and practically never in other diseases. They consist of reddish streaks upon the anterior arch of the gums, which persist throughout the course of the disease. They vary in breadth from 2 to 3 mm., and rarely involve the extreme edge. The edges are sharp, the color is bright red, changing to bluish in anemic cases. They produce either no subjective symptoms, or only a slight feeling of discomfort in the throat, as if it were being slightly compressed. He has also observed, in a case of chronic influenza, a peculiar strawberry-like alteration of the tip of the tongue, resembling that seen in

scarlet fever. This Franke ascribes to neuritis of the nerves following influenza. The patient also had a peculiar reddening of the gums. He also describes a typical tongue in influenza, which is characterized by swelling of the papillae. This is most common in cases of recurrent influenza. It has not hitherto been described. The enlargement of the spleen is also peculiar in influenza, because it is subject to great variations in size, which occur very suddenly. In fact Franke speaks of it as a sort of barometer of the disease. [J. S.]

15.—Zaudy has examined a number of cases of diabetes mellitus, and in 2 of them found lipemia. His attention was first called to this by the appearance of small white points in a drop of blood drawn for other investigations, and he therefore prepared a hanging drop in which, in the course of 24 hours, a considerable amount of fat had gathered at the surface. The man died and at the autopsy there was found lipemia, fatty necrosis of the pancreas, retention of chyle in the intestines and mesenteric lymph glands, and some changes in the pancreatic duct. In addition the usual changes of diabetes and milky hydrocephalus. The second patient developed diabetic coma, and on the day of his death a drop of blood withdrawn the day previously showed the presence of fat. In a third case (which is merely mentioned) lipemia was also discovered. Zaudy warns that fat can only be recognized when within an hour after the withdrawal of the blood the serum of the hanging drop has become bluish white or milky, and when microscopic examination shows the absence of fibrin. In a postscript he states that in 12 cases in which he examined for lipemia it was absent in 11, including one of diabetes, and present in the 12th, a boy suffering from a very severe form. A careful analysis of the urine in the first case by Frenkel is appended to the article. [J. S.]

16.—Lange reports two very interesting cases of what is apparently a new disease. The first, a girl of 22, developed cough and then chill and headache. From this time there were progressive dyspnea with cough and moderate expectoration, considerable fever and finally death on 9th day. At the autopsy all the organs were normal with the exception of the lungs which were apparently the seat of an acute miliary tuberculosis. However, upon careful histological studies it was found that tuberculosis did not exist, but there was an inflammatory condition of the bronchioles, which showed the following types of alteration. First, bronchioles were found whose lumen was obliterated by desquamated epithelium, in the midst of which a moderate number of leukocytes could be seen. Many of the leukocytes contained eosinophile granules. Second, the small bronchi whose lumen was obliterated with a more or less homogeneous substance that took the Weigert fibrin stain, and in the midst of which leukocytes could be observed. Third, bronchioles whose lumen was occluded by fibrin throughout which spindle cells were growing, and which contained numerous connective tissue fibres. Fourth, foel consisting of young connective tissue cells newly formed by vessels, and masses of leukocytes mixed together, and showing their original relation to the bronchus on account of the presence of ciliated epithelium and circular muscle fibres, and fifth, alveoli filled with an exudate resembling the hemorrhagic exudate. Serial sections showed that these types of changes were not distinct but extended from the bronchioles into the alveoli in the order in which they have been described. The lung tissue lying between the obliterated bronchioles showed very slight alterations. The alveoli contained a few cells filled with brown pigment, and on the septum some masses staining homogenous red with eosin. Bacteria could not be found. The second case, a man of 32, had been troubled with cough for about 6 months, he then developed dyspnea, which became so severe that he was obliged to give up work. There was no temperature or cyanosis, but the dyspnea increased and the patient died after a sickness of 4 weeks. All the organs were normal except the lungs which showed the same appearance of miliary tuberculosis that was found in the previous case. Microscopical examination showed exactly the same type of alteration. There was no alteration in the blood vessels, and no bacteria of any kind could be found. It appears that the disease is characterized by a fibrinous exudate in the bronchi which interferes with admission of air into the alveoli, and causes death by dyspnea. [J. S.]

17.—Deetz reports an interesting case occurring in a man

of 50 years of age. He developed symptoms of renal colic which were always associated with evacuation of sand-like masses with the feces. He was requested to save some of this material and, as a matter of fact, it was found to have the appearance of sand. It was insoluble in sodium chloride, in nitric acid, and in water, ether, alcohol and chloroform. Microscopically the granules appeared in the form of spheres or half spheres with clear projections. They did not contain any of the constituents of gall stones. The patient did not eat fruit and therefore these cells were not the stone cells described by botanists. Chemically they contained an organic substance and calcium. Further investigations showed that they consisted of calcium oxalate and phosphate. The nature of the organic constituent was not determined. The characteristic picture of this disease is that the patient, habitually constipated, suddenly has a severe attack of colic, and then an evacuation in which sand can be observed. The attacks occur with varying frequency in different cases, sometimes several times in a month, sometimes three or four times in a year. They usually come on a few hours after a meal. Many of the cases also have membranous enteritis. Treatment consists of morphia to relieve the pain, and, in the intervals, massage of the abdomen and laxative pills. In addition patients may be treated by high lavage of the intestines, with luke-warm water and perhaps the Carlsbad treatment. [J. S.]

18.—Petzold reports the results of the treatment of croupous pneumonia with subcutaneous injections of quinine hydrochlorate. These were employed in the more severe cases that came to the Magdeburger Altstadt hospital, and the results showed that the mortality was something less than half that of the other hospitals in Magdeburg, and bore about the same relation to the mortality in 3 of the largest hospitals in Berlin, where the number of cases was considerably greater. Comparing the 3 hospitals of Magdeburg, the mortality, excluding cases dying within 12 hours after admission, in whom no quinine injections were used, showed for the Altstadt 8.8%; for Sudenburg 22.5%; and for Schweisan 30%. Including the cases that died shortly after admission, the percentages were respectively, 12.2; 24 and 30. The total number of cases was 271 and the mortality 33. Of these 10 died shortly after admission; 12 were not treated with quinine injections, and 11 died in spite of them. Many of these cases were atypical, and in 8 of them the pneumococci could not be found, and Petzold therefore concludes that certain and undoubted results can be obtained by injections of quinine in typical croupous pneumonia whose cause is the diplococcus. A number of cases are reported in order to prove this statement. However, he is also convinced that in streptococic and pneumo-bacillic pneumonia the results are almost equally favorable. It is a curious fact that the more severe cases of pneumonia that were treated with quinine gave a lower mortality than the milder cases in which it was not employed. In his own cases 84 were treated with quinine with 11 deaths, and 187 without quinine with 22 deaths. Of these 187, however, 74 occurred in children less than 10 years of age, among whom there were no deaths, the disease running an extraordinarily mild course and ceasing spontaneously. Omitting these, the mortality is, for the quinine cases 13%, and for the cases treated by other methods 19.7%. In 4 cases complicated by pregnancy, quinine was employed and 2 recovered and 2 died as the result of premature parturition. Complications do not appear to contra-indicate the use of quinine, but on the contrary it seems to act most favorably whether there be weakness of the heart, delirium or delirium tremens. Even the cases complicated by nephritis may be so treated without danger. It does not, however, appear to check the development of jaundice. Quinine does not apparently hasten the crisis, but benefits the general condition of the patient, strengthens the pulse, diminishes the dyspnea and cyanosis, and clears up the semi comatose or delirious condition of the patient. Sometimes a single injection was sufficient; sometimes a second or third was required. Petzold believes with Aufrecht that the general action of the quinine is upon the cause of the disease. The method of employment is as follows. 0.5 gram is dissolved in 17 ccm. of water, and injected under the most rigid aseptic precautions. The most favorable situa-

tion is the side of the abdomen. It is important that the point of the needle should penetrate to the subcutaneous tissue, otherwise necrosis is apt to occur. One case occurred in the practice of Petzold, in which a phlegmous infiltration of the wall of the abdomen lasted for 2 months. Ordinarily 2 injections of 0.5 gm each on consecutive days is sufficient, but it was the custom to repeat the injections every day as long as the patient appeared to be seriously ill. In case of pain at the site of injection a hypodermic injection of morphia may be employed. [J. S.]

23.—Merkens has collected 25 histories of patients with otitic abscess of the temporal lobe, in whom the inability to say words aloud existed. They recognized objects, knew their uses, wrote the words, but could not pronounce them. In severer cases there occurred word deafness, the impossibility to repeat a word after hearing it pronounced, to write it, to read it, or to understand it when it was seen or heard. Nine of the 25 patients, whose histories are given, could not read correctly, eight showed word-deafness, seven could not write correctly, etc. A number of intricate diagrams shows the course of the conducting fibers, explaining how these results followed an abscess of the left temporal lobe. They are exceptionally due to a lesion of the speech centers, the conducting fibers being affected generally, especially those fibers which connect the sound and conception centers; occasionally those between the sound and writing centers. Optic aphasia, which may occur, is but a form of mind-blindness. Distinct disturbance of speech aids the surgeon in forming an early diagnosis of otitic abscess of the left temporal lobe and in performing an early operation. In making the diagnosis, tumors, encephalitis, etc., must be excluded.

[M. O.]

24.—Orlow reports the case histories of five patients upon whom closed echinococotomy by the Posadas-Bobrow method was performed, out of eight cases of echinococcus cysts of the liver which he has operated upon during the last fifteen months. This method consists of evacuating the cyst and then sewing it up. This should never be done if inflammation or suppuration has occurred. In none of the cases were there hepatic symptoms after operation. After the operation, the lungs and pleura are often affected and purulent parotitis may result. All but one of his cases recovered, that one dying at home some time after leaving the hospital. Orlow states that special care should

be taken to clean out the sac, and to search for more echinococcus cysts throughout the liver, before the sac is closed. [M. O.]

25.—After a review of the literature, Tavel reports three cases of wound diphtheria. In a whitlow, an abscess of the muscles of the back, and paronychia of the index finger, diphtheria bacilli were found. The case-histories are given in full. In none of them was the course of the affection at all different from what it would have been without diphtheria bacilli. There was absolutely no suspicion of a membrane. The diagnosis is impossible without a bacteriological examination, since most cases with the formation of a membrane are due to staphylococci and streptococci. Tavel concludes that the same kinds of disease may be caused by different bacteria, and the same bacteria may cause different forms of disease. [M. O.]

26.—Dohrn gives the case-histories of 17 patients who received severe skin burns, 13 of whom died. The blood was not found thickened, nor was there congestion of the internal organs. The red blood corpuscles showed poikilocytosis, bits broken off, variations of form, microcytes, etc. Light bodies were noted in the erythrocytes, and leukocytosis occurred. Hemoglobin or methemoglobin was found in the urine in but two cases. These changes Dohrn believes are due to the heat of the burn. But such changes can occur without producing the death of the individual. Thrombosis was found rarely, and then only in the capillaries of the brain and lungs. Albumin occurred in the urine almost constantly. Among the nine autopsies, which are given in detail, nephritis was seen in only three cases. There was, however, a marked increase in the brain pressure, some edema of the brain substance, and a beginning diffuse encephalitis. While this resembled poisoning, it explained the nervous symptoms which occur with burns. From these investigations, Dohrn believes that the cause of early death after skin burns, is a powerful intoxication due directly to the effect of the burn. [M. O.]

27.—Jenckel describes a remarkable mixed tumor of the kidney, without a sign of malignant degeneration either histologically or clinically, in a woman of 43. The tumor had grown for eight years, more upon the right side of the abdomen than the left. Laparotomy showed that it was retroperitoneal, attached to the left kidney. She recovered slowly and perfectly, in spite of the immense size of the tumor removed. This was 37x28x15 cm. and weighed 14½ pounds. Its circumference measured 96 cm. Examination showed that it had grown from three combined calices which had failed to form normal pyramids. It was composed of highly developed connective tissue with a few nuclei, myxomatous young tissue full of cells, smooth muscle tissue, fat, elastic fibers, and glandular elements with cuboidal and cylindrical epithelium. After a full discussion of the possible origin of the tumor, with the description of two other congenital tumors of the kidney, Jenckel concludes that the theory of Wilms is unnecessary to explain this case, since all the tissues found in the tumor rose from normal kidney structure. [M. O.]

28.—Eversmann reports two cases of outward dislocation of the elbow-joint, with separation and interposition of the internal condyle of the humerus, in boys of 13 and 11. The former fell upon his outstretched left hand, with immediate pain at the elbow. The dislocation was reduced with difficulty under anesthesia. There was loss of feeling in half of the fourth finger and in the entire fifth finger, with loss of power to flex the little finger. The internal condyle of the humerus, which had been broken off, was only located by the Röntgen rays, between the sigmoid cavity and the trochlea. This was removed by operation, and he recovered full use of the arm. The other boy fell upon his left elbow. Pain only appeared later, but persisted then. The conditions found were similar to those in the preceding case. He also recovered after removal of the separated epitrochlear fragment. In some cases the lack of the epitrochlea is noted distinctly;

in some it is felt in its abnormal position upon certain motions; in others it will come in between the bones, upon moving them, and so its interposition is at once recognized. It may be in the joint-capsule, or just outside of it. Eversmann advises primary arthrotomy and excision of the separated internal condyle of the humerus, suturing the joint-capsule. The incision upon the inner side of the joint will also expose the ulnar nerve. [M. O.]

29.—After a full review of the literature of dislocations of the patella, Auler describes an extrasynovial plastic operation upon the knee-joint, performed by Professor Bardenheuer. In both cases incision was made into the quadriceps tendon, which was again sutured, making it 1 cm. shorter. The end of the ligamentum patellae was separated from the tuberosity of the tibia and attached to the periosteum of the tibia. In both cases the results were excellent. Similar operations were performed upon 11 cases of genu valgum; two cases of chronic hydrops articuli; four cases of chronic rheumatism and arthritis deformans; one case of septic arthritis of the knee-joint; and one case of dislocation of the meniscus externus, with uniform success. The technique of the operations and the 21 case-histories are given in full. [M. O.]

30.—Nordmann reports a unique case of lymphatic cyst of the buttock, in a woman of 34, following a fall. The cyst, which measured 21x11 cm., upon operation, was seen to contain pure lymph. The wound healed slowly. The cyst replaced the fascia lata, for upon its removal the muscles of the thigh were uncovered. Very few similar cases were found in the literature. [M. O.]

31.—Borchard reports a case of dislocation of the patella with complete semi-torsion, caused by muscular traction, in a boy of 17. Reduction was the means of diagnosis in this case, as the patella untwisted to return into place. The diagnosis of this condition is extraordinarily difficult, and reduction should not be attempted without an anesthetic. Rest is necessary after reduction. [M. O.]

32.—von Meer reports the case of a woman of 62, with the symptoms of incarcerated hernia. Laparotomy showed a hernia of the ileum through the left obturator foramen. As she was very weak, the radical operation was not performed. Eighteen months later the condition recurred, and laparotomy was again performed. This time the hernia was again reduced, and she has kept well since. Only seven such cases have been operated. The poor general condition of the patient excluded all possibility of herniotomy. [M. O.]

33.—Rydygier insists that the operation of circular pylorotomy, when the incision is made in the linea alba, and the duodenum is sutured directly to the wound made by resecting the stomach, should bear his name, and his name only. [M. O.]

34.—Matthiolius reports the case of a young man who had been shot in the forehead four years before. Severe headache followed. As Röntgen photographs localized the bullet in the frontal bone, it was removed by operation. He has kept well ever since. [M. O.]

1.—Cramer has made some careful experiments with *bacifol* and *lysoform* in order to determine their real disinfecting qualities. He tested them with a great number of culture media, and removed samples from these cultures at varying intervals up to an hour. It was found that in 2% solutions all growth ceased at once; in 1% solutions all growth ceased after 5 minutes and in 0.5% solutions it ceased in 10 minutes. With *lysoform* the results were very unsatisfactory. In some cases even after an hour's exposure numerous colonies could still be obtained from a 3% solution. *Bacifol* is a product of the distillation of tar; its active principle is cresol, which occurs in a proportion of 52%. It is entirely without odor, and is very cheap. It will probably serve to replace many other antiseptics, for example for the disinfection of the sputum, and in all cases where *lysol* has hitherto been used. *Lysoform* is an oily, soapy liquid, perfumed and smelling of formalin; it is soluble in water, and has remarkable odorizing qualities. It is expensive, and its germicidal properties are very unsatisfactory. [J. S.]

2.—Bettmann reports a case of *psoriasis vulgaris* that occurred in a baker, 29 years of age, who previously had been tattooed on the right forearm without further results. About 6 months ago he was tattooed on the left forearm, and 14 days later a desquamating disease of the skin appeared, limited to this area. This developed into a typical case of *psoriasis* and gradually extended to other parts of the body, remaining, however, more severe on the left fore-arm. The question arises whether the tattooing determined the localization of the *psoriasis* on account of irritation of the skin in that situation, or whether some parasite, which may be responsible in the causation of the disease, was introduced into the skin in the process of tattooing. The facts in favor of the infectious character of *psoriasis* are that the clinical course of the disease resembles in some respects the clinical course of diseases which are known to be due to microorganisms; that certain cases appear to prove the contagiousness of the disease; and the discovery of certain organisms in the diseased skin, whose etiological relation however, is still questionable. Finally, experiments have apparently shown that it is possible to produce a skin disease in animals which resembles more or less closely *psoriasis*; and in one case a physician inoculated himself and produced the typical type of the disease with numerous relapses. [J. S.]

3.—Eichel divides the various forms of intra-abdominal hemorrhage into: subcutaneous laceration of the gastrointestinal canal; injuries to the genitourinary system, and those cases in which the hemorrhage into the abdominal cavity dominates the whole clinical picture. Of course it is possible that injuries to several organs exist at the same time. The usual method by which the injury is produced is a crushing blow that is inflicted upon the abdomen when the body is supported against some hard object such as the ground. Ruptures of the liver, however, may occur as a result of a fall from a high place. The latter injury is greatly favored by fatty degeneration of the liver. Ruptures of the spleen are more likely to occur if the organ is enlarged, as for example, in malaria. The line of rupture in both liver and spleen is usually irregular, and perhaps more frequently on the convex surface. There is no pathognomonic symptom for intra-peritoneal hemorrhage. If shock occurs and the patient fails to improve under stimulants, it is probable that bleeding is taking place. If the patient's condition grows rapidly worse an hour after the injury and there is no reason to suppose intra-cranial hemorrhage, abdominal hemorrhage is again to be suspected. If dulness appears in the flanks very early, that may also be looked upon as a suspicious feature. He reports a case of a soldier 22 years of age who after great excess in eating and drinking suddenly felt severe pain in the abdomen, and his condition, in spite of all remedies rapidly grew worse. An operation was therefore performed, peritonitis was discovered due to rupture of a gastric ulcer.

in this case the absence of any history of gastric disturbance rendered the diagnosis difficult. In cases of rupture of the spleen the dulness may be limited to the left side of the abdomen. [J. S.]

4.—Tonzig has performed a number of experiments with the object of determining to what extent thorough washing of the circulatory system controls the tetanus intoxication. For this purpose he selected rabbits which were inoculated with various amounts of culture, and then some of them were given intraperitoneal and subcutaneous injections of normal salt solution daily either before or after the appearance of the symptoms, and in some cases several times a day. The cultures varied considerably in virulence, making it possible sometimes to obtain cases of very slow course. The results did not seem to show that the treatment with normal salt solution was of any effect, and Tonzig concludes that it is not possible to hope for a favorable outcome in a case of tetanus as a result of the mere washing out of the organism, and that therefore the virus of tetanus does not circulate in the body, but remains attached to the tissue elements. When, however, the case is mild from the outset, the lavage of the tissues may delay the fatal termination, or at least the appearance of the symptoms, and the procedure should be employed especially in those cases in which serum cannot be given at the beginning. [J. S.]

5.—Georgli calls attention to the importance of Ledderhose's teaching upon the treatment of wounded fingers. He believes that we are entirely too conservative in regard to this, and it is far more important to have a stump covered with loose normal skin, than to have it covered by tender scar tissue, perhaps adherent to the bone and limiting the movements of the part. He therefore contends that in all cases of injury to the fingers sufficient bone be resected to secure ample flaps of normal skin. [J. S.]

6.—Hoffmann reports two cases, the first a man with the septum unusually short, so that the naso-pharyngeal space was abnormally long and as a result the inferior turbinates projected into the space. He believes that the disturbance of the circulation of air contributed to the causation of a chronic rhinitis with the symptoms of eczema. The shortness of the septum was due to the forward dislocation of the vomer. The second case showed also shortening of the septum, and the appearance of enlarged nasal tonsils with a thickening of the mucous membrane of the septum. As the mucous membrane was very sensitive to irritation, severe coughing occurred whenever it was touched, even during deep chloroform anesthesia. [J. S.]

7.—See editorial, *Philadelphia Medical Journal*, Dec. 7, 1901, p. 969.

8.—Diehl reports the case of a man 26 years of age who had been an alcoholic for about 2 years. The result of this was that in the night, particularly after drinking too much, he would have an attack in which he would have convulsive movements, would bite the tongue, but did not lose consciousness. There was apparently no possibility of hysteria, or attacks the result of suggestion. These attacks were preceded by aura and followed by a feeling of exhaustion and depression. The general character of the patient resembled strongly that of those suffering with epilepsy. [J. S.]

9.—Gottstein has carefully studied the mortality statistics of the city of Berlin with the object of determining what proportion of infants die of tuberculosis. For this purpose he included the cases of glandular suppuration, pulmonary tuberculosis and infantile tuberculosis, and in addition the cases of chronic bronchitis and inflammation of the brain, although it is obvious that in this condition were many instances not tuberculous. These studies show that a considerable proportion of all deaths occurred in this tuberculous group; about 15%. The figures also show that the number of deaths in infants due to tuberculosis is steadily increasing, although the total mortality from tuberculosis is decreasing. He supposes this is due to the fact that children are infected in some method different from that in which adults are infected, and he believes this due to the communication of tubercle bacilli through the food. [J. S.]

VRATCH.

September 22, 1901. (Vol. XXII, No. 38).

1. Chronicle of Corporal Punishment in Russia in the Twentieth Century. D. N. ZSHBANKOFF.
2. A Case of Hypertrophic Sclerosis of the Brain in Epilepsy. A. S. MANUILOFF.
3. On the Question of Prevention of Typhoid Fever. P. ENJKO.
4. Syphilis in the District of Paraflevsk, County of Borzensk, Government of Tshernigoff, According to Family Records Kept for the Last Three Years. S. N. GENEROPITOMTSEFF.

2.—Manuiloff reports a case of hypertrophic sclerosis of the brain in a woman, 29 years old, who during life presented none of the characteristics of that affection. There were no paralyses, trophic disturbances, deformities of the skull, physical underdevelopment, lowering of the mental faculties or idiotism. The only condition present was epilepsy, but that alone was not sufficient to establish a diagnosis. On the other hand the autopsy revealed, both macro- and microscopically, a typical picture of hypertrophic sclerosis of the brain. The pathology of this affection is discussed and the bibliography given. The article is also accompanied by an illustration, showing the microscopical appearance of the sclerotic areas in the brain. [A. R.]

3.—Enjko presented in 1894 statistics from the St. Petersburg Alexandroff Institute, showing that typhoid fever may be prevented by excluding from the table uncooked fruit and vegetables and unboiled water. In the present article he shows how the morbidity from typhoid fever may be reduced to a minimum by the use of boiled water. An interesting fact mentioned by the author is the very low rate of mortality observed by him. For a period of 30 years the mortality-rate averaged 1%. (The ages of the inmates of the Institute, as gathered from one of the author's tables, range from less than 10 to over 19). [A. R.]

4.—Generopitomtseff presents statistical data concerning syphilis among the peasants, as revealed by a thorough and systematic investigation carried on for a period of 3 years. The district in which the observations were made has a population of 9594. Of these 472 or 5% were found affected with syphilis. The tables furnished by the author show a marked predominance of syphilis among women and children. Thus, syphilis in men was found in 21%, in women in 43.4% and in children in 35.6%. Similar data were obtained by Speranski and Timoschok. This is explained by the fact that the children inherit the disease from their parents (fathers) and transmit it to their mothers and nurses. The "innocents" thus constitute the most important factor in the dissemination of the disease in rural communities. The transmission of the disease by direct sexual intercourse is infrequent as compared with the other modes, as shown by the following table:

Mode of infection	Men	Women	Children	Total	Per Ct.
Sexual	14	8	—	22	4.7
Living together	27	52	3	82	17.3
Hereditary	42	105	165	312	66.1
Unknown	16	40	—	56	11.9

4. A Few Surgical Observations at the Novoladozshsk Zemski Hospital. A. V. MARTINOFF.

2.—Will be abstracted when concluded.

3.—Bukoemski performed at the Out-patients' Department of the Odessa City Hospital 154 curettements of the uterus. 116 were made for the cure of fungous endometritis and endometritis following abortion, 35 after recent abortions and 3 for diagnostic purposes. Of the 116 cases

of endometritis complete success was achieved in 102. In the other 14 additional intrauterine injections of iodine were required to accomplish a cure. Of the 35 cases of abortion subsequent hemorrhages were observed in 2, owing to an incomplete removal of the placental tissue. Only in 1 case did parametritis follow the curettage. The operation was performed at the office, the patient leaving the room after a 3 hour's rest. [A. R.]

4.—Will be abstracted when concluded.

October 6, 1901. (Vol. XXII, No. 40.)

1. On Catheterization of the Ureters; Its Application in Cases of Tuberculosis of the Kidneys and Inflammation of the Renal Pelvis Dependent on Calculi. I. E. GAGENTORN.
2. On the Question of Popular Healing at the Orthodox Christian Monasteries. V. PH. BUSCHUEFF.
3. The Alkalinity of the Blood Under Physiological and Pathological Conditions. V. F. ORLOVSKI.
4. Infant Mortality According to the Statistics of the Moscow Maternity Establishment. S. S. CHOLMOGOROFF.
5. A Few Surgical Observations at the Novoladozshsk Zemski Hospital. A. V. MARTINOFF.
6. A Case of Intestinal Obstruction Treated with Atropine, after Batsch. P. M. KALABUCHOFF and M. V. SAVVIN.

1.—Will be abstracted when concluded.

3.—Orlovski describes in detail his experiments and observations on the alkalinity of the blood under physiological and pathological conditions, the present paper being practically a continuation of the one published in the *Tratch*, July 28, 1901. (See *Philadelphia Medical Journal*, November 9, 1901). He found that the alkalinity of the blood is kept constant by the fixed alkalies, and the variations observed both in health and disease are due to the variations in the number of the red blood corpuscles which furnish approximately 45-53% of the general alkalinity. He investigated the blood in 62 cases of diverse diseases and found an absolute diminution of the alkalinity only in 3 diseases, namely, cancerous cachexia, hematuria of long standing and diabetes; in all other cases the alkalinity of the plasma remained as a rule constant. The effect of alkalies on the alkalinity of the blood both in health and diabetes was also determined. It was found that in healthy individuals a single dose of bicarbonate of soda administered by the mouth produced a slight and transient increase in the alkalinity of the blood. Warm rectal injections of the alkali caused a greater increase of the alkalinity, but also slight and transient. On the other hand, the rectal alkaline injections in diabetics produced a more marked and lasting increase in the alkalinity of the blood or plasma. This fact establishes the *rationale* of the use of alkaline injections in impending diabetic coma. The injections, however, should be continued after the disappearance of the first symptoms, owing to the temporary effect of the alkali. [A. R.]

4.—Cholmogoroff found by interrogating the patients seeking admission to the Moscow Maternity Hospital that the 1500 women gave birth to 5139 children. Of these only 35.91% remained alive. He considers such a high rate of mortality (64.06%) a sufficient cause for alarm. [A. R.]

5.—Martinoff performed successfully a large number of major operations in a small hospital with an operating room in which septic cases were treated and all the dressings made. Only reasonable cleanliness was possible. A considerable number of cases of diverse surgical affections are described and the details of the surgical treatment given. [A. R.]

6.—Kalabuchoff and Savvin report a case of intestinal obstruction in a man, 42 years old, which yielded to hypodermic injections of 0.002 to 0.005 grms. of atropine sulphate. The condition of the patient was such that surgical intervention was deemed necessary, but the patient declined an operation, and the atropine was employed as a last resort. [A. R.]

WIENER KLINISCHE WOCHENSCHRIFT.

October 24, 1901. (XIV Jahrgang, No. 43).

1. The Operations for Stone in the Bladder.
OTTO ZUCKERKANDL.
2. The Diagnosis of Aneurysm of the Mesenteric Artery.
GUSTAV GABRIEL.
3. Tracheoplasty. ROMAN VON BARACZ.

1.—While fifteen years ago suprapubic lithotomy was the rule in the treatment of vesical calculus, Zuckerkandl, out of 150 operations, did lithotripsy in 107 patients, perineal lithotripsy once, and suprapubic lithotomy in 37 cases. In two cases vaginal lithotomy was performed, and two small stones were removed with the evacuator. Of the 109 lithotrites, done by the Bigelow method, two were upon women. The average age was 61 years. Chloroform was the anesthetic used in most cases though cocaine locally, and antipyrin (2.5 to 5 g. by rectum) were also employed. The last method was used in 21 cases. Cystoscopy confirmed the diagnosis before operation. Four cases died after operation (3.6%), two from urinary sepsis, one from shock, and one from septic peritonitis. There was recurrence in twelve cases, the longest period between calculi being 28 years. The perineal lithotripsy was followed by complete recovery. The average age of the 37 patients upon whom suprapubic lithotomy was performed was 58 years. Chloroform was used in all but four cases, in which cocaine or antipyrin was employed. Five deaths occurred (13%), two with emboli, two with urinary sepsis, and one with intestinal obstruction. He concludes that lithotripsy is the operation of choice, rarely perineal lithotripsy, but that suprapubic lithotomy is needed for the removal of very large stones. [M. O.]

2.—In a search through the literature Gabriel found but four cases of mycotic, embolic aneurysm of the mesenteric arteries. He reports the case-history of an aneurysm of the superior mesenteric artery in a boy of 10. The heart showed recent mitral and aortic insufficiency, with endarteritis which had caused hemiplegia and aneurysm formation. The staphylococcus aureus was found in the heart and the aneurysm. [M. O.]

3.—Dieffenbach described bronchoplasty some years ago. von Baracz operated upon a boy of 14 whose trachea showed a large defect, existing since diphtheria with subsequent laryngeal stenosis at the age of five. Tracheotomy had been performed twice, with other operations later. All symptoms had disappeared for over one year. After closing the wound temporarily, to see that he could get on with it closed, he performed tracheoplasty. The wound healed by first intention, and the boy has kept perfectly well with the wound permanently closed, which had been kept open for nine years. [M. O.]

CENTRALBLATT FUER INNERE MEDIZIN.

August 24, 1901.

1. The Relation Between Sweating and Leukocytosis.
WALTHER HANNES.

1.—The previous work of Bohland is referred to, showing that the hydriotics and antihydriotics have a very great influence upon the leukocytes. Hannes has carried this further, and determined that mere sweating itself, even when no drugs are used in producing the sweating, causes marked increase in the number of leukocytes. He examined 29 children and found that in 77% decided leukocytosis followed the occurrence of sweating, whether this was spontaneous or was produced by hot air baths or similar measures. In 5 instances the leukocytes remained normal or actually decreased in number. Eight children were under one year of age, 12 under 30 months, and the remaining 9 between 4 and 11 years of age. Some of the children were perfectly well and had thoroughly good family histories; others of them had various diseases. Hannes was, however, careful to determine that none of the children had any infectious disease, or any other condition which in itself would be likely to cause an increase in the leukocytes. One interesting observation was the fact that in all the in-

stances in which leukopenia occurred, marked rachitis was present. Leukocytosis was not considered to be present unless the number of leukocytes rose above 13,000. In most cases the increase in number was from 3000 to 5000, and in some instances was still more marked. The leukocytes could be made to decrease by stopping the secretion of sweat, and they usually fell to normal about one half hour after the child was dried and re-clothed. Hannes concludes that the increase in leukocytes is due to the positive chemotactic influence exerted by substances which are constantly present in the body, and which exert this action under the influence of anything which causes sweating.

[D. L. E.]

August 31, 1901.

On Skatol Red and Other Urinary Pigments.

KARL ROESSLER.

In making indican tests one may often observe that the fluid assumes various colors from brown to violet. The pigment is usually absorbed by amyl alcohol, and commonly becomes brownish in color as it is absorbed. There has been no definite work concerning the nature of this pigment; various reports have been made concerning it, but no one has investigated its exact nature. Rossler found that it was neither indigo red nor urorosein. This led him to believe that the pigment was skatol red. He attempted to get a reaction for skatol with the pigment which he extracted from about 0.5 a litre of urine by means of amyl alcohol. The quantity was, however, so small as to be unsatisfactory and the result of the test was negative. In order to increase the amount of skatol he repeatedly administered to a patient 0.5 to 1.5 grms. of skatol, and then isolated the pigment from the urine, and after obtaining considerable quantities of it, found that it did give definite reactions for skatol. He therefore reaches the definite conclusion that this pigment is skatol red. The method of determining its presence in the urine is to add to 10 cc. of fresh urine the same volume of fuming HCl and after about 5 minutes to shake with 5 cc. of amyl alcohol. If no brownish coloration appears, one should repeat the test after having previously precipitated with lead acetate and filtered. It is well also in this case to add chloroform with the HCl in order to extract indigo blue and indigo red, and then to shake the supernatant fluid with amyl alcohol. The clinical importance of the test is as yet unknown. [D. L. E.]

September 7, 1901.

1. Contribution to Mechano-Therapy. B. H. ZEEHUISEN.

1.—Zeehuisen believes that while the importance of mechano-therapy in disease of the respiratory and circulatory systems is well recognized, this method of treatment has not been sufficiently freely used in the management of other conditions. He considers mechano-therapy of great advantage in the treatment of convalescence from acute disease, as well as in a series of other conditions. He regularly uses the following procedures. Adduction and abduction of the lower extremities; flexion and extension at the knee joint; pronation and supination at the same joint, flexion and extension at the knee joint, and flexion and extension at the ankle. The upper extremities are also exercised in appropriate cases. In the beginning the movements should be entirely passive; they should then become partly active, and ultimately should be wholly active, and undertaken against the resistance of the person giving the treatment, the resistance being gradually increased. The cases in which it is especially beneficial during convalescence are those in which prolonged confinement to bed has been necessary. He also considers it very important in convalescents who have a marked tendency to nervous disturbances and in cases of chronic disease in which prolonged rest is necessary. He has found it very valuable in many instances of general weakness. For instance in early tuberculosis, chlorosis, gastric ulcer, and in the weakness that sometimes persists for a long period after acute in-

fectious disease. He also recommends it in so-called uric acid diathesis, and as an aid to active exercise in adiposis. In neurasthenia mechano-therapy may be used, but only with the utmost care, and the use of resistance should be extremely gradual. Traumatic neuroses, particularly those occurring in soldiers, he has found to be very satisfactorily influenced by this treatment. [D. L. E.]

CENTRALBLATT FUER CHIRURGIE.

September 7, 1901. (28 Jahrgang, No. 36).

1. The Use of Gold Wire and a New Instrument in the Radical Operation for Hernia.

G. de FRANCISCO.

1.—Francisco reports the results of 120 cases of hernia operated upon by Professor Tansini, with excellent results. In order to prevent the hand of the surgeon or his assistant from touching the wound, he uses a hook to hold up the spermatic cord, a rake-like instrument to keep the aponeurosis of the external oblique muscle apart, and a spatula to hold the lower parts down, thus preventing injury from the needle. To these instruments, together with the use of gold wire for sutures, Francisco attributes Tansini's success. [M. O.]

September 28, 1901. (No. 39).

Operation in Epityphlitis During the Quiescent Period.

E. MARTIN.

The author first alludes to the results obtained by Jaffe as reported in No. 31, *Centralblatt für Chirurgie*. The cases alluded to are rare but doubtlessly occur, and are those in which for some anatomical or technical reasons it is not only impossible to isolate the appendix, but actually impossible to find it. Resection of the cecum was successful in two cases reported by Jaffe, although they were complicated by long continued intestinal fistulae. The author reports a case in which enteroanastomosis was performed with a favorable result. The patient was a man who had suffered for three years from typical recurrent epityphlitis. The attacks were afebrile and a tumor was present in the iliac region; there was pain and signs of disturbed fecal evacuation. Enteroanastomosis of the ileum and colon was performed by means of a continual suture. Nine months after the operation the patient was still healthy and improving. The author believes that absolute deductions cannot be as yet made on account of the short period of observation. [M. R. D.]

NORDISKT MEDICINSKT ARKIV.

1901. (Afd. 1, No. 2).

8. Fractures of the Thigh While Snowshoeing.

G. EKEHORN.

9. Primary Intestinal Tuberculosis with Multiple Strictures of the Small Intestine.

V. GRIMSGAARD and JOHAN NICOLAYSEN.

10. A Case of Cholecystitis, Cholangitis, Hepatitis, and Subphrenic Abscess. G. NAUMANN.

11. The Influence of the Umbilical Vesicle and the Umbilical Duct Upon the Insertion of the Umbilical Cord in the Placenta. INGOLF LOENNBORG.

12. Simultaneous Extrauterine and Intrauterine Pregnancy. HANNA CHRISTER-NILSSON.

13. The Indications and Technique of Gynecological Laparotomies. C. D. JOSEPHSON.

8.—Ekehorn reports eleven cases of fractured femur which occurred while snowshoeing, in boys ranging from 9 to 16 years in age. Some of the boys felt their legs break as they jumped or fell in the snow. Eight of the fractures were near the middle of the femur; in two cases the fracture was in the upper third; and in one case it was in the lower third, near the knee-joint. The majority of the fractures were oblique and uncomplicated. All the boys recovered rapidly. [M. O.]

9.—Grimsgaard and Nicolaysen report the case of a woman of 59, who had occasional severe attacks of colic

with enteritis during ten years. In the last year these attacks grew more frequent. Nine months after she became ill, edema, ascites, meteorism, and irregular bowel movements appeared. Tubercle bacilli were found in the stools. There was no vomiting at any time, nor was excessive acid found in the gastric juice. Noises were audible in the intestines, Kôaig's sign of intestinal stricture, and laparotomy was performed. A stricture was found in the ileum, and ileocolostomy done. She died five weeks later. The autopsy showed four strictures between the duodeno-jejunal fold and the cecal valve. Some of the mesenteric glands were enlarged. The lungs were free from phthisis. They consider this a case of true primary intestinal tuberculosis. The fatty heart and liver explain the cachexia found. They tabulated 114 cases, all younger than this one. They believe that her age caused compensatory hypertrophy, so that the symptoms only appeared late in the disease. [M. O.]

10.—Naumann reports a case of cholecystitis, cholangitis, hepatitis, and subphrenic abscess in an Englishman aged 34. First the ninth rib was resected, then laparotomy was performed, the gall bladder being sutured to the abdominal wall, and later resection of the eleventh rib was performed, the fistula closed, and he recovered. His history shows that he had probably had gallstones in childhood, and had cholecystitis. Cholangitis followed, with hepatitis and a subphrenic abscess which was evacuated by resecting the eleventh rib. No abscess of the liver was found. Since his return home, he has kept well. The gall bladder was drained through the fistula until it finally closed. [M. O.]

11.—Schultze first explained the origin of velamentous insertion of the umbilical cord from abnormal adhesion of the umbilical vesicle to the chorion or amnion, and from traction upon the vessels of the allantois by the remains of the umbilical duct. Lönnberg studied nine cases of velamentous insertion of the umbilical cord in the placenta, describing the condition found. From the examination of over 200 placentas, he found that the remnant of the umbilical duct did exert an influence upon the cord, in that it pulled the insertion of the cord toward one side of the placenta. In only a few cases did the condition resemble that described by Schultze. Many details and diagrams are given. [M. O.]

12.—Chister-Nilsson has collected 68 cases of simultaneous extrauterine and intrauterine pregnancy, one of them observed by herself. All occurred between the ages of 20 and 40 years, mainly in multiparae. The extrauterine pregnancy was tubal in 36 patients, in some of whom twin pregnancy preceded this condition. Abortion occurred or several years elapsed between the last pregnancy and this condition in many cases. In some both conceptions took place at the same time, in others one preceded the other. There was irregular metorrhagia in a few cases, while regular menstruation continued in others. Pain developed, and later the signs of pregnancy. In 20 cases both pregnancies went on to full term, uninterrupted. In 10 cases abortion occurred. In 27 cases the extrauterine fetus died; in the other cases tubal abortion followed. As a rule, rupture of the tubal pregnancy was preceded by intrauterine abortion. In most cases the ectopic fetus survived its intrauterine twin. Symptoms of peritonitis occurred and operation was frequently necessary. In 29 cases the intrauterine fetus was born at full term, living in only 23; abortion occurred in 27 cases, while the mother died before term in 6 cases. The ectopic gestation went on to term in 25 cases, both infants reaching full term in 20 patients. The diagnosis of the condition is exceedingly difficult. In 15 cases operative interference was needed to remove the extrauterine gestation sac, total extirpation in 9 cases, in which gestation had only reached four months. Of 10 cases in whom laparotomy was performed after abortion, 9 recovered. 19 of the 38 cases treated expectantly died, 10 of rupture, 5 of peritonitis, and 2

of hemorrhage. Only 10 of those treated expectantly recovered, the extrauterine gestation reaching full term. Three of the extrauterine infants were brought into the world at term, living. A description of her case follows with a table of 68 cases collected. [M. O.]

13.—Josephson reports 131 abdominal laparotomies and 12 vaginal laparotomies. Only two deaths occurred, one of thrombosis, the other of acute nephritis, both from the ether. 47 operations were for ovarian tumor, 42 for myoma, 21 for tubal disease, 16 for uterine cancer, and 17 for peritonitis, foreign bodies, ruptured uterus, Cesarean section, etc. Silk sutures were used, while no septic cases were touched during the two days preceding operation, the hands were well disinfected, and the operation was as aseptic as possible. Cysts were enucleated, then pulled out of the connective tissue, without hemorrhage. Of the 47 ovarian tumors operated, 16 were retention cysts, 17 glandular cysts, and the rest dermoid, parovarian, suppurating, and papillary cysts. Of the 42 laparotomies for myoma all but two were abdominal. 32 were performed by the Chrobak method, while two cases of panhysterectomy and six cases of enucleation were done. Hemorrhage was the indication for operation in 20 of the cases. Of the 21 cases of tubal disease, laparotomy was performed 9 times for tubal pregnancy, twice for hydrosalpinx, and 10 times for salpingo-oophoritis. Of the 16 cases of uterine cancer, 8 were adenomyomata, and 8 cancer of the cervix. Josephson's operative technique in all cases is given in full. Only four accidents occurred in the 143 operations. A forceps was left in the wound, but was removed by another laparotomy, later; a vesical fistula resulted which healed spontaneously; an incision was made into the bladder; and a ureteral fistula resulted. Tables of the cases described follow. [M. O.]

LA PRESSE MEDICALE.

October 16, 1901. (No. 83.)

1. Radial Paralysis from Elongation of the Nerve.

MARCEL LABBE.

2. Albumosuria and the Bence Jones and Jacquemet Reactions. A. SICARD.

1.—Labbe reports the case of a man of 39, who fell while lifting large stones. He noticed but slight pain, and continued at work that day. The next day, however, he could not extend the fingers of his right hand, showing marked radial paralysis. He could not extend the end phalanges of the fingers, but when they were raised, he was easily able to move the fingers. Some muscular atrophy followed. Upon electrical treatment he quickly recovered. The cause of the paralysis was evidently the fall, in which the radial nerve had been stretched. [M. O.]

2.—Sicard believes that tests for albumose should always be made in urine examination. The albumoses are hydrated albumins, before they become peptones. For the recognition of albumose in the urine, there are two test-reactions, that of Bence Jones and that of Jacquemet. Bence Jones, after filtering the urine, finds a cloudiness when it is heated to 60°, which disappears on boiling. Jacquemet adds ether to urine containing albumose, and a gelatinous ring is at once formed. Albumin, mucin, and the phosphates may give this reaction, but they can be removed by adding sodium chloride, filtering, adding acetic acid, boiling, cooling, and filtering again. Jacquemet gives the details for quantitative examination also. While the Bence Jones reaction is rarely seen, that of Jacquemet has often been observed. Still Sicard thinks that the subject is by no means settled, since there is as yet no exact definition of the albumoses. [M. O.]

October 19, 1901. (No. 84.)

1. Bloodless Reduction of Congenital Dislocation of the Hip. F. BRUN.

2. Iron in Chlorosis. E. FIQUET.

1.—Brun, who has had several more successful results from bloodless reduction of congenital dislocation of the

hip, considers this method of treating congenital luxation of the hip by far the best. Success is exceptional when the child has passed ten years, though he had good results in one of twelve. At 3 or 5 years the operation is always successful. Before that age it is difficult to maintain reduction. The main obstacle is the contraction of the adductor muscles of the hip. To return the head of the femur to the cavity of the acetabulum, this adductor cord must be destroyed mechanically. The method of operation is fully explained by diagrams, and radiograms of a case before and after reduction are given. At least three plaster casts are put on, one after another, to keep the dislocation reduced. This is well illustrated by photographs. Epiphyseal separation or sores from the plaster may occur, while sciatic paralysis is very rarely seen. [M. O.]

2.—Iron was used in chlorosis by the ancients. It is now believed that the iron is assimilated, the erythrocytes increasing in number, and the hemoglobin becoming darker by the addition of more iron. For iron acts as an oxydase, easily taking up oxygen and carrying it to the body tissues. Especially is this the case with the crenate of iron, which is indicated in chlorosis, since such patients absorb less oxygen and eliminate less carbon dioxide proportionally than normal individuals. Iron in chlorosis acts reconstructively, furnishing the iron necessary to the erythrocytes and bringing oxygen to the body cells. [M. O.]

October 23, 1901. (No. 85.)

1. Syphilis of the Frontal Lobe with Jacksonian Epilepsy.

G. DIEULAFOY.

1.—Dieulafoy reports the case of a man of 40, who entered the hospital in an almost comatose condition. He had had one attack, epileptic in character, at night, had bitten his tongue, and urinated in bed. Ten years before he had been treated for syphilis. Respiration, upon admission, was stertorous, and several attacks of typical epileptic convulsions followed. His tongue and face were turned to the right, and there was right-sided hemiplegia. The attacks lasted less than a minute. As he was known to be syphilitic, the diagnosis of gumma of the left Rolandic region was made, and 8 mg. of mercuric biniodide were injected, which were later increased to 12 mg. In spite of treatment, he died. The autopsy showed a perfectly healthy left Rolandic region, while two lesions were found, close to one another, one in the white matter of the left frontal lobe, the other in the anterior third of the left, three frontal convolutions, in the gray matter. Histological examination confirmed the diagnosis of syphilitic gummata. Other cases of frontal lesions which caused typical motor epilepsy are quoted. While Jacksonian epilepsy may be caused either by frontal or by Rolandic lesions, an attack beginning in the leg is rarely frontal in origin. Other symptoms are identical. Since parts of the cerebrum are but slightly sensitive, these gummata reach an almost fatal size before they cause a symptom. But in this case they caused death in one week. [M. O.]

October 26, 1901. (No. 86.)

1. Serofibrinous Pleurisy and Pneumogenic, Pseudo-pleuritic Pleural Effusions. P. LEDAMANY.

1.—LeDaman discusses this subject in detail, and concludes that while purulent pleurisy is due to pyogenic micro-organisms, serofibrinous or serosanguinolent pleurisy can only be tubercular. But pseudo-pleuritic pneumogenic effusions can occur. These may be serous, with edema of the lungs; serofibrinous or serosanguinolent, with tumors, tuberculosis, pneumonia, congestion, and infarcts; and seropurulent or purulent, with pyogenic pneumonia. While pleurisy is spoken of with typhoid fever, rheumatism, Bright's disease, etc., these cases are either tubercular, or simple pneumogenic, pseudo-pleuritic pleural effusions. [M. O.]

October 30, 1901. (No. 87.)

1. The Wounds of the late President McKinley.

2. Prostatectomy in the Inverted Perineal Position.

ROBERT PROUST.

1.—A review of Dr. Mann's article.

2.—Proust describes, with very many good diagrams,

his method of extirpating the prostate, called subtotal prostatectomy, done in the inverted perineal position. The incision is pre-rectal, the rectum then being lowered, thus bringing the prostate into view. An instrument called a "desenclavier" is then introduced into the urethra, and the prostate is cut upon this. Each lobe is then dissected off, and the pedicles are sutured. The vasa deferentia and the slit in the urethra are also sutured, while a catheter is left in place. Proust believes that this new method will prove of great service. [M. O.]

November 2, 1901. (No. 88.)

1. Pyloric Ulcero-Cancer. G. HAYEM.

1.—Hayem reports a case of gastric ulcer in a strong, healthy man of 40, of good family and personal history, who had been ill for five years. At first he noted only pain after meals; then eructation and vomiting followed. This recurred in attacks, and he grew worse. There were slight hyperchlorhydria, hematemesis, and melena. Then anemia followed with constipation. After much suffering, hemorrhage, and weakness, he died. An ulcer was found surrounding the pyloric opening, its edges already showing cancerous degeneration. There were no enlarged, cancerous lymph-glands in the neighborhood of the stomach. This case demonstrates plainly the fact that gastric ulcer may become cancerous. [M. O.]

LA SEMAINE MEDICALE.

October 9, 1901.

1. Associated Epidemics. V. BABES and G. ROBIN.

1.—These authors remark that our knowledge of epidemics and their causes is still far from precise. We are in the habit of considering them as specific entities, each having its particular microbial cause, and of regarding the cases of the disease as practically identical whether they occur singly or as epidemics in hospitals, as erysipelas, etc. Babes called attention in 1895 to a hospital epidemic in which there was a very high mortality and in which the recognized cause did not seem to be specific. The original pyogenic organisms seemed to have acquired great virulence by their passage through several individuals and infected subjects already suffering from some other morbid state, and the course of this re-infection was violent and rapid. Frequently there exists an epidemic of influenza or pneumonia complicating a pre-existing epidemic, and in such an instance the second disease will very frequently form an atypical picture with the clinical signs of the first infection. In such instances the virulence of the disease in the second type seems to be much increased. These considerations were suggested by the bacteriological researches which these authors have made for the purpose of discovering microorganisms, and possessing the characteristics of the *Bacillus* of Pfeiffer in infections of a grippal nature which have been classed in general under the term, influenza. They have described 8 fatal cases appearing in epidemic form, in which they presented the clinical picture of typhus fever, and in these 8 cases the *Bacilli* of Pfeiffer were found. 40 cases were included in the epidemic of which the 8 mentioned were fatal. The disease does not seem to have been an atypical typhoid, for the agglutinating reaction was not to be found in many of the cases early, but did become positive later. Neither do they fit into the syndrome of influenza, as specific organisms of this disease were not found early, but also appeared later, and they were found in old lesions such as pneumonic or gangrenous foci. They have distinguished these cases by the term **Associated Epidemics**. The majority of them resemble typhoid fever, but two cases took on the clinical picture of measles; others of influenza. [T. L. C.]

Society Reports.

NEW YORK ACADEMY OF MEDICINE. SECTION ON ORTHOPEDIC SURGERY.

Meeting of November 15, Dr. G. R. Elliott in the Chair.

Dr. Homer Gibney read a paper on the orthopedic operations for intractable cerebro-spinal lesions, reporting two cases of Friedreich's ataxia, in which marked improvement in locomotion followed operation. Incoordination was overcome by tenotomy and fasciotomy. He first corrected deformity and with properly adjusted apparatus, worn for a long time, he claimed marked benefit and, in many cases, removal of the interference due to the paralysis. Dr. H. L. Taylor agreed with Dr. Gibney upon the value of operation in paralytic deformity in children. Dr. John M. Woodbury expressed the opinion that operation offered a possibility of recovery; non-operative measures alone were simply palliative. Dr. Elliott said that many a cripple was bed-ridden, or had contractures and post-paralytic deformities that should be relieved. He cited a patient upon whom he had recently operated, bed-ridden for three years from post-typhoid contractures of spinal origin. By tenotomies, manipulation, and the subsequent use of apparatus, the girl was now walking well. Dr. Taylor read a paper on the effect of osteitis of the knee on the growth of the limb. From measurements of the femora, tibia, feet, and patella during or after osteitis of the knee, in forty patients in whom the disease had begun in childhood, the following conclusions were reached: The affected limb was longer in the first four years in the large majority of cases. In adolescents and adults it was several inches shorter, when the disease lasted over seven years. The affected leg was nearly always longer in the first four years, from lengthening of the femur. In the older cases, after a duration of seven years or more, the femur was shortened. The tibiae were usually equal in length in the early stages; later the tibia of the affected side might be slightly longer for a time, but oftener shorter; the shortening increased considerably after the subsidence of inflammation. With limbs of equal length and a duration of several years, the femur of the affected side was found longer and the tibia shorter than its mate. The foot and patella showed a difference in favor of the sound side after one year. The stimulation of growth in the affected femur was accompanied by a retardation in the tibia, foot and other parts; growth in the femur was finally retarded. The final result was considerable shortening. Dr. T. H. Myers said that his observations were almost identical. In fifteen cases observed by him the lengthening was generally in the femur, in some cases the femur lengthened while the tibia shortened, in others both bones were lengthened during the active stages of the disease. The proper functioning of the joint, after the cure of the disease, was a most important element in securing nutrition and development. Dr. H. A. Parish stated that ultimate shortening occurred in the majority of cases. He cited a case, a girl of 16, with osteitis of 13 years' duration, with great lengthening during the active stage of the disease. After partial excision, ten years ago, and, recently, supra-condylar osteotomy of the femur, and cuneiform section of the tibia for the relief of flexion, there existed only $\frac{3}{4}$ of an inch shortening, with the limb at an angle of 175° . Dr. V. P. Gibney said that, years ago, Dr. Berry, examining 50 cases, found the femur increased in length. While lengthening was generally believed to be the rule, it could readily be understood how shortening might occur from interference with the nerve supply, by pressure of the head of the tibia on the popliteal space. He referred to a patient seen ten years ago who had $1\frac{1}{2}$ inches lengthening after a long course of protective treatment. The girl was young and the disease cured; she was allowed to use the limb, and atrophy set in. At the same time the healthy limb was protected and after four or five years the normal femur lengthened and the diseased one shortened, so that $\frac{1}{4}$ inch difference was the result. Dr. Taylor said that lengthening of the femur was the rule while the disease was active, though it was probable that shortening occurred in deformed and badly managed cases, when the result would usually be considerable shortening in adult life. He referred to the work of Leusden, who took measurements of radiograms, and reached nearly identical conclusions.

Original Articles.

MEDICAL CARE AND TREATMENT OF INEBRIETY.

By T. D. CROTHERS, M. D.,

Of Hartford, Conn.

Superintendent, Walnut Lodge Hospital, etc., Hartford, Conn. Professor of Diseases of the Brain and Nervous System in New York School of Clinical Medicine, New York.

In inebriety the problem to determine is this: First. The present condition. The organic and functional derangements of digestion, nutrition, and also of the brain and nervous system. Second. The use of alcohol and other drugs and their effect on the nerves and brain. Third. Was the drug and alcoholic condition at first only a symptom or an active causation? Fourth. What neuroses and heredity were the active or latent factors in the history of the case?

A study of these questions will point out the line of treatment that will assist toward recovery. A common case will illustrate this more clearly. You are called to see a man who has gastritis, who has taken but very little food for weeks, but has drunk continuously various forms of spirits. Both digestion and nutrition are seriously impaired. General hyperemia and defective motor and sensory control, with feeble, unstable brain power, are present. If the case is treated from these symptoms alone, very little can be expected. If the inquiry goes back to the effects of spirits on the body, and when and under what conditions they were taken, and also the origin of the drink addiction, many new indications will appear.

If it is found that the use of spirits began from some severe strain or state of exhaustion, or following some disease, or was the result of irregularity in the mental and physical surroundings, further light is added.

If the history points to a neurotic inheritance direct, as from alcoholic ancestors, or indirect, as from insane, consumptive, or epileptic, or any of the neuroses, a new view obtains.

The treatment of a case that simply checks the brain and nerve irritations by narcotics, or by removal of spirits, or by elimination removes the congestion and relieves the gastritis, is only partial.

Suppose the pledge or conversion, or any moral and mental stimulation fills the mind with an ardent confidence that he never will use spirits again; or suppose he is given narcotics until the system is saturated, the same effect follows. The mind is buoyed up with the hope that all desire for spirits has ceased, and he is henceforth a free man. All this is empirical, and is neither medical art nor science. A cathartic or narcotic given for some superficial symptoms may do good, and yet it is a mere accident. Moral advice may help the case, and the drink craze may die out; this is also an accident entirely unforeseen.

The inebriate is diseased, and the question of medical care and treatment turns on an exact knowledge of the causation and his present condition.

Such a knowledge will enable the physician to point out the conditions from which a return to

health may be expected. He can point to the oncoming insanity of which the drink impulse is only a symptom. He can anticipate the general paresis which is so commonly preceded by an impulsive craze for alcohol. Melancholy suicide, and acute delirium can all be seen in advance, and the more accurately the case is studied, the clearer will be the prognosis. There are no cases that can be more accurately anticipated than these. Certain cases in definite surroundings will have a uniform line of progress that will rarely differ. Take a hundred inebriates and from a knowledge of their heredity, environment, present condition, and the general action of alcohol on the brain and nerves, a prognosis can be made that will be verified in a large percentage of all such cases.

The first question that confronts the physician when called to a case is, what is the present condition and what means can be used to alleviate it? All inebriates suffer from degrees of paralysis, both vaso-motor, sensory, and functional. There is present always functional palsy and subacute inflammation that is generally local. The heart is enfeebled, and often enlarged. The liver is congested and the seat of a low grade of inflammation. The stomach is palsied, and often acutely inflamed. In cases of long standing, neuritis of the extremities in a greater or less degree is present.

The first treatment is preliminary, and should begin with a warm bath and thorough rubbing to counteract the vaso-motor palsies of the arteries. One of the marked effects of these palsies is to retard and prevent elimination of waste matter through the skin. As a result new sources of danger arise from the chemical decomposition of waste effete matters retained in the system. Potomaine poisonings and new sources of irritation, new soils for the growth of bacteria, appear.

The bath is a cutaneous stimulant to aid in the elimination of these products.

Recently the electrical light bath has been found valuable as a stimulant and powerful eliminator, promoting increased activity of the organic processes, and in many ways, not clear at present, increasing the normal metabolism of the body.

After the bath comes what is termed internal lavage or washing, based on the same reason, viz., that of eliminating the poisonous products which are formed by the paralysis, both functional and organic.

The lavage is best secured by a saline or mercurial cathartic and copious draughts of warm or acid waters.

For the nerve paralysis and irritation, the various forms of bromide seem sufficient. I think large doses of one hundred grains-at a time are most practical.

Of course all spirits are removed at once, and for another purpose, to uncover the real causes which may be masked behind, and appear when the spirits are removed.

If collapse and acute delirium follows this treatment, I give some form of concealed preparation of opium, usually the deodorized tincture in cinchona bark infusions. This is withdrawn as soon

as possible and the bark preparations continued. If digestion is seriously impaired, I give nuxvomica in 1-40 grain doses.

In this preliminary treatment salines, mineral waters, and fruit acids are the commonly associated remedies. Rest in a recumbent position and passive exercise from massage, together with restraint, are all important.

During this preliminary treatment a study of the physiological and pathological history will indicate the causes most active in the craze for spirits. When they are traceable to syphilitic poison and general exhaustion from bad living, a long course of mercury and arsenic, with total change of life and surroundings, are indicated.

When the first causes are clearly head injuries, and a slow degeneration from subacute inflammations and other obscure brain and nerve changes very active constitutional treatment with changes of living are essential.

Baths, diet, mineral, and acid tonics should be alternated with bark infusions.

Where heredity is prominent, the drink craze is a symptom of a constitutional impulse or proclivity to acute degeneration, exhaustion, and death.

The same prognosis should suggest the most radical changes of life and living, and all medication should be directed to this end.

When a tendency to use stimulants or drugs that are irritant and sedative to the system exists in young persons, a grave future is before them. Often such persons are found in the best families, and will seek advice for some digestive troubles, when it will appear that the real trouble is that some form of alcohol is freely used at the table, or as a family medicine for all disturbances.

Where a neurotic heredity is present, the future is equally grave.

A recent work on the treatment of children's diseases advocates the use of brandy as a tonic in constitutional debility and general anemia. The author would be astonished if chloral or morphine were urged for these conditions, and yet he advocates substantially the same thing. Alcohol to a child is nothing more than a narcotic.

A craving for drugs, of which alcohol is prominent, is a dangerous symptom.

Where the causation of the inebriety has apparently come from the exhaustion due to overwork, imperfect nourishment, and general starvation, the treatment must be directed to remove and change these conditions.

Where it has started from nutrient disorders, such as indigestion and tissue starvation, the treatment must be based on a careful examination of all the probable complications that exist.

The faults of functional and chemical processes of the liver, stomach, and intestines are to be treated as in complex states of dyspepsia.

The mental treatment is often of great value, and the physician should always remember that psychological therapeutics are essential in all these cases.

Another class will have a clear history of acquiring the drink impulse by contagion, or, more

popularly called, bad company, bad example, bad social companions and surroundings.

Many such cases will be found defective in both brain and nervous structure. They come from defective race-stock, and have a heredity or neurotic tendency; this, with faulty training, is quickly followed by an unstable brain equilibrium, and consequent exhaustion, for which alcohol soon becomes a grateful narcotic. Such cases have brain defects with central neurasthenic conditions. They need change of every condition of life and surroundings. They should go back to the country and live far removed from every possible strain on the brain and nervous system.

The primary condition in these cases is failure of the central brain structure. The exhaustion and losses of vital energy are slowly restored by natural processes. Full restoration seldom occurs, and this is manifest in weakness, debility, and lowered vitality ever after. Alcohol stills this demand for relief by narcotism and paralysis. The heart's action is raised, then lowered. Currents of blood are driven rapidly to all parts of the system, then slowed down. The temperature is lowered, and the early exhaustion is increased.

In periodic cases the abnormal brain force accumulates and is discharged in an epileptoid condition, only instead of the spasm attended by tonic and clonic contractions, it becomes an insane thirst for the narcotic effects of alcohol. When this is accomplished, a long period of rest and general anemia follows. If this insane thirst for spirits can be neutralized and changed, it may be broken up. Fortunately many of these cases have exact and distinct cycles which rarely vary, and whose return can be predicted. When this is understood, anticipating treatment can be used.

Active cathartics and prolonged hot baths, outdoor exercise, where the person leads a sedentary life, or rest where the person is actively engaged, are valuable.

Bromide given at night is sometimes of great value.

In a case of an active business man in New York who feels intensely nervous and irritable with his surroundings at distinct intervals, he goes away to the Catskills, tramping for days with dog and gun, and by this means averts a drink paroxysm.

A noted physician, who suffers in this way, goes to a hotel, takes large doses of bromide, and remains in bed for several days.

Many and various devices are used by this class, with more or less success to prevent the drink storm.

The real therapeutic aids should go farther back and seek to avert the causes which culminate in this way. In one case under my care, sexual exhaustion was the cause. The man had been a periodic drinker for ten years; his wife died, and he recovered, and was temperate for six years. He married again, and a few months later these drink storms returned. Two years later his wife went to New York and was treated six months for an ovarian tumor. He was temperate again and has been so for a year; his wife meantime is travelling in Europe. These cases are more common than one

would suppose, and indicate a neurotic basis at the beginning.

This periodic return of the drink impulse should suggest some active exciting cause that may be found and corrected.

A case was noted by Dr. Brainard, of Columbus, O., where the expulsion of a tapeworm was followed by a total subsidence of the drink impulse.

A soldier, who had been a severe drinker for years, recovered after an operation in which a spicula of dead bone was removed. This had existed from the close of the war.

The train-despatcher of a large railroad, who worked at night and had for many years long and severe drink excesses, recovered by merely changing his work to the day and sleeping at night.

A prominent hotel man, who has been under treatment, will have a drink excess if he sits up past midnight. If he is careful to retire regularly he can keep temperate.

Another case has been noted of a quiet farmer who never drinks except after a religious revival. He will take a very active part in the revival meetings, and when they end commence to drink and be much intoxicated for a week, then suffer from some acute indigestion, and after some medical care recover, never drinking again until another revival comes.

Many of these cases only drink on holidays or days of general celebration, and remain sober the rest of the time. Some condition of brain exhaustion exists which is partially controlled until these stated periods of relaxation, when it breaks out again. Such cases need treatment, and often can be cured.

These periodic cases have always a strong tendency to merge into epilepsy and acute dementia. Suicide and homicide are frequently associated and follow. The transient paralyses of the brain in these drink excesses are always perilous to brain integrity. It is a safe conclusion to infer that the brain in these cases is seriously impaired and cannot be trusted for sound consistent work.

The treatment for this condition is most important, as is also the removal of the active exciting causes.

When the case is that of a continuous drinker, the possibility of general paresis should be considered.

Often a prodromic stage of months and years occurs in which the drink impulse will be the leading symptom, then merge into paresis, which speedily culminates in death. The long formative period was noted principally for inebriety and possibly sexual excess, and slow, growing delusions of grandeur.

A noted senator has for two years developed this drink craze, which is concealed as much as possible, yet it is only symptomatic of oncoming paralysis.

These cases are numerous, complex, and are more or less amenable to medical care and treatment. They are medical cases and can only be benefited by medical advice and treatment. The radical changes of life and living can often be best secured in an asylum where they are under the con-

stant care of the medical man. The drink impulse is often only a symptom, and remedies addressed to this alone are not curative. The case is a constitutional one, to be reached by general remedies, along lines of scientific study. Here, as elsewhere, no specific remedies will be found, for the reason that the causes are complex, and include all the functions and organic processes of the body. The action of alcohol is equally complex and general, extending to all parts of the body; not only changing the chemical conditions of the nutrition and cell-growth but paralyzing and breaking up its normal action.

Therapeutic art has not advanced far enough to point out remedies that will reach or neutralize all these diseased conditions. Theories of the action of this or that remedy are open to grave suspicion of error. The more inebriety is studied, the more doubtful specific remedies will appear. Only the charlatan and the ignorant will ever urge special remedies for this disease.

In this brief outline of the medical care of such cases, my object is to make prominent the fact that these are curable cases, and always more or less benefited by exact scientific, medical care.

These armies of inebriates open up a new field for medical practice, one that can show triumphs of science and art equal to that of any other department of medicine. Unfortunately, to-day this realm has not been rescued from the mysticism of moralists and quacks. A vast army of squatters, pietists, politicians, and reformed inebriates, are teaching the world the nature and treatment of inebriety. Specifics surrounded with mystery, and urged with the most ignorant dogmatism, are accepted as truths, and the press and pulpit hail their appearance with extravagant praise. Even weak, credulous members of the profession join in the popular current. Medical men, who should be teachers and leaders of the public sentiment regarding alcohol and the inebriate, are silent, or carried away by the sentiment of the hour. Over a hundred thousand persons are dying yearly, directly or indirectly, from this disorder, and yet it receives no study or attention except from a class who, of all others, are the least able to comprehend its nature and treatment. It will be a source of wonder and amazement in the coming century that the medical man of to-day should have neglected and shown such indifference to one of the great scientific topics of the age. We look back a century and find insanity and various epidemics utterly ignored by medical men; given over to the clergy, the politician, and the moralist. History is repeated in the present indifference concerning inebriety. There are over a hundred thousand physicians in this country, and only a very few have ever given inebriety any study. Yet more than half a million temperance men in this country, of all grades, are talking, writing, and teaching what inebriety is, and how to treat it. What a terrible sarcasm on our scientific intelligence. A field for scientific work and study is open before us, occupied by quacks and an army of non-experts to-day.

As scientific men but one course remains before us. That is, to study the inebriate and his malady,

and teach the public the real facts and their meaning; to assert our true position as teachers, and thus rise above the dense ignorance of the quacks, the clergy, the politicians, the reformers, the moralists, and the inebriates themselves.

Let us show the coming generations that we had some idea of the disease of inebriety and its curability by medical means and measures in this our day and generation.

THE TYPHOID SPINE.*

By WILLIAM J. TAYLOR, M. D.,

of Philadelphia.

Attending Surgeon to the Orthopedic Hospital and Infirmary for Nervous Diseases and to St. Agnes Hospital; Consulting Surgeon to the West Philadelphia Hospital for Women.

Since Doctor Gibney's original paper was read before this Association, describing a very painful sequel of typhoid fever, which he called the "typhoid spine" and described as a peri-spondylitis, various articles have appeared by different writers under this heading. The cases described by them differ very materially in their history and their symptoms, and my object in writing this paper is to report in full one case and to try to reconcile somewhat these different opinions.

There are certainly three distinct conditions of the spine which may arise after typhoid fever. First, the true peri-spondylitis of Gibney; second, a painful condition of the muscles of the spine, resulting from a mechanical strain or injury and which is not a peri-spondylitis; and third, the hyper-sensitive neurasthenic painful spine, which is merely a neurosis and, consequently, not based upon the same pathological findings.

Doctor Osler in his paper (Johns Hopkins Hospital Report) does not define these differences with clearness, for he classifies all of these conditions under the one heading and is inclined to believe that all are bordering upon neurasthenia. Doctor Keen (The Surgical Sequels and Complications of Typhoid Fever) does not even mention this so-called typhoid spine, believing that it is merely a functional neurosis and not due to any special pathological lesion. He thus dismisses the subject as not being a surgical complication. I think, however, that if the reports of the various cases and their histories be studied with care and especially if the one case which has come under my own personal observation—the history of which I give here in full—be given due consideration, it will be seen that a definite pronounced affection of the tissues, periosteum, ligaments and deep fascia is occasionally met with and that it is distinctly a surgical sequel of this most prevalent and all-pervading malady.

The argument which has been advanced, that the typhoid bacillus, if it find a lodgment in any of the periosteal tissues, is prone to remain and produce suppuration, is, of course, well recognized, but it is not always the case by any means, for most of us have seen a marked periosteitis of the shin bone,

which in the course of time subsides or leaves only a thickening of the tissues, and resolution occur without suppuration and subsequent necrosis of the underlying bone. If this occur in the shin bone—and it undoubtedly occurs in other bones as well—why may it not also occur in the spine?

The case which I have to report is that of a man, aged 27, a pattern-maker, who was referred to me by Doctor Wharton Sinkler in May 1899. The family history was good; he had had measles, scarlet fever and diphtheria when a child and inflammatory rheumatism two years before the present attack. He has used alcohol and tobacco moderately and had one attack of gonorrhea ten years ago.

He was taken with typhoid fever February 4, 1899, and was in bed for nine weeks. The attack was quite severe but there was nothing especial about it. At the end of this time he got up and was about for a few days. He then began to have pain in the back, which was especially marked in the lumbar region and about the hips. On May 8th he had to go to bed, as the pain was very intense and extended along the whole spine, but had now become localized in the lumbar region. When he was admitted to the Orthopedic Hospital, he had not slept for three nights because of pain, which was dull and heavy but not shooting. The right hip was painful, with numbness extending to the knee, the appetite was good, the bowels constipated, the knee-jerks active, being slightly increased, the sensations normal, and there was no ankle clonus. There was a slight prominence of the spine to the right of the sacrum and also in the lumbar region and his pain was increased very much on turning from side to side. The urine contained hyaline and granular casts with pus and blood, which was probably due to some kidney complication during the fever.

At first he was treated, on the supposition that his condition was due to neurasthenia, by massage, electricity, trional at night and a liberal diet, but by the end of a week a diagnosis of Gibney's post-typhoid spine was made. His temperature was slightly above normal, but by the 20th he developed a large alveolar abscess on the right side of the jaw, which materially increased his fever. His average range of temperature was from 102 to 99, with a morning fall to normal or nearly so. His appetite continued good and he was fairly comfortable as long as he remained in bed without moving his spine. His slightest efforts, however, to move, either turning in bed or in an attempt to sit up, brought on agonizing pain.

One very peculiar symptom which was noticed in the early part of his spinal trouble was a condition of rhythmic palpitation of the abdominal walls; such a condition I have never seen before or since, and it would occur almost invariably when his abdomen was exposed in an attempt to make a physical examination. He was given salicylates, tonic and rest, but no attempt was made to lift him with a jacket or to get him out of bed. He had certain of the stigmata of hysteria, it is true, but there was undoubtedly a true pathological process in the lumbar spine, which produced thickening and a slight posterior deformity which was very distinct. Several attempts were made after he had been in bed for nearly two months, to get him out of bed, but each time the pain was so severe that he was obliged to remain quiet. His pain gradually grew less, his general health improved, the thickening about the spine subsided, the rigidity became less pronounced, and by the first of September, he was able to be up and about the wards, and was shortly after that discharged from the Hospital, apparently perfectly well, with all of the movements of the spine perfectly normal and with no pain whatever.

I saw him last on the 25th of February, 1900, when he came at my request to enable me to examine his back. He had had no pain whatever since leaving the hospital in September and had been working steadily as a draftsman. The spine was perfectly flexible in all directions, the thickening which formerly extended into the lumbar region had now entirely disappeared and he considered himself to be absolutely well.

I have lately heard from him (May 6, 1901) and learned that he has been entirely well, with no return whatever of pain or any symptoms referable to his spine.

While I believe that the majority of cases of

*Read at the meeting of the American Orthopedic Association, Niagara Falls, June 13, 1901.

painful spine after typhoid fever are neuroses known as spinal irritation, you cannot have pain, thickening, tenderness and deformity without there being a definite pathological lesion. In my own case all of these conditions were present; they were not such as you would expect to see in a tuberculous condition, nor would the subsequent history at all lead to this as an explanation; recovery has been too prompt and apparently without any limitation as to the flexibility of the spine, nor has there been any persistence or deformity. The symptoms as generally described have come on either late in the convalescence or after the patient has recovered from typhoid fever and returned to work. In most there is no history of injury, but this has been present in some. The pain is, as a rule, in the lumbar region, intense, sharp, and shooting in character which is comparatively bearable as long as the patient is lying flat on his back, but is much aggravated by any movement of the spine, either antero-posteriorly or laterally, even turning in bed is extremely painful and it is only by making a muscular effort and fixing the spine by all the voluntary muscles that it can be accomplished and then only by the aid of the nurse.

Deformity has been present, more or less marked, in every case where a true pathological lesion could be considered, but in those where the neurotic element far out-balanced the local conditions, this is not seen.

Osler's second case, a man aged 24, after a convalescence from typhoid fever, had some pain in the back, but was up and about and even able to play tennis. After a fall he suffered excruciating pain in the lumbar region and could only rest in the recumbent posture. Deep pressure over the iliac region on the left side and antero-posterior motion caused excessive pain; there was some fever. These symptoms continued from the end of November to January and it was March before he was well.

Pepper mentions (American Textbook of Medicine) a condition of obstinate periosteitis of the front of the spinal column, resulting from typhoid fever.

Periosteal thickening may disappear without suppuration, but we do not have protracted periosteal thickening lasting for weeks and months as a rule without suppuration, and it is very difficult to conceive of any attack of pain lasting for months as a result of a simple peri-spondylitis, and yet none of these cases have passed on to the formation of pus.

Lovett & Withington (*Boston Medical and Surgical Journal*, March 29, 1900, page 317), report a very interesting case where there was undoubtedly a mild, self-limited osteo-myelitis of the bodies of the vertebra, which was attended with nervous symptoms of a character usually considered hysterical and yet having at the same time pressure phenomena. Unfortunately in our study of these cases no opportunity has been given for careful pathological study as, without exception, all have recovered.

ABSTRACT OF A PAPER "A RESUME OF THE SUBJECT OF ACTINOMYCOSIS WITH REPORT OF A CASE OF ACTINOMYCOSIS ABDOMINALIS."*

By A. VANDERVEER, M.D., and ARTHUR W. ELTING, M.D.,
of Albany, New York.

Mr. President:—I desire to express my appreciation of Dr. Elting's contribution in the careful study of this subject, and in the reference he has made to various authors, French and German in especial.

The polymorphous fungus belonging to the genus of oospores was first recognized by von Langenbeck in 1845. In 1857 Lebert described a case of thoracic actinomycosis, observed by Louis in 1848, and published cuts of the actinomyces in his atlas, believing, however, that these fungi were the debris of cysticerci.

From 1868 to 1875 Rivolti and Perroncito demonstrated the so-called sarcomata of the jaws of cattle to be due to actinomyces. Bollinger, at the same time, recognizing the characteristic fungus in "Lump Jaw" in cattle, and referred it to the botanist Harz, who classified and gave to it the name of actinomycosis.

Actinomycosis in human pathology dates from the works of Israel in 1878, this author and Ponfick recognizing the identity of bovine and human actinomyces, even before the transmissibility of the disease had been proven by inoculation experiments, the latter, however, not being successful until 1880, when Joline produced the disease in a cow inoculated with some of the actinomycotic granules obtained from an animal of the same species. In 1883 Israel successfully inoculated the human actinomyces into a rabbit.

During the decade from 1880 to 1890 there were published two important articles, i. e., the classical monograph of Israel, in 1885, with a report of 37 cases of human actinomycosis, comparatively little having been added since; the second article was published by Böstrom, in which he paid special attention to human actinomycosis, and the transmissibility of the disease through vegetable life.

During the past decade much interest has been aroused in France, and among the best of the numerous publications is the exhaustive monograph of Poncet and Berard.

To-day the literature upon the subject in America is quite extensive, the disease no longer being regarded as of infrequent occurrence.

A great variety of names has been proposed for the fungus, the true distinction, however, between Madura foot and the group of pseudo actinomycoses being clearly established by Blanchard in 1895.

In the infected tissue, contents of abscess cavities, or discharge from fistulous passages, the actinomyces are usually present, in the form of small, yellowish, more or less opaque granules, in size from .15 to .75 mm. although larger granules often occur, are usually grayish-white, transparent, easily broken up, and of a consistency of soft jelly. Becoming older the granule grows more opaque and yellow, finally becoming impregnated with calcium

* Read at the Semi-Annual Meeting of the Medical Society of the State of New York, New York City, October 16th, 1901.

salts, which gives rise to a structureless concretion.

The actinomyces stain readily with ordinary basic aniline dyes, not being decolorized by Gram's method, are a facultative anaerobe and grow upon most of the common bacteriological media. The best temperature is from 33° to 37°c and even under these conditions culture development is slow, requiring from 5 to 15 days. Very often actinomyces are mixed with other micro-organisms, the latter having a more vigorous growth, and tending to obscure the former. The most common of these micro-organisms are the staphylococci, the streptococci, colon bacillus and leptothrix bucalis.

Actinomyces possess a surprising ability to develop upon cereals and vegetable media in general. At 45°c the growth of the fungus is arrested, and rapidly destroyed at 60°c.

The spores are more resistant to injurious agencies than the mycelium, although less so than the spores of bacteria. Greater resistance to noxious agencies is possessed by the spores grown upon cereals, experiments by Berard and Nicolas showing that some spores have lived as long as 4 years upon certain cereals and under unfavorable conditions.

There are a few cases on record where it seemed probable man had contracted the disease from animals, but it would appear that prolonged, intimate and close contact is necessary, which seems to indicate that the virulence and infectiousness of the actinomyces are diminished in animal organisms.

The consensus of opinion is that the great carriers of actinomycotic contagion are the different forms of cereals, especially barley, through their agency both man and domestic animals becoming infected. Pieces of cereal grains have been found in the focus of infection, the history of the case pointing almost definitely to their being the source of the disease.

Vegetables, especially those grown above ground, may also convey the contagion to man and animals.

Men are much more frequently infected than women, probably as a result of their being more exposed to infection.

Of 357 cases of human actinomycosis, collected by Huttyra, one-third occurred in the third decade of recognition of the disease.

Five chief avenues of infection have been distinguished—

1. Through the mouth and pharynx.
2. Through the respiratory tract.
3. Through the gastro-intestinal tract.
4. Through the skin, wounds, etc., and
5. A group of cases in which no definite portal of entry is discoverable.

Microscopically a focus of actinomycotic infection is characterized by a central zone, containing the fungus either free or attached to the foreign body by means of which it gained access to the part, this zone containing more or less cellular detritus and products of degeneration.

The blood vessels in the immediate vicinity of the focus are but rarely obliterated.

All the actinomycotic lesions can be divided into two great classes:—

1. The neoplastic type, which is usually found in horses and cattle.

2. The inflammatory type usually found in man and hogs.

The neoplastic type is the form in which spontaneous recovery not infrequently occurs.

In the inflammatory type the process of destruction exceeds in rapidity and intensity that of defense, tends to the production of sinuses but not of large abscess cavities, the latter usually being the result of a secondary infection.

The muscles and bones afford a very unfavorable medium for development or extension of actinomycotic foci.

The tendency to the formation of fistulous passages is quite characteristic, the discharge presenting marked differences. In some instances it is serous, in others sero-purulent and in others distinctly purulent. Secondary infection practically always exists in fistulous cases.

Another characteristic feature of actinomycotic lesions is the tendency to extend by continuity rather than by metastasis.

Poncet and Berard propose a division of actinomycotic infections into the following groups:—

1. Cervico-facial.
 2. Thoracic.
 3. Abdominal.
 4. Cutaneous.
- Foci in bone, the spinal column, the genito-urinary organs, the brain, special organs of sense, etc., being regarded as complications.

Statistics prove that about 55% of the cases were of the cervico-facial type; 20% thoracic and pulmonary; about 20% the abdominal type, and about 5% of a variety of types.

There has never been a definitely authenticated case of primary abdominal actinomycosis reported which did not originate from the gastro-intestinal tract, adhesions and abscesses being the characteristic feature, and abscesses always resulting from a secondary infection.

The actinomyces gain access to the stomach along with either animal or vegetable food, most commonly the latter. Neither the gastric juice nor the bile appear to have any very decidedly harmful effect upon the fungus.

The different portions of the alimentary tract seem to be affected in direct proportion to the length of time which the intestinal contents remain in the different parts.

Intestinal actinomycosis appears first as a small nodule in the submucosa, which undergoes degeneration at its centre, and presently gives rise to a small ulcer with undermined edges, which may extend either by progression or by confluence of several small ulcers, which, in certain instances, heal and leave irregular pigmented scars.

As the process extends, there is a decided tendency for the involved portion of the intestine to become adherent to other portions of the intestine, the abdominal viscera or the abdominal wall, preventing, in most instances, a perforation into the general peritoneal cavity. When the process originates from the colon, i. e., a portion of intestine not provided with a mesentery, retroperitoneal abscess is not an uncommon complication.

In some instances the intestine adherent to the

abdominal wall has perforated externally, forming a fecal fistula.

Perforation into the bladder is of rare occurrence, although cases have been reported by Böstrom, Hesse, Billroth and others.

The prostate has, in a few instances, been involved by extension of the disease from the rectum.

In women the pelvic viscera have sometimes been extensively involved by extension of the process from the primary intestinal focus.

In all the literature Grill was unable to find a single authentic case where abdominal actinomycosis had extended through the lymph channels.

Metastasis, in the great majority of cases, takes place through the veins rather than the arteries.

Among the secondary lesions of abdominal actinomycosis those of the liver are the most frequent, involvement occurring either by continuity, contiguity or metastasis. In 20 of the 30 cases of hepatic actinomycosis collected by Aribaud the primary focus was intestinal.

In from 50 to 60% of abdominal actinomycosis the primary focus is the cecum, appendix, or contiguous portions of the ileum and colon, i. e., in the right iliac fossa; from 10 to 15% of the cases in the rectum. In comparatively few cases has the primary focus occurred in the small intestine. There thus remain a certain number of cases in which the primary focus is undetermined, even though careful post-mortem examinations have been made.

Grill has distinguished three typical periods in the course of abdominal actinomycosis:—

1. The initial period.
2. The period of tumor formation.
3. The period of fistula.

To these three periods Hinglais has added a fourth—a period of repair.

Although in certain cases this or that period may predominate or be entirely absent, nevertheless, the periods mentioned are usually characteristic of the disease, when localized in the abdomen.

Pain, while usually present, is rarely severe, being rather a sensation of tension and discomfort.

In rectal actinomycosis the fistulae usually open about the anus and occasionally in the loin or above the pubis. Spontaneous recovery is possible, even though there be extensive infiltration of the abdominal wall, with numerous fistulae.

The duration of the disease is quite variable—from a few weeks to several years.

The prognosis in abdominal actinomycosis, even though the process be extensive, is not necessarily hopeless, for there are on record a considerable number of cases that have recovered.

In general one can say that those cases offer the best prognosis which are most amenable to surgical treatment, i. e., the abdominal form rather than the thoracic. The oldest cases are most unfavorable because of the possibilities offered for extension or metastasis.

In 77 cases of abdominal actinomycosis treated surgically, Grill found 22 recoveries 10 improvements and 45 deaths.

It is practically impossible to recognize abdominal actinomycosis in its earliest stage, although examination of fecal matter has, in a few instances,

led to a comparatively early diagnosis. In the later stages, when tunefaction is extensive, with foci of suppuration and numerous fistulae, and the discharge contains characteristic granules, diagnosis is comparatively easy.

Sarcoma, carcinoma and tuberculosis of the cecal region must also be considered in differential diagnosis.

Greater care in the selection and preparation of cereals and vegetables would certainly diminish the number of infections by this avenue. Since thorough cooking destroys the spores of actinomyces in flesh, prevention of the infection from this source would appear to be comparatively easy.

Therapeutically a so-called specific for actinomycosis has never been discovered, although iodide of potassium possesses certain qualities which produce a favorable result. In general iodide of potassium appears to act more satisfactorily and effectually, the earlier in the course of the disease it is administered, and in large and gradually increasing doses. Experiments have shown that it has little or no effect upon the growth of the actinomyces on artificial media.

Billroth, Kahler and others have tried the effect of tuberculin, improvement seeming to have followed its employment in a few instances. An interesting fact brought out by Kahler, Illich and Wolff, and confirmed by Arloing, is that men and animals infected with actinomycosis react to Koch's tuberculin the same as in cases of tuberculosis.

Ziegler has reported a favorable result following the injection of protein obtained from cultures of the staphylococcus pyogenes aureus.

Gautier has seen favorable results follow the use of electrolysis and Braum recommends the use of Fowler's solution.

In general, however, combined medical and surgical treatment would appear to have produced the best results, especially in the forms of actinomycosis more superficially placed.

It is frequently difficult to determine the extent of the process and consequently the extent of surgical intervention required.

Careful exploration of the fistulae and foci should be practiced, so far as possible, with the removal of as much diseased tissue as consistent. If apparent recovery occurs, the case should, nevertheless, be watched for several years because of the great possibility of recurrence.

Mr. A. S., Castleton, N. Y., aet 45; native of United States; carpenter by occupation; married. Admitted to Albany Hospital February 22d, 1901. Provisional diagnosis sarcoma of cecum or mesentery; corrected diagnosis actinomycosis abdominalis. Treatment: Operation and medical. Family history good. Previous history: patient had usual diseases of childhood; typhoid fever at the age of 15; was quite ill, but made a good recovery. Denies venereal disease of any kind. Patient has partaken sparingly of stimulants; smokes and chews tobacco rather excessively; has associated much with animals; never worked in grain. General health always good; no serious injuries. Present illness began November 27th, 1900. While at work had pain in stomach; however, finished day's work, and then tried various remedies without relief. Had sharp cramps in lower portion of abdomen; very severe for 3 or 5 minutes, recurring at first every half hour or so. Did not obtain relief for a week, although under the care of a physician. Pain gradually diminished, but did not disappear for eight weeks from onset. No chills, fever or vomiting, but

slightly nauseated. Pain not localized or radiating, but seemed, to patient, to be in abdomen. No jaundice; no distension of abdomen that patient ever noticed. Bowels and kidneys normal in functions.

January 1, 1901, patient was able to be up, around and improved quite rapidly. Middle of January, superintended an ice gang.

February 1, as well as usual, and had regained normal weight.

February 20th, still feeling as well as ever, but noticed a small tumor in region of umbilicus, for which he came to the Albany Hospital February 22, under my care.

Physical diagnosis: distinct tumor, size of fist, in right iliac region; smaller tumor, inflammatory in character, evidently containing pus, at umbilicus; smaller masses to be felt through and in abdominal wall, giving an impression of sarcoma of the mesentery. Heart, lungs, spleen and stomach normal. Liver dulness extended about one finger's breadth below the costal margin. Skin over tumor red, with yellow spot in centre. Urine amber, 1030, acid, no albumin or sugar, sediment slight, and a very large number of calcium oxalate crystals present. Blood examination revealed leukocytes 18,500, reds 4,710,000.

Operation, February 28, 1901. Abdominal incision 6 cm. long in median line. Peritoneum found adherent to coils of small intestines in various places, with a flattened tumor, size of half a hand, springing from right iliac crest. While supposed to be a case of multiple sarcoma of the mesentery, yet it differed from any similar case I had ever seen. There was a distinct hardening of this portion of the peritoneum extending to umbilicus, along the course of the urachus and round ligament of liver, with an abscess presenting just under the skin. The latter was not opened for fear of infecting the peritoneum. Incision in peritoneum closed with fine silk, continuous sutures; wound closed with interrupted silkworm gut sutures and iodoform gauze introduced in lower end of incision, then standard dressing. Gauze removed on 4th day, and drainage encouraged there-

after, the abscess of umbilicus having opened and discharged a creamy, flaky-like substance. Specimens of discharge and tumor were saved, but lost later, and did not reach the Bender Laboratory for examination.

Patient put upon syrup of hydriodic acid, strychnia and elixir of callisaya, with as good nourishment as possible. Not feeling at all certain of my diagnosis, and the possibility of actinomycosis, about April 1st I asked Dr. Elting to look the case over carefully, and make a thorough examination of the discharge. This was done and the case found to be one of typical actinomycosis. Cover slips stained by Gram's method showed the characteristic fungi. Cultures from several of the abscesses showed so vigorous a growth of the bacillus coli communis that the growth of the actinomyces was obscured. Patient was now administered iodide of potassium in increasing doses, i. e., a saturated solution, commencing with 3 drops in a wineglassful of water before each meal, increasing 3 drops each day until 60 drops were reached and this dose continued.

May 1, 1901: Condition improved somewhat, although necessary on two occasions to open abscesses in the abdominal wall. Less numerous actinomycotic granules in discharge than before the administration of iodide of potassium was begun. Large tumor still in right lower quadrant of abdomen, extensive induration and infiltration of abdominal wall, and four fistulous openings.

June 15th: Patient's general condition not quite as satisfactory as at previous note. Three discharging sinuses in abdominal wall, the discharge sero-purulent, and containing a moderate amount of actinomycotic granules. Appetite good, no gastro-intestinal symptoms. At patient's request he was discharged from the hospital and advised to continue the large doses of iodide of potassium.

June 25th: Patient readmitted to hospital for further observation. General condition somewhat improved but there are more discharging sinuses than at last note. Condition at this time indicated by accompanying photographs. Figs. 1 and 2.

FIG. 1

FIG. 2

August 20th. Patient returns feeling much better than when seen about 3 weeks ago. Condition of abdomen distinctly improved. Some of the sinuses closed, and discharge from remaining ones decidedly less.

Patient says two weeks ago a small pimple or blackhead developed on right side of the nose, near inner angle of eye. This was squeezed by his wife, who had attended to the abdominal wounds. 48 hours later patient noticed some pain and swelling about nose, which gradually increased, and a tumor, the size of a hen's egg, developed, which almost closed right eye. Hot applications employed and about a week from onset tumor broke and discharged considerable pus. There still remains a tumor the size of a large pigeon's egg, the skin near and around presenting a livid appearance. Discharge sero-purulent and contains a few typical actinomycotic granules. Potassium still continued.

September 20th. Patient returns feeling much improved. Abscess of nose entirely healed. Abdominal condition much improved. There are still a few actinomycotic granules in discharge from sinuses in abdominal wall.

October 12th. Patient shows still further improvement. Has been doing light work for several weeks past. Color good and general appearance excellent. Four or five discharging sinuses in abdominal wall, containing a small amount of discharge, with an occasional actinomycotic granule, mostly in an early stage of development. Condition of patient's abdomen at this time indicated in Figs 3 and 4.

FIG. 4.

containing yellowish-like pus and granules. All of these conditions are indicative of actinomycosis, also the patient's improvement for a time after operative intervention, and still further improvement when getting under the full effect of the iodide of potassium; the infection of the nose, and rapid recovery, all aid in confirming the previous diagnosis.

The photographs illustrate very nicely the appearance of the patient when improvement had commenced, and still later on when in a condition of convalescence.

CYSTIC LIVER.*

By ISRAEL CLEAVER, M. D.,

of Reading, Pa.

The specimen of liver shown here to-day needs no description to convince you of its interest and rarity.

Its dimensions are as follows: width, 12½ inches, the left lobe being 4 inches, vertical length, 8 inches, and thickness, 5½ inches. I had no means of having it weighed at the time of the autopsy.

The portion of large cyst projecting above the surface of the liver measures 7½ inches in circumference, occupies the under face of the right lobe, and crowds the gall bladder, also much enlarged.

You will notice another cyst of the size of a wa-

* Read before the Berks County Medical Society, September 14th, 1897.

FIG. 3.

If this case is studied carefully, it is very striking to observe the characteristic conditions that have been described by many authors, i. e., the tumors to be felt in the peritoneal cavity, and in the abdominal walls, the peculiar reddish-blue appearance of the surface of the abdomen and the multiple abscesses

nut, sessile on the upper margin of the left lobe, while four more of the size of hulled shellbarks, peep through the surface of the same face, but to the right of the large cyst. The gall bladder contained twenty-six calculi, varying as you see (specimens shown) in size from a wheat grain to a peanut kernel, irregular in shape, with worn facets, showing the different striae of their formation. They are the kind usually found in such subjects, and by the way, I have found these concretions so frequently in autopsies of the aged, without a previous suspicion of their existence, that I judge they are no unusual concomitant of senile degeneration, but I have not had time to search for bibliography on this point, and my memory does not just now serve me. Sections of the organ in places not occupied by the cysts, macroscopically, appear healthy.

I have submitted portions to both Drs. Frankhauser and Wethered, and they tell me that there is no parenchymatous change, and both being present, can give you their observations. Relative to the rarity of such specimens, the only mention I find thereof in such books as were at my command, is in *Treat's Annual*, 1895, a contribution from A. W. Mayo Robson, F. R. C. S., wherein he speaks of a like case reported by Dr. John B. Roberts, of Philadelphia, Pa., and another previously by himself.

Dr. Roberts' case appears in Vol. XIX, *Annals of Surgery*, p. 251, the liver weighing eleven and a half pounds, and "riddled throughout with cysts." He reports: "For ten years she had noticed a swelling in the right side of the abdomen below the ribs. * * * The tumor was irregular in outline and near the middle line presented a particularly marked elevation, which was elastic on pressure, and gave the examiner the impression that it was a cyst." No echinococcus hooklets could be detected. Operation was made, evacuating eight or ten cysts of various sizes and the patient did well for three weeks, when she unexpectedly died, autopsy revealing the condition above given.

Dr. Robson's case was also an "enormously enlarged liver filled with cysts." Hepatotomy was performed, but the case disappeared by removal and the result therefore is in doubt.

Cystic Liver.

The specimen before you differs from those, in the fact of the cysts being not so numerous, but of vastly larger dimensions.

The reporter of Dr. Roberts' patient says he had been unable to find in literature "a case of such extensive cystic degeneration of the liver." I think it very right, therefore, to offer this paper for record.

Touching the patient from whom this was taken: he was a gentleman, eighty-one years of age at his death.

He had never been intemperate, and for the last sixty years of his life was a teetotaler in practice. He had no hereditary transmission, robust frame, and until within a few years of death enjoyed vigorous health, saving that when about 35 years old he had an attack of "bilious fever." He was also subject at irregular intervals to attacks of "sick headache," occurring perhaps two or three times a year, but after attaining the age of fifty, they were still less frequent in their appearance.

Eight years previous to death he began to be troubled with rheumatoid arthritis, growing gradually worse until, during the last two years, he could only walk with the aid of crutches.

For the last four or five years he was also the subject of a more or less frequent cough and bronchorrhea, but nothing more than is usual with senile degeneration of the respiratory tract.

About the beginning of last March, 1897, he showed unusual debility, following an attack of indigestion, caused by rather free eating of fat meat. From this time food had no relish, owing mainly to apparent *loss of taste*: soups, meat, bread, etc., everything tasting "like chips." The tongue was always heavily coated, sometimes with a brown crust, but generally a white or somewhat yellow color. He suffered no pain except in his knees with moving. He was too weak to sit up, and hence was rarely out of bed during the whole of his last illness, which was six weeks in duration. The bowels were constipated, but stools of normal color, even when prompted by purgatives.

Two or three weeks after this seizure he complained of frequent micturition, and examination revealed the bladder much distended, and which was relieved by catheter at two sittings, five pints of urine being drawn with the two operations. From this time on he never voided urine without instrumental aid. At this time was also noticed an enlarged condition of the right hypochondrium, percussion and palpation, both proving the cause to be an enlarged liver. Two weeks before death he complained of considerable pain in this region, relieved by lying on the right side. There was slight fever, much thirst, but no jaundice at any time, some tenderness.

Also at this time there was first noticed an elevation of the surface about the size of an egg and similar in shape, located one and a half inches to the right of median line and about the same distance below the ribs. It was fluctuating in character, not painful to pressure and no marked tympany surrounding it.

Distended gall bladder was my diagnosis and confirmed by the consultant called in next day. Of course, little was to be done except to continue the

tonics already given, and as much nourishment as possible. No material change occurred, except that the pain on some days was worse and associated with pressure symptoms, interfering with easy respiration. On the morning of April 23d last, seeming as well as for the previous several days, he asked for a drink of water, which he received sitting up in bed, when he immediately lay back and expired with a few convulsive gasps. The autopsy showed all the other viscera of abdomen and chest healthy, except the stomach, which was slightly enlarged.

In the surprise of seeing such a specimen of the liver, search for the kidneys was overlooked. Recent adhesions were about the large fold of the peritoneum over the liver, doubtless explaining the pain of the past two weeks.

Of course several pertinent questions are suggested by reflection on this history.

Why was this cyst mistaken for the gall bladder? The absence of jaundice, normal stool, with no special acute disease should have negated this idea.

I confess to some degree of chagrin in not having conjectured the presence of a cyst.

In the report of Dr. Roberts' case there is no proof that a positive diagnosis was made before operation.

My patient was too feeble and too aged to entertain any thought of operation, but had he been a younger and more vigorous subject, I feel that the issue would have presented some very keen questionings.

I, however, learned a lesson that may save *me* in the future, and be of like benefit to some of *you*. I realize that the idea of a "distended gall bladder" was so dominant in my thought, that the possibility of its being anything else never crossed my mind, teaching that in the investigation of diagnoses, even when you know (?) that you are *right*, take time to consider whether you are *wrong*.

Some apology may be advanced on the line that the disease is rare, literature pertaining thereto meagre, and that it is impossible for a busy general practitioner to keep fully posted on those items, that rarely or never come within the pale of his experience, but it, nevertheless, shows how important it is to be posted.

THE RELATION OF THE MIDDLE TURBINATE BODY TO CHRONIC DISEASES.*

By CHARLES H. BAKER, M. D.,
of Bay City, Michigan.

Chronic nasal catarrh is so prevalent on this side of the Atlantic as to have received the epithet of "The American Disease," and the failure of medical men to find means for the cure or amelioration of the disorder has become an approbrium to the profession and a prominent feature in the bids of the charlatans for patronage. We cannot ignore the influence of climate and habits of living among us as the exciting causes, but there are long periods of the year in which these are not prejudicially active in keeping alive the trouble, so we must seek elsewhere for the causes which operate to prevent the natural tendency to spontaneous recovery which

exists in the presence of acute nasal disorders. The easy accessibility of the inferior turbinate body, and its proneness to participate in all nasal irritations, and respond by swelling and producing nasal obstruction, has made it the scapegoat for the rest of the offending organ, and it has been seared and cut, pinched and stabbed without mercy, until, if it had a tongue, its prayer for relief would have ascended to the skies.

Acute observers long since recognized that chronic nasal disorders existed which were out of the sphere of influence of the inferior turbinate, but the weight of authority favored nasal stenosis as the cause of nasal disease and the possibility of other factors being more active than this one was overlooked. My purpose in the present paper is to call attention to the much greater influence which the middle turbinate has upon the course and progress of nasal disorders, in the hope that it may assist the work of others along the same line, and sooner usher in the day when we may promise our patients with chronic nasal troubles a cure which will stay a cure. In this, as in other diseases, a knowledge of the anatomy of the organ involved must first be had before we are in a position to know what are pathological changes, so I will hastily review the anatomy of the middle turbinate.

The middle turbinate body is so located as to be in the most intimate and important relations with the meati and accessory sinuses of the nose, the olfactory nerve and the most sensitive portions of the septum. In its normal state this body protrudes from the side wall of the nasal chamber and is bent sharply downward, lying parallel to the septum and midway between it and the lateral cell. It occupies most of the space between this wall and the septum from its point of attachment down close to the superior surface of the lower turbinate. In the living subject the space between the turbinate and the septum, or turbinate and side wall, varies between one-thirtieth and three-sixteenths of an inch, but may be obliterated by swelling of the membrane or hypertrophy of the bone. The turbinate covers the outlet of the maxillary antrum, the hiatus semilunaris in which are the orifices of the anterior ethmoid cells and of the frontal sinus, while its rear portion is in close relation with the sphenoidal foramen; all of which openings are the outlets for considerable sized cavities liable to inflammation consecutive to disease of the nasal membranes. The soft tissues of the middle are much less erectile than those of the inferior turbinate, and when thickened are less amenable to shrinkage by medicinal means, as cocaine, supral-renal extract, etc. The shape and size of the middle turbinate varies considerably within what may be termed physiological limits. For instance, it may be thin and knifelike from front to rear, with uniform thickness and equal spacing from the lateral walls. Again its attachment varies greatly in altitude, sometimes low down and again very high; the high horizontal portion may be wide or scarcely demonstrable; the anterior, the middle or the posterior part may be either wider or thicker than the balance of the bone. According to these variations the anatomical relation to the surrounding tissues vary, but so long as there is no pathological change or inflammation present these

*Presented at the 36th Annual Meeting of the Mich. State Medical Society.

variations do not signify. The bone is very thin, being filled with pneumatic cells with fragile lamellar walls. From various causes, developmental or nutritional, these cells are prone to enlargement, altering the structure, shape and relations of the bone to surrounding parts. The soft tissues overlying the middle turbinate bone become edematous when inflamed or irritated by discharges from neighboring sinuses, and by their swelling close off the upper meati and the outlets of the various sinuses. The sinuses are slow to become involved in inflammations of the nasal cavities, and are also slow to recover from them. They are occluded by the swollen turbinate, which in turn is irritated by their discharges and the condition is thus self perpetuated.

With the obstruction of the meati acute inflammations soon pass over into chronic and a creamy pus exudes continually, which, running over the mucous membrane produces granulation tissue just as a similar discharge elsewhere will do. In the nose this assumes the form of hyperplasia of the mucous elements, rather than the vessel loops and connective tissue of granulation elsewhere, and the abundant serum supply, aided by gravitation, makes them hypertrophy often to an enormous degree. The mucous membrane of the middle turbinate having to stand the brunt of the irritation is the first, and very often, the sole seat of polypoid growths. Everyone who removes polypus with the snare, under good illumination, will have seen on removal of those lying toward the maxillary antrum, a gush of pus as if the stopper of a bottle had been removed. This issues from some of the sinuses, and however frequently and thoroughly you may remove the polypi, you will not usually cure the discharge, except you remove the turbinate, owing to the swelling of the membranes retaining the discharges until a new polypus forms. The most careful extirpation with snare, curette, caustic, or cautery will not cure them until the turbinate is removed either in whole or in part. Very often polypi are concealed above and behind, which cannot be seen or reached by the probe, and yet are found on removal of the turbinate, and I submit that it would be impossible to cure such a case and leave the turbinate *in situ*. It is a common practice to cauterize the base from which polypi have sprung with a view to checking their formation, but my experience is that this procedure fails more often than it succeeds, while it is a fruitful source of adhesions which are very obstinate to removal. In some of these cases the amount of polypi concealed by the turbinate is astonishing, equaling or exceeding those that were visible before it was taken out.

A second indication for removal of the middle turbinate is sinus occlusion by swollen membrane, which is not yet polypoid and which does not respond to other recognized modes of treatment by cleansing and disinfection. In this class of patients the membrane seems irritable and swells to the occlusion of the sinuses, but either from the pus being produced by other organisms, or because of individual difference in resisting power, does not go on to form polypus. No method of cleansing which has ever been used will be efficient in these patients until the obstruction is removed, and this is impossible while the

turbinate body is left *in situ*. I have known two of these cases to die from cerebral involvement that I am sure could have been saved by early removal of the turbinate so as to provide free drainage from the infected sinuses.

A third indication for removal of the middle turbinate is fetid crusting of the discharges in the upper portion of the nasal chambers in non-specific cases.

Cobb in the *Archives of Otolaryngology** refers to the cure of cases of pharyngeal crusting by removal of the hypertrophied rear portion of this bone, and in case this can be demonstrated to be the only part involved, it is sufficient, but I extend the operation to the whole bone whenever the crusting extends to the middle or anterior portion of the middle fossa. A fourth indication for removal is so called "bulbous" hypertrophy, which is not a true hypertrophy of the bone, for the cells are simply ballooned out and the mucous membrane overlying is atrophied. The inferior turbinate is sometimes entirely absent as a result of the atrophying process extending to the whole nasal chamber. The membrane overlying the middle turbinate will be found covered with a number of bluish umbilicated spots resembling the mouths of tonsillar crypts. Secretion is excessive, but dries and crusts, and the only cure is removal of the bone which appears to be the focus of infection. It is remarkable how rapidly such a case improves after the operation.

Class Five.—As has been mentioned, on the septal side the turbinate lies in close proximity to the most sensitive area of the nasal mucous membrane, and when contact occurs various disturbances of the nervous system arise. Thus are produced severe sneezing, coughing, nasal asthma, hydrorrhea, headache, various eye reflexes, vertigo, tinnitus and even chorea and epilepsy, any one of which may be severe or obstinate enough to require removal of the bone as the offending cause. I have in the past year had two patients in whom persistent and ceaseless sneezing was the only symptom, but who were cured by this means after failure of other remedies.

A sixth class is that of vasomotor rhinitis, running along into other than the normal period of the year, who with the return of patency and improved breathing still suffer from pressure, sneezing, asthma, reflex cough or congestion of the eyes. On examination the turbinate is found crowding tightly against the septum and does not admit the thin probe after a liberal use of adrenal extract. I do not contend that removal of the turbinate will cure such a case without other treatment, but it will greatly shorten the period of suffering, which is a priceless boon to these patients.

I operate as follows: After as thorough cleansing as possible I apply 8 per cent. cocaine with a pledget of cotton on applicator, followed by thin pledgets laid along the upper surface and between the bone and outer wall, where they remain about ten minutes. Suprarenal extract or adrenalin is then applied, which procures an almost bloodless operation. Holmes' middle turbinate scissors, right and left, are then used, and the attachment of the bone to the lateral wall divided from before backward. If the rear portion is out of reach of the scissors

* Archives of Otolaryngology, vol. XXIX, 2 & 3.

it is cut off with the snare. The cavity is packed with a long, thin strip of iodoform gauze, which is usually removed on the following day, and generally no more packing is required. Frequent cleansing with borax solution is done by the patient until healing is complete. I have found healing promoted by insufflations of dermatine, a lead iodide compound which for this particular place has proven better than any other substance tried. Performed in this way the operation is painless and practically bloodless, and brings to a satisfactory end many otherwise tedious or hopeless conditions of disease.

THE RELATION OF THE SYMPATHETIC NERVOUS SYSTEM TO FUNCTIONAL AMBLYOPIA.*

By HARRY S. PEARSE, M. D.,

of Washington, D. C.

In reviewing the literature considerable confusion is noticed in the use of the terms "amblyopia" and "amaurosis," and only in recent years has the distinct line which divides them been generally recognized, though not always adhered to. Though there is some difference in the views concerning the application of the terms; with most observers the derivations, amblyopia from *amblys*, blunt, and *ops* sight, and amaurosis, from *amauros*, dark, form the basis of a classification which is simple and yet allows little latitude for complex amplification. Amblyopia is designated to those cases of weak sight which cannot be relieved by glasses, no matter what the cause may be. Amaurosis applies to all cases of absolute blindness, temporary or permanent, whether due to functional or pathological change in any structure concerned in the visual act; thus, blindness due to hysteria is called hysterical amaurosis, and that due to cerebral lesion, cerebral amaurosis. And this sub-classification prevails right through, each form of amblyopia or amaurosis receiving its name according to its causal factor. Of the amblyopias there are: Congenital amblyopia, dimness of vision from time of birth, and in the majority of cases due to high degrees of refractive error; amblyopia ex anopsia, dim vision from non-use, as in a squinting eye; hemeralopia, dimness of vision at night only, and its opposite, nyctalopia, dimness of vision during the day but normal at night; reflex amblyopia, due to irritation in another part of the body; traumatic amblyopia, uremic, glycosuric, malarial, anemic amblyopia, dependent respectively upon these general conditions; toxic amblyopia, from the use or abuse of drugs, and the amblyopia of central origin, due to brain lesion, and with which there may be a gradual failure of vision accompanying a descending degeneration of the optic nerve, ending in atrophy of that nerve and total blindness. Hemianopsia, a blindness of one-half of the field of vision indicates a disturbance of the brain or some part of the visual tract. Many of the above amblyopic conditions may and do progress to total blindness. The quantity of vision present determining the class to which each belongs. This aphorism can be applied to every case where there is sub-normal visual acuity. In addition to

these conditions of amaurosis following amblyopia, there are a number of cases of total blindness which do not have a common etiology with the amblyopias, viz., color blindness; scotomas, which may be scintillating or black areas in the field of vision, and monocular blindness as the result of an embolism or thrombus of the central artery of the retina.

There is a very large group of cases, including all degrees of acuity of vision, the etiology of which is still a matter of controversy. I refer to the disturbances of vision accompanying hysteria and neurasthenia. To say that a case of amaurosis is "hysterical," or that an amblyopia is "neurasthenic," does not indicate a definite pathological basis of diagnosis, and for want of a better or more descriptive scientific term these conditions are called "functional," which means, as expressed by Fuchs,¹ "an altered condition of circulation and nutrition resulting in disturbance of function." It has been conclusively proven that the sympathetic nervous system plays an active part in the control of the functions of the secretive glands and of the arterial circulation; also in the visual act through its influence over the muscles of accommodation. Strümpell² and other writers maintain that vaso-motor irritations may proceed from the cerebrum as in flushing and pallor from mental emotions. If this is so, the word "functional" bears the burden of many of the intricate and evasive phenomena of the neuroses and psychoses. And there can be no doubt but that many cases of diminution of visual acuity are due to the influence of the central nervous system upon the cellular elements of the retina, but in just what manner it is not positively known. The eye-ground, in the majority of cases, presents no visible abnormality to assist us. Severe shock or violent mental emotions in the form of grief, joy, anger, fright, etc., have produced complete blindness, undoubtedly by paralyzing the retinal elements or the visual centres in the cortex, rendering them incapable of receiving or interpreting visual impressions. Whether or not the sympathetic is concerned in this action we cannot say, but there certainly is a suspension of the functional activity of these elements (the retina or visual centres). Based on the study of 7,500 cases, Connor³ makes the statement that "there is no positive evidence of the existence of amblyopia from suppression, viz., a loss of sight from the inhibitory action of the brain upon the visual centre." It is true that the suppression theory is based on negative evidence, but it is the most plausible thus far advanced, and must be considered until more positive knowledge is forthcoming. Baas⁴ reports a case of amaurosis following the blepharospasm of phlyctenular conjunctivitis in a child. The child died of pneumonia. Upon autopsy there could not be found any microscopical lesion of the optic tract or visual centres. He regarded the condition as probably functional.

There are, however, many cases of amblyopia and amaurosis, functional in character, which can be explained upon a firm anatomical and physiological basis. Cases where there is a visible contraction

* Read before the Albany County Medical Society, April 10th 1901.

of the blood vessels of the retina traceable directly to the influence of the sympathetic.

Anatomical Connection Between the Central Sympathetic System and the Arteries of the Retina and the Muscles of Accommodation.

From the cavernous plexus of the sympathetic, located on the internal carotid artery, have been traced distinct fibrous ramifications to the vessels of the retina, to the motor and sensory nerves supplying the internal and external muscles of the eyeball and the muscles of the eyelids. It is not within the scope of this paper to consider at any length the distribution of the sympathetic to the external ocular muscles or the lid. The intercommunicating branches of the third, fourth, fifth, sixth, and seventh nerves, in and about the orbit, form a complicated mesh which can only be understood by following out the branches of each individual nerve and of the attending ganglia. In visual disturbances accompanying affections of these nerves, their origin, or any tissue in relation to them, communication can, in the majority of cases, be traced between the eye and the point of lesion. In affections of the third, fourth, and sixth, the connection is apparent, but when of the fifth or seventh, it is more difficult to trace; however, it can usually be worked out. All of these nerves contain sympathetic filaments, and their areas of distribution are therefore subject to the influence of that system.

The distribution of the sympathetic to the vessels of the fundus oculi and the internal ocular muscles is through the medium of the ciliary ganglion, situated within the orbit, very close to the optic nerve and directly anterior to the sphenoidal fissure. This ganglion receives its motor root from the third, its sensory from the fifth, and its sympathetic root from the cavernous plexus of the sympathetic, and, according to some observers, a filament from Meckel's ganglion. It supplies nerves of sensation to the eye-ball, motor filaments to the ciliary muscle and sphincter of the pupil, sympathetic filaments to the radiating fibres of the iris; and, according to Brunton,⁵ *sympathetic filaments to the vessels of the eye are given off from the sympathetic nerve before it reaches the sympathetic ganglion.* Tiedemann⁶ also says, *that a small filament penetrates the optic nerve with the arteria centralis retinac.*

Physiological Action of the Sympathetic Nerves in the Eye.

The vaso-constrictor and dilator actions of the sympathetic are as yet not fully understood. Experiments upon animals have shown that stimulation of the vaso-motor fibres terminating in the arterioles of a gland will dilate those arterioles and increase the secretion of that gland; that stimulation of the fibres to the arterioles of the skin will contract them and produce pallor. Sections of these fibres will in each case have directly the opposite effect, *i. e.*, diminution of glandular secretion and flushing of the skin. Showing that in the glands vaso-dilator fibres prevail, and in the skin, vaso-constrictor.

The action of the sympathetic upon the internal muscles of the eye and the circulation of its lining tunic is very interesting. In the head, the vaso-constrictor fibres predominate over the vaso-dilator.

The vaso-constrictor fibres ending in the structures of the eye can be traced down to the upper thoracic ganglion and stimulation will produce a contraction of the bloodvessels of the iris. This same stimulation, however, will produce dilatation of the pupil. Whereas, section of these fibres has a directly opposite effect, dilatation of the vessels of the iris and contraction of the pupil. So, as far as it is at present known, the influence of the sympathetic upon the structures of the eye is exerted to a great extent, through its action on the bloodvessels. The fact that sympathetic filaments to the vessels of the fundus have been traced by Brunton and Tiedemann, together with our knowledge of the sympathetic upon the capillaries of the skin, lead to the most reasonable inference that the capillaries of the fundus would be subject to the same influence of the sympathetic as the capillaries of the skin especially so as vaso-constrictor fibres predominate in the sympathetic nerves of the head and of the skin.

Application of Knowledge of Anatomy and Physiology of the Sympathetic to the Diagnosis of Functional Visual Disturbances.

Collins and Fränkel, in a recent paper, maintained that they had proven experimentally that the functional nervous disorders were "primarily conditioned through the sympathetic system, and were the result of a trophic disease." In discussion Worcester said that the sympathetic was probably less concerned in functional disorders than the cerebro-spinal system, and Osler said that it (the paper) was an "exhibition of retrograde-tendency." In closing Collins asked the question: "How are variations in blood-pressure brought about; does the cerebro-spinal system send any filaments to the blood-vessels?" There is the situation—on one side justifiable conclusion based on anatomical knowledge and physiological experiments; on the other the cellular activity or influence incidental to abnormal nervous or psychic processes.

The functional disturbances of vision with which we are here particularly concerned are positive conditions—disordered states of the retinal or vascular elements of the eye, or both, caused by a change in the innervation of these structures, which change may be due to an irritation of the innervating channels or to the influence of the cells in the brain, themselves disturbed by psychic processes. These irritations and disturbances act as direct causes of amblyopia and amaurosis, though in the majority of cases they produced no visible change in the retina, or in the vessels of the fundus. On the other hand, according to Barrett,⁸ and other observers, in several instances, contracted blood-vessels have been seen. Noyes⁹ reported a case in which a man of fifty-five, while talking, suddenly lost the sight of both eyes; upon examination twenty-four hours later, the retinal arteries were nearly empty and thread-like. Complete recovery of vision followed in five minutes under inhalations of amyl nitrite, which restored the calibre of the retinal arteries. Whether this drug acts by paralyzing the muscular coats of the arteries, or has a sedative action on the vaso-constrictor fibres of the sympathetic is a matter of controversy. H. C. Wood¹⁰ favors the latter view, and has many followers. Benson¹¹ re-

ports a case of temporary and partial obscuration of vision with spasm of *one* of the retinal vessels, and states that "spasm of the retinal vessels is sufficient to arrest the circulation and cause blindness." Spasm of these vessels rarely produces permanent blindness, however, because the retina is partially nourished by the choroid.

Strümpell follows up each symptom of spastic hemicrania and traces it to an *irritation* of the sympathetic; also, each symptom of paralytic hemicrania and traces it to a *paralysis* of the sympathetic, adding that when the eye is involved the vessels supplying the retina are affected as shown by spots and bright scintillations before the eyes, scintillating scotomas and hemianopsia. Von Graefe's symptom in exophthalmic goitre (lagging of the upper lid when the pupil is directed downward) is explained by that observer as due to the spasmodic contraction of the involuntary fibres of Müller, which aid in raising the eyelid and receive their nerve supply from the cervical sympathetic. The same irritation which produces this spasm may act on the vaso-constrictor fibres terminating in the retinal vessels, and which can be traced as above shown, to the same source, the cervical portion of the sympathetic. Brailey and Eyre¹² report five cases of exophthalmic goitre with increased intra-ocular tension, limitation of field of vision and amblyopia, assigning the probable causes of these conditions to the nervous and vascular disturbances at the root of the disease. Many observers advance the theory that the etiological factor of exophthalmic goitre is an infection of the cervical sympathetic ganglion. In simple glaucoma the extirpation of this ganglion has its foundation in the theory that an irritation of the sympathetic produces an increased arterial tension in the fundus, with resulting venous stasis and increased secretion of intraocular fluids, which Donders describes as a "neuriosis of secretion."

The contraction of the retinal arteries, produced by the action of quinine and acetanilid, and that of functional anemia are analogous, with the same result, transitory diminution of vision. The condition is one of mechanical anemia. Non-oxygenated blood will also produce transitory blindness by irritation of the vaso-motor centres. On the other hand, the temporary blindness following excessive hemorrhage is due, not to any change in the vessel walls, but to the insufficient blood supply to the retina and nerve centres.

A large proportion of the cases have, as I have said, the obscure etiology, hysteria, and it remains for the pathologist and neurologist to determine the basic cellular changes in this disease. Dana¹³ has reported forty-five cases of hysteria, twenty-three of which presented marked ocular symptoms, the most characteristic one being a concentric limitation of the visual field. This condition is due, I believe, to one of two conditions, or both; a diminished sensitiveness of the rods and cones in the periphery of the fundus to external impressions, or a lessening of the interpreting power of the central visual areas. Nuel¹⁴ has reported sixteen cases of what he called sympathetic amblyopia with absence of visible ophthalmic signs, following corneal injuries from flying scraps of metal. I have recently

had under observation a case similar to these in character, where sudden and absolute blindness developed one week after injury to the cornea by a piece of metal. Complete restoration of vision followed inhalations of nitrite of amyl and hypodermic injections of nitrate of strychnine. In this case there was, however, a recognizable contraction of the retinal arteries. The cases of Nuel and my own case were undoubtedly of a reflex nature, in which the sympathetic played the part which is generally attributed to it in all reflex conditions. In another recent case, a very hysterical woman, who complained of violent periodical headaches, there was a well-marked anemia of the temporal half of the optic nerve and retina of the right eye. This would seem to indicate that all of the arteries of the retina need not necessarily be involved.

Conclusions.

Our knowledge of the manifold manifestations of the disease, hysteria, in every structure of the body will not permit us to say positively that the retinal elements, the conducting channels of visual sensation, or the visual centres themselves, are free from the influence of this disease. The effect upon the visual apparatus of fright, shock, emotion, mental exhaustion, overexertion, etc., is essentially the same as in hysteria, and whether the sympathetic is concerned in this action is yet a question.

In view of the known sphere of action of the sympathetic and of the many cases observed which present the same conditions in the vessels of the fundus which the influence of the sympathetic produces elsewhere in the body, if the sympathetic does *not* influence the fundus vessels, what does? Until a more plausible source of influence is positively demonstrated, we cannot do better than accept this explanation, which is far removed from a theory.

A Case of Tetanus on the Thirteenth Day After Vaginal Salpingectomy.—Platon and Aubert report the case of a woman of 31, ill three days with symptoms of pelvic peritonitis. Leukorrhea had begun three years before, and she had been ill over two years. Examination revealed right sided pyosalpinx. Vaginal salpingectomy followed, the operation lasting 48 minutes. The wound healed without fever for 10 days. On the thirteenth day she had an angina, trismus following, with pain and tetanic spasms of the right leg. These became generalized and she died 10 days later, in spite of the antitetanic serum used. Investigations into all material and people that she came in contact with failed to bring to light the source of the infection. (*Bulletin Medical*, July 13, 1901, No. 55). [M. O.]

Health Reports: The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon General, U. S. Marine Hospital Service, during the week ended December 21, 1901:

Gastropotosis and Enteroptosis.—At the Saint Antoine Hospital, Hayem recently discussed the ptoses. (*Medecine Moderne*, July 10, 1901, No. 28). He showed a case, a woman aged 39, who had had stomach trouble for 12 years. She had anorexia and gastric pain in half-yearly attacks. Then menstruation became irregular, headache, vertigo, pain in the hips, spine, and on the right side developed. Examination showed some scoliosis, and the heart sounds seemed exaggerated. Her stomach had descended, and was dilated or distended, showing hyperchlorhydria. The intestines had also descended, and in the colon scybalous masses were felt. In man, pure gastric dilation is common; in woman, gastropotosis and enteroptosis occur most frequently, due to greater mechanical constriction of the liver, or ptosis follows a sudden loss of flesh. In the case shown both corsets and pregnancy collaborated to produce the ptoses. The condition existed for years, however, before she showed any symptoms. This period of latency may be very long. She also has some true gastritis, probably secondary to the gastropotosis. The treatment will consist of a binder, and massage, continued persistently. Substantial soft diet, three meals daily, only, was prescribed, with rest, the head low, for two hours after meals. Hayem also advised the daily injection of oil. [M. O.]

JOURNAL DE MEDECINE DE BORDEAUX.

October 27, 1901. (31me. Année, No. 43.)

1. A Clinical and Bacteriological Study of Urinary Ophthalmia. AUBARET and DENIER.

1.—Urine is commonly used as an eye-wash throughout France. This was the cause of 8, out of 4, cases of severe purulent ophthalmia, the other six being gonorrheal in character. The 8 case-histories follow in detail. Bacteriological examination in every case showed the gonococcus with various other cocci. In three cases grave complications developed, the other five recovering. Aubaret and Denier conclude that this is a form of purulent ophthalmia due to the urine; that these cases must be differentiated from hypopyon keratitis; they they are less severe in form than true gonorrheal ophthalmia; that gonococci are found with various other micro-organisms; and finally that iritis and keratitis may occur. [M. O.]

LA SEMAINE MEDICALE.

October 16, 1901.

1. A Simple Method of Estimating the Size of the Cavity in Pneumothorax. PROFESSOR L. BARD.

1.—Dr. L. Bard describes his method for estimating the size of the cavity in pneumothorax. His clinical and experimental researches have been conducted on the principle of determining the intrapleural pressure in pneumothorax and in effusions. The idea was suggested to him by the law of Mariotto, depending upon the constant relation which exists between the changes of volume of a gas, and the determination of the variations as indicated by the modification of pressure which is exercised. This contribution is an elaborate one, depending, in brief, upon the following principle: He takes the pressure of the intrapleural gas by means of an intramediary canula introduced through the intercostal space. The closed canula is connected with a short piece of rubber tubing inserted upon a branch of a glass Y, the other top arm of which is connected with a manometer and the bottom with a Potain flask, the exact capacity of which is known. Steps are placed on the rubber tubes permitting the regulation of the admitted air. These stops also permit, by their communications, the establishment of the volume by insufflation of air into the pleural cavity and in the flask of the positive or negative pressure which can be exactly determined. There is an established connection between the new pressure which results from the admixture of these gases. The estimation can be made in a very few minutes without fatigue or danger to the patient, and no especial apparatus is necessary such as the one he describes. Dr. Bard then goes on to give the physical method by which the determination is made. He multiplies the known value of the flask by the difference between the pressure at once recognized in the flask and that which exists after the cock is turned on, thus establishing a connection with the thoracic cavity. This is then divided by the difference between the pressures both known of the mixed gases and that of the thoracic cavity before the connection with the flask was established.

[T. L. C.]

Verrucose Tuberculosis of the Anus.—G. Augier and J. Voituriez report a case of verrucose tuberculosis of the anus in a man of 53. (*Journal des Sciences Medicales de Lille*, July 13, 1901, No. 28). He had been ill for 5 years. At first he thought that he had hemorrhoids. There has always been some pain with defecation. He is in excellent general health, but noticed that pus passed from the anus two weeks before entering the hospital. Examination showed irregular, firm, verrucose plates about the anal orifice. No glands were enlarged. As it was believed to be an epithelioma, it was wholly extirpated. He recovered rapidly. Examination of the tumor removed showed localized tuberculosis, without sclerosis. The prognosis seems favorable in these cases. There was no other tuberculosis in the individual. The diagnosis is always difficult, and the treatment surgical, total removal of the growth. The few other cases in the literature are quoted.
